STEAM TRAP. Jarad W. Lytton, Franklin, Va., assignor to Lytton Manufacturing Corporation, Franklin, Va., a Corporation of Virginia. 983,384.

LINING FOR ENGINE CYLINDERS. Einar N. Sorensen, Athens, Penn. 983,409.

CARBURETER. William T. Dawson, Helena, Ark. 983,541.

ROTARY GAS-ENGINE VALVE. William E. Ewart, Seattle, Wash. 983,546.

VALVE GEAR FOR ENGINES. Charles D. Parker, Worcester, Mass. 983,564.

COMPRESSOR. Henry W. N. Cole, Brooklyn, N. Y. 983,605.

COAL-HANDLING APPARATUS. George E. Titcomb, Philadelphia, Penn., assignor to the J. M. Dodge Company, Naugatuck, Conn., a Corporation of Pennsylvania. 983,659.

HOSE COUPLING. John E. W. Boesch, Columbia, Nev. 983,671.

LOCK COCK. Joseph Schneible, Weehawken, N. J., assignor to Schneible Company, Buffalo, N. Y., a Corporation of New Jersey. 983,842.

ELECTRICAL INVENTIONS AND APPLICATIONS

ELECTRIC HEATER. Milton M. Kohn, New York, N. Y. 983,291.

ELECTRIC FURNACE. Hans Nathusius, Friedenshütte, near Morgenroth, Germany. 983,303.

ELECTRICAL SIGNALING DEVICE. Joy Glenn Schafer, Brighton, Iowa. 983,403.

MOTOR-CONTROL SYSTEM. Emmett W. Stull, Milwaukee, Wis., assignor to Allis-Chalmers Company, Milwaukee, Wis., a Corporation of New Jersey. 983,519.

ELECTRIC SWITCH. Charles S. Van Nuis, Philadelphia, Penn. 983,680.

ALTERNATING-CURRENT SYSTEM OF DISTRIBUTION, REGULATION AND CONTROL. Joseph Bijur, New York, N. Y., assignor, by mesne assignments, to the Electric Storage Battery Company, Philadelphia, Penn., a Corporation of New Jersey. 983,670.

ELECTRICAL WRITING APPARATUS. Dinshah Pestanji Framji Ghadiali, Surat, India. 983,703.

INSULATOR FOR ELECTRIC INSTALLATION CANOPIES. George W. Gardiner, Chicago, Ill. 983,701.

POWER PLANT TOOLS

PIPE WRENCH. Frank F. Corbin, Easthampton, Mass. 983,267.

PIPE WRENCH. Ernst Enderes, Littleport, Iowa. 983,271.

WRENCH. William N. Jay, Moscow, Idaho. 983,447.

WRENCH. Andrew J. Curtis, East Williamson, N. Y., assignor of one-half to Daniel Wagemaker, East Williamson, N. Y. 983,483.

PIPE-FLANGE WRENCH. Michael Murray, Chicago, Ill. 983,562.

WRENCH. Robert D. Lindsay, Monaca, Penn. 983,628.

WRENCH. Edward Kukuruda, Saginaw, Mich. 983,728.

WRENCH. Ellnathan Allen, Chicago, Ill. 983,796.

ENGINEERING SOCIETIES

AMERICAN SOCIETY OF MECHANICAL ENGINEERS

Pres., Col. E. D. Meier; sec., Calvin W. Rice, Engineering Societies building, 29 West 39th St., New York. Monthly meetings in New York City. Spring meeting in Pittsburg, May 30 to June 2.

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS

Pres., Dugald C. Jackson; sec., Ralph W. Pope, 33 W. Thirty-ninth St., New York. Meetings monthly.

NATIONAL ELECTRIC LIGHT ASSOCIATION

Pres., Frank W. Frueauff; sec., T. C. Martin, 31 West Thirty-ninth St., New York. Next meeting in New York City, May 29 to June 3.

AMERICAN SOCIETY OF NAVAL ENGINEERS

Pres., Engineer-in-Chief Hutch I. Cone, U. S. N.; sec. and treas., Lieutenant Commander U. T. Holmes, U. S. N., Bureau of Steam Engineering, Navy Department, Washington, D. C.

AMERICAN BOILER MANUFACTURERS' ASSOCIATION

Pres., E. D. Meier, 11 Broadway, New York; sec., J. D. Farasey, cor. 37th St. and Erie Railroad, Cleveland, O. Next meeting to be held September, 1911, in Boston, Mass.

WESTERN SOCIETY OF ENGINEERS

Pres., O. P. Chamberlain; sec., J. H. Warder, 1735 Monadnock Block, Chicago, Ill.

ENGINEERS' SOCIETY OF WESTERN PENNSYLVANIA

Pres., Walter Riddle; sec., E. K. Hiles, Oliver building, Pittsburg, Penn. Meetings 1st and 3d Tuesdays.

AMERICAN SOCIETY OF HEATING AND VENTILATING ENGINEERS

Pres., R. P. Bolton; sec., W. W. Macon, 29 West Thirty-ninth street, New York City.

NATIONAL ASSOCIATION OF STATIONARY ENGINEERS

Pres., Carl S. Pearse, Denver, Colo.; sec., F. W. Raven, 325 Dearborn street, Chicago, Ill. Next convention, Cincinnati, Ohio.

AMERICAN ORDER OF STEAM ENGINEERS

Supr. Chief Engr., Frederick Markoe, Philadelphia, Pa.; Supr. Cor. Engr., William S. Wetzler, 753 N. Forty-fourth St., Philadelphia, Pa. Next meeting at Philadelphia, June, 1911.

NATIONAL MARINE ENGINEERS BENEFICIAL ASSOCIATIONS

Pres., William F. Yates, New York, N. Y.; sec., George A. Grubb, 1040 Dakin street, Chicago, Ill. Next meeting at Detroit, Mich., January, 1912.

INTERNAL COMBUSTION ENGINEERS' ASSOCIATION

Pres., Arthur J. Frith; sec., Charles Kratsch, 416 W. Indiana St., Chicago. Meetings the second Friday in each month at Fraternity Halls, Chicago.

UNIVERSAL CRAFTSMEN COUNCIL OF ENGINEERS

Grand Worthy Chief, John Cope; sec., J. U. Bunce, Hotel Statler, Buffalo, N. Y. Next annual meeting in Philadelphia, Penn., week commencing Monday, August 7, 1911.

OHIO SOCIETY OF MECHANICAL ELECTRICAL AND STEAM ENGINEERS

Pres., O. F. Rabbe; acting sec., Charles P. Crowe, Ohio State University, Columbus, Ohio. Next meeting, Youngstown, Ohio, May 18 and 19, 1911.

INTERNATIONAL MASTER BOILER MAKERS' ASSOCIATION

Pres., A. N. Lucas; sec., Harry D. Vaught, 95 Liberty street, New York. Next meeting at Omaha, Neb., May, 1911.

INTERNATIONAL UNION OF STEAM ENGINEERS

Pres., Matt. Comerford; sec., J. G. Hannahan, Chicago, Ill. Next meeting at St. Paul, Minn., September, 1911.

NATIONAL DISTRICT HEATING ASSOCIATION

Pres., G. W. Wright, Baltimore, Md.; sec. and treas., D. L. Gaskill, Greenville, O.

POWER

NEW YORK, MARCH 7, 1911

When the hotel owner with one glass eye returned to his establishment after his first trip through the land in ten years, he remarked to the steward that anyone with even half an eye should be able to see that many things in the said establishment were "all to the bad," or words to that effect.

Things were not by far as uptodate as they should be. The steward had evidently been "asleep at the switch."

For one thing, why had not the steward looked up the suitability of a set of those new Marks-Davis steam tables for use in the restaurant kitchens? He of the one eye had discovered that they gave more heat per pound of steam than the old Peabody type.

Most emphatically, things would have to be watched more carefully in the future, else there would be a new steward on the job.

Now, the steward had no excuse to offer. His trouble was that he stuck too close to actual business to be an all-round big success. He bothered personally with too many details, most of which should have been entrusted to suitably selected subordinates. The result was that while he was always busy "stewarding" he wasn't getting the results that he should. He never had time in which to look around and see what progress others were making.

Engineers are troubled with this same complaint. Partly the engineers themselves are to blame, and partly the employers.

When an engineer's horizon extends only as far as the walls of his plant it is a fairly safe wager that he is not and never will be of very great caliber.

Unquestionably, many an employer could make a profitable investment by sending his engineer out on a trip of discovery to plants similar to his own, say, once a year. Such a trip would be a mental tonic for the engineer, giving him a different point of view of his plant and imbuing him with new ideas to be used to advantage in the future.

The engineer, himself, should get outside of his plant as much as possible on his own "hook." By that we mean that he should do some outside reading and studying bearing on his line of work, should take advantage of every legitimate opportunity to see neighboring plants and should talk with other engineers and with salesmen that happen to call on him.

Try to see your plant as others see it—see its defects and its weak points as well as its strong ones.

A Modern Blast Furnace Equipment

By A. R. Maujer

The most interesting features are a constant-volume turbine-driven centrifugal air compressor, a barometric injector condenser which produces a vacuum of over 28 inches and a single-wall radial-brick chimney which is withstanding temperatures up to 1400 degrees. The suction line for the condensing water is made with welded and Van Stone joints.

The Empire Steel and Iron Company has recently made some extensive changes in the equipment of its blast furnace at Oxford Furnace, N. J. Chief among the several interesting pieces of new apparatus is the steam turbine-driven centrifugal air compressor, built by the General Electric Company, which is used to furnish the air blast for the furnace. Next, is the highly efficient barometric condenser. And third, is the radial-brick chimney which is successfully withstanding continuous high temperature.

A general view of the plant is offered in Fig. 1. The large, square brick building in the foreground is the old blowing-engine house. The brick extension upon the left contains the new compressor. The boilers which furnish steam for the compressor and auxiliary apparatus are just back of this building. The boiler equipment consists of three 300-horsepower Babcock & Wilcox boilers and two 200-horsepower Wheeler vertical boilers. The former are served by the big brick chimney and the latter by the two short steel stacks, shown in Fig. 1, extending a little above the roof line. Steam is generated at 140 pounds gage pressure. Blast-furnace gas is the fuel used under the boilers.

The brick chimney also serves the four 20x80-foot two-pass stoves, which stand back of it. Beyond the stoves is the blast furnace itself, 80 feet high, 17 feet 6 inches in diameter at the bosh and 11 feet at the hearth. Its average production is 200 tons of pig iron in 24 hours.

Centrifugal Compressor

Until the centrifugal air compressor, shown in Fig. 2, was installed and put into service at Oxford Furnace, the air blast for all of the blast furnaces in this country was furnished by reciprocating compressors, or blowing engines, either steam or gas driven.

The two engines at Oxford Furnace which formerly furnished the air blast are typical of the majority of the steam-driven blowing engines at present in use. They are of the single-cylinder long-crosshead steeple type. The steam cylinder, which is below the air cylinder, is 54 inches in diameter; the air cylinder is 72 inches in diameter with a stroke of 72 inches. There are two large flywheels, one on either side of the engine. The connecting rod for each wheel is on the outside; hence, the crosshead extends from one side of the frame clear to the other. Normally the engines ran at 26 revolutions and each furnished 8000 cubic feet of air per minute. The maximum combined capacity of the two engines is 20,000 cubic feet.

The centrifugal compressor has a rated

Fig. 1. General View of Oxford Furnace Plant of Empire Steel and Iron Company

capacity of 22,500 cubic feet of air per minute, but at present it is handling only about 17,000 cubic feet. The normal speed of the machine is 1650 revolutions per minute and the normal discharge pressure is 15 pounds per square inch. The pressure varies, however, with the operation of the furnace, the compressor being regulated to deliver a fixed quantity of air at a variable pressure. The compressor has six stages, each of which contains a disk on which are mounted steel blades or vanes. The disks are separated by water-cooled diaphragms. diaphragms between stages, is water cooled; the cooling-water jets and intake pipes are above the casing, as shown in Fig. 2, where they are in plain sight of the operator.

The driving end of the unit consists of a Curtis horizontal four-stage steam turbine. The impeller disks of the compressor are so designed that there is no unbalanced end thrust; hence, the ordinary means used in the Curtis turbine for locating the rotating elements and preserving the proper clearances are sufficient for the entire apparatus.

from the bearings and cylinder to a tank where it is settled and strained before reuse. As a precaution against any stoppage of circulation, an alarm is provided which causes a steam whistle to blow when the oil pressure falls to 5 pounds per square inch. The oil is cooled in the bearings at the point where the heat is generated by means of water-cooled coils, embedded in the bearing linings.

When delivering 22,500 cubic feet of air per minute against a pressure of 15 pounds per square inch, the turbine runs at a speed of 1650 revolutions per min-

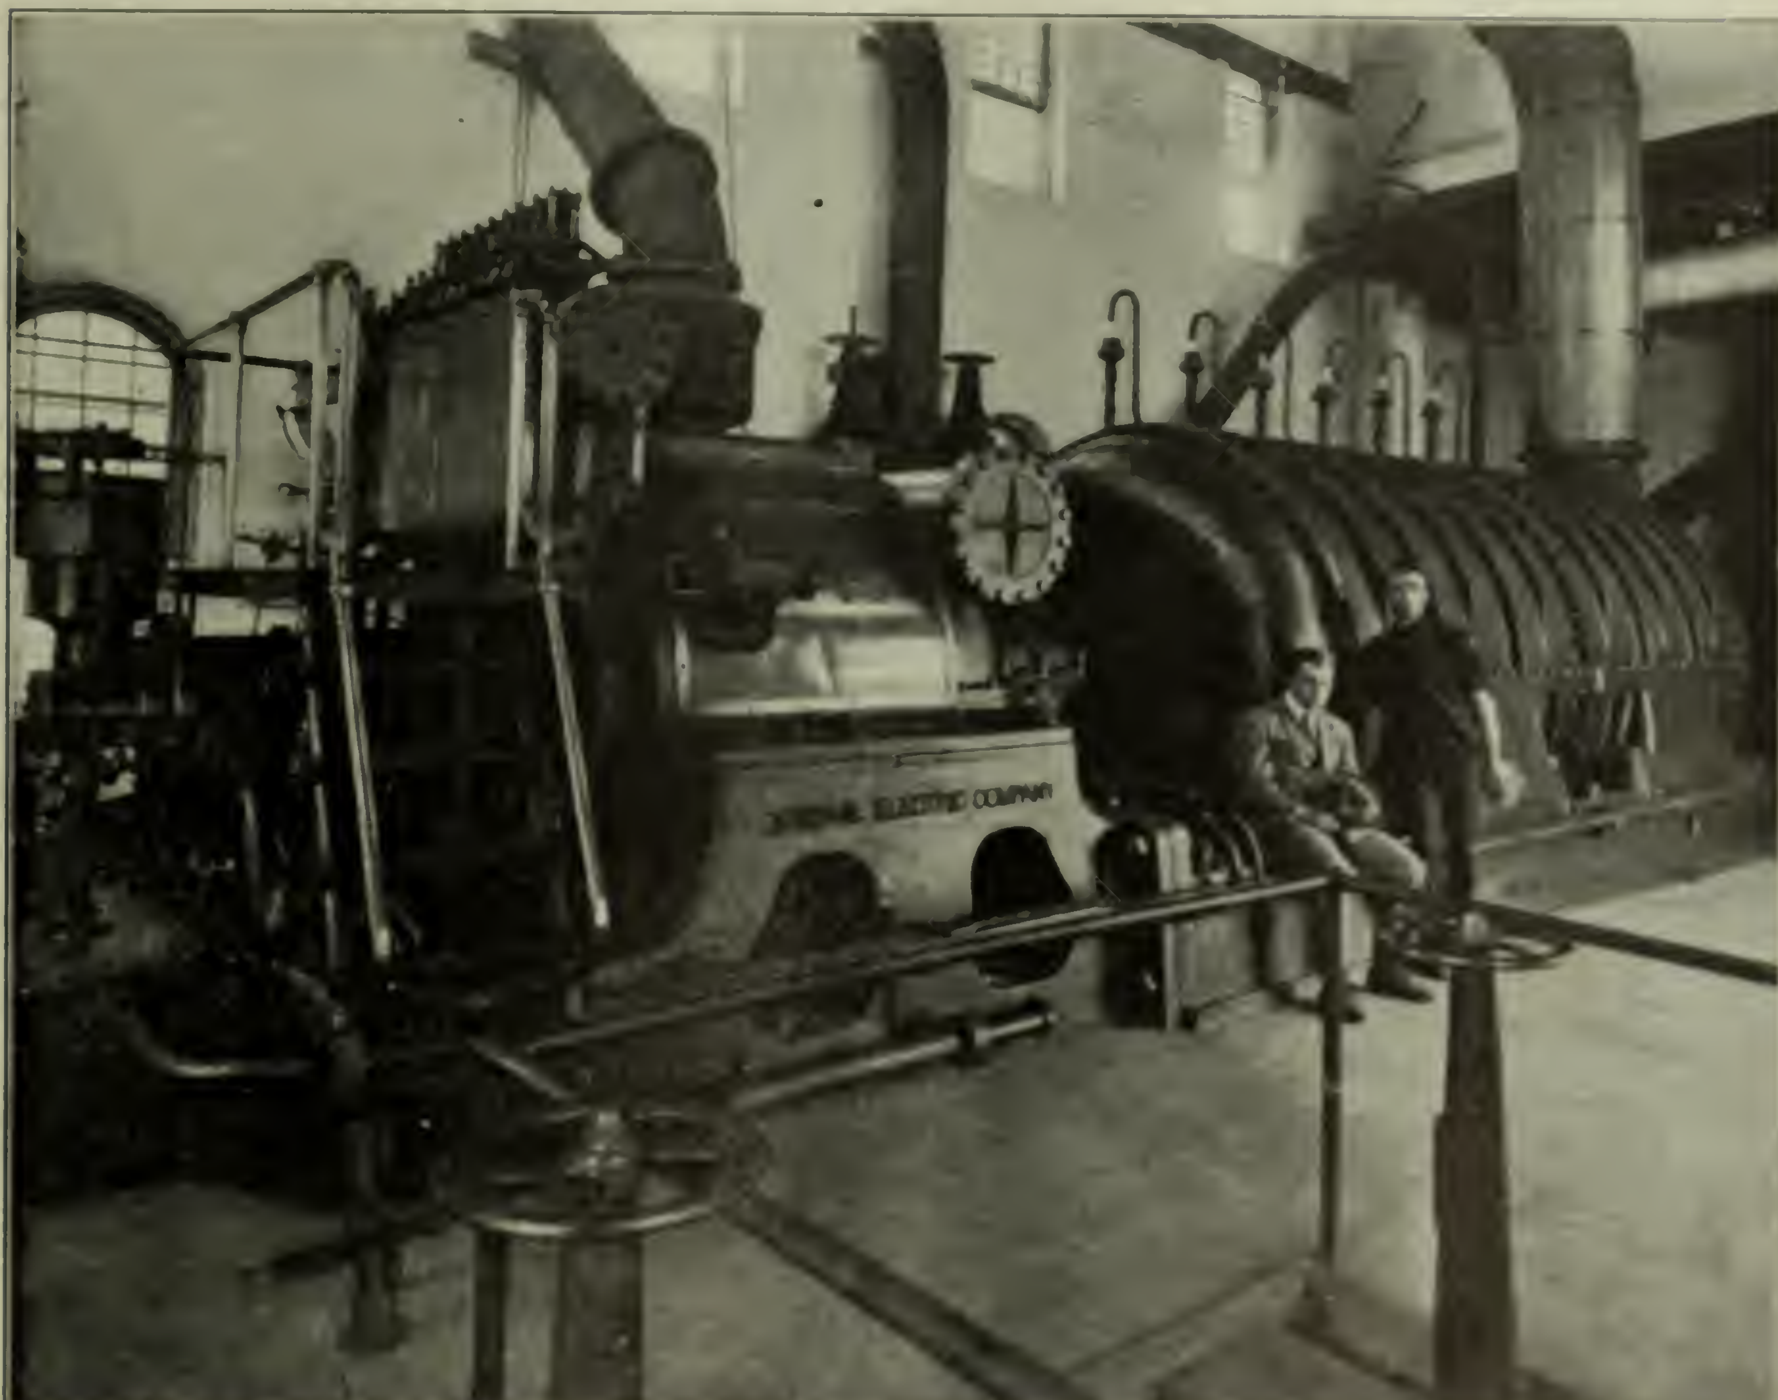

FIG. 2 THE TURBINE-DRIVEN CENTRIFUGAL AIR COMPRESSOR

Air is drawn in at the turbine end of the compressor and passes through each stage successively, the pressure being gradually increased to that which the conditions in the furnace may require. The discharge pipe is at the far end of the compressor, as is shown in Fig. 2; it is insulated with wood-covered lagging. The pipe passes across the old blowing-engine house and out through the wall just above the lower windows, as shown in Fig. 1. It then drops down and connects into the header which in turn connects with the stoves. The compressor shell, as well as the

There are three bearings, one at the head end of the turbine, one between the turbine and the compressor and one at the discharge end of the compressor.

As in all high-speed apparatus the continuity of the oil supply is important. The oil is circulated automatically by a valveless gear pump driven through a worm gear by the main shaft. The oil is pumped through the bearings at a pressure of from 15 to 25 pounds. The same pump supplies oil to the hydraulic cylinder, which operates the automatic steam-valve gear. The oil is returned

ute and develops 1790 brake horsepower with a guaranteed steam consumption of 19.1 pounds per horsepower-hour. When delivering the same quantity of air against 25 pounds pressure, the speed of the compressor is 1875 revolutions per minute; the horsepower developed is 2600 and the guaranteed steam consumption is 14.6 pounds.

Method of Regulation

The manner in which the steam is regulated to deliver constantly a predetermined volume of air against any ressure within the limits of the capacity f the machine is illustrated in Fig. 3. A unterweighted-steel disk is sustained by e current of inflowing air in the conical nlargement of the intake pipe. The rod which the disk is attached passes

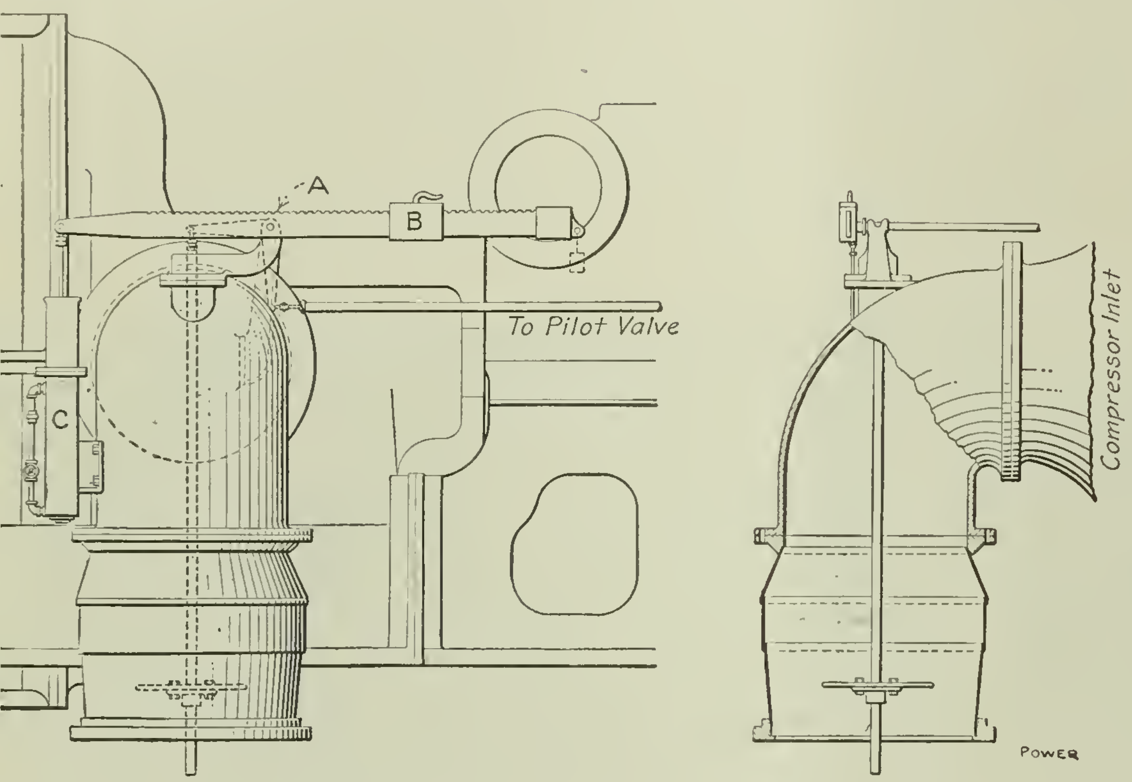

Fig. 3. Showing Method of Regulating Compressor

rough a stuffing box in the elbow of e intake and is connected to the weight eam *A* and to a system of levers which perates the pilot valve of the hydraulic alve gear, mounted over the head end f the turbine.

The notches on the beam are marked correspond with various quantities of ir delivered per minute. When the eight *B* is set at a given notch to deer a certain quantity of air, the disk ands normally at a certain level in the take cone. When the pressure against hich the compressor is working ineases for any reason the amount of r delivered begins to fall off. This reuces the velocity of the air being drawn rough the intake cone and unbalances e disk, which consequently sinks to a wer level. The movement of the disk, cting through the system of levers, the lot valve and the hydraulic valve gear, auses more steam to be admitted to the rbine. The turbine then speeds up and eëstablishes the proper rate of flow gainst the increased pressure.

This may be continued until the speed mit, 1975 revolutions per minute, is eached when a centrifugal governor omes into action and prevents any inease in the rate of steam admission. he dashpot *C*, Fig. 3, coupled to the eight beam, prevents undue fluctuation speed and any tendency to race.

The turbine is fitted with an emergency overnor which shuts down the machine hen the speed for any reason exceeds 10 per cent. the limit for which the peed governor is set.

The advantages of this type of comressor over the reciprocating types, either gas- or steam-driven, are, briefly: better over-all economy, economy in space occupied and more uniform operation. A rough idea of the saving in space occupied and the consequent saving in the cost of building effected by the use of a centrifugal compressor may be gained by observing the difference between the size of the old and that of the new engine house as shown in Fig. 1. The more uniform operation of the compressor results in an increase in the capacity of the furnace and an improvement in the quality of the product.

Condenser

The condenser is of the twin-barometric injector type and was designed by F. E. Johnson, of the M. W. Kellogg Company, New York. The location of the condenser is shown in Fig. 1 and its general arrangement in Fig. 4. The details of the heads are shown in Fig. 5.

The exhaust from the turbine passes out of the building below the turbine floor and enters the 36-inch cast-iron riser, Fig. 4. At the top of the riser the exhaust divides, one-half going to each condensing unit. The water belts of these units are connected by a 4-inch equalizing pipe, which eliminates all possibility of the units bucking each other on account of an unequal distribution of the exhaust steam or of the injection water.

The cast-iron elbow which connects

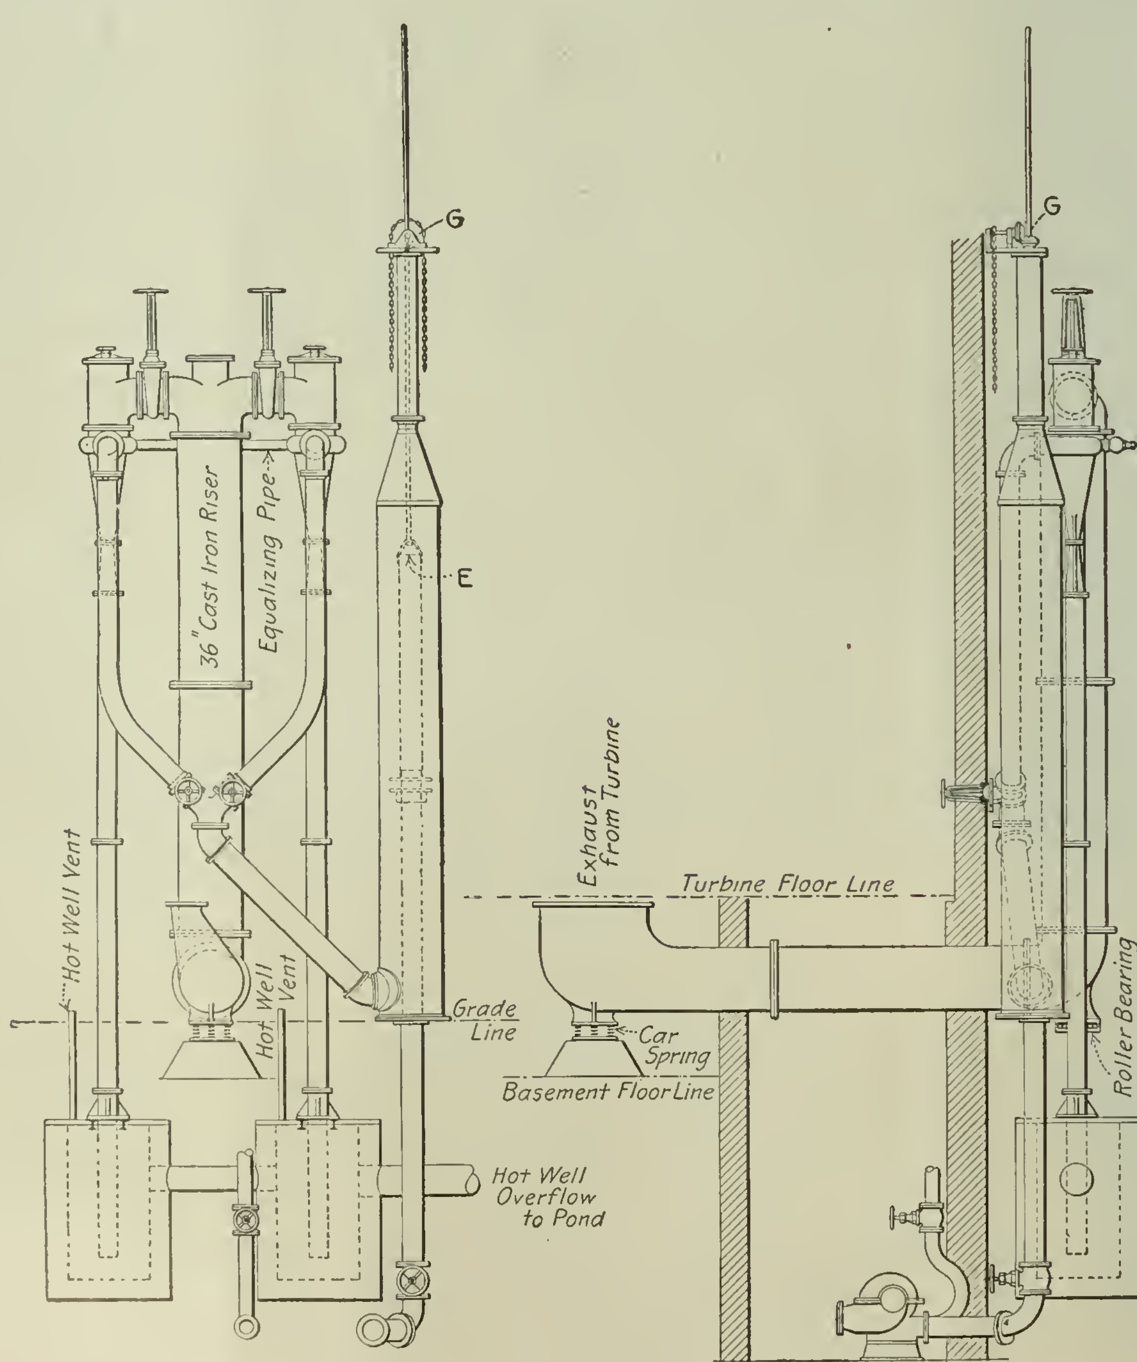

Fig. 4. General Arrangement of Condenser

with the exhaust outlet of the turbine is supported on heavy car springs. By this simple arrangement the use of an expansion joint between the elbow and the exhaust outlet was avoided, and expansion joints are not the most satisfactory of things that have been devised. The base of the riser rests on a roller bearing so that provision is made for lateral as well as vertical expansion.

The condenser was sold under a guarantee that it would maintain a vacuum of 28 inches of mercury, referred to a 30-inch barometer, when condensing 30,000 pounds of steam per hour with injection water at 70 degrees and produce a hotwell temperature within 10 per cent. of that theoretically obtainable.

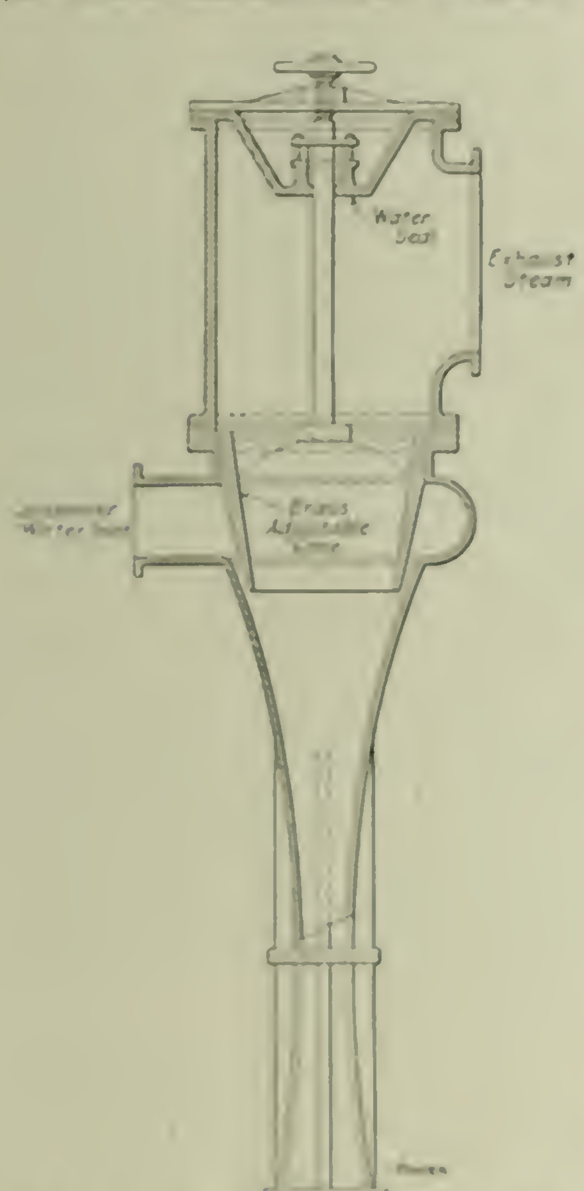

FIG. 5. DETAILS OF CONDENSER HEAD

The injection water leaves the pump through the 12-inch vertical pipe shown in Fig. 4 and spills over the edge of the open end *E* into the 30-inch steel-riveted standpipe from the base of which it is drawn to the condenser belt. In spilling out of the 21-inch pipe in a comparatively thin stream the water liberates a large proportion of the entrained air which escapes through the vent at *G*. Thus, the injection water goes through the condenser in an almost air-free condition and such air as is mingled with the exhaust steam is practically all that must be handled by the condenser.

PIPING AND PUMPS

The injection water is drawn from a pond 450 feet from the pump and 8 feet below the pump suction inlet. The suction line is 16 inches in diameter and made up of standard 20-foot lengths of pipe welded into 40-foot sections by the Kellogg system of electric welding, 40 feet being the limit of length convenient for transportation. Standard Van Stone joints are used between the sections. Due to this construction, which is unique in suction-pipe work, the line is absolutely air tight.

The injection water is handled by a 12-inch Morris Machine Works centrifugal pump, located as shown in Fig. 4, direct driven by a 100-horsepower noncondensing Terry turbine running at 1650 revolutions per minute. The pump has a capacity of 3300 gallons per minute against a normal static discharge head of 37 feet or a total normal static head of 45 feet.

The condenser-discharge water is received by the two hotwells shown in Fig. 4, from which it flows back to the pond by gravity. The hotwells are at a net hight of 15 feet above the pond. A natural-draft wooden cooling tower has been erected and will be put into service for the summer months. It stands at a level between that of the hotwells and that of the pond; hence, no pump will be required for the return of the discharge water even when the tower is in use.

In addition to the condenser pump, an 8-inch Morris Machine Works centrifugal pump is connected to the Terry turbine on the same shaft. This pump supplies 1200 gallons of water per minute to an elevated reservoir from which cooling water for the blast furnace and the air compressor is supplied by gravity. The total static head against which this pump works is 68 feet.

The amount of water which passes through the compressor jackets is just sufficient for the boiler feed. This water leaves the jackets at a temperature of about 100 degrees and enters a Cochrane open heater in which it is mingled with the exhaust steam from the Terry turbine. The temperature of the water as it enters the boilers is 180 to 200 degrees. The boiler feed pumps, two in number, are 12 and 8 by 12 inches in size and of the outside-packed duplex type. They were furnished by the Scranton Pump Company, Scranton, Penn.

Steam from the boilers enters a 12-inch header, 100 feet long, through welded nozzles carrying welded flanges. This construction eliminates about 70 per cent. of the joints ordinarily necessary.

CHIMNEY

The brick chimney which serves the blast-furnace stoves and the three Babcock & Wilcox boilers represents the latest chimney practice and is remarkable inasmuch as it is successfully withstanding, although only partially lined, temperatures which never fall below 800 degrees and sometimes run as high as 1100.

The hight of the chimney above its foundations is 175 feet, and the internal

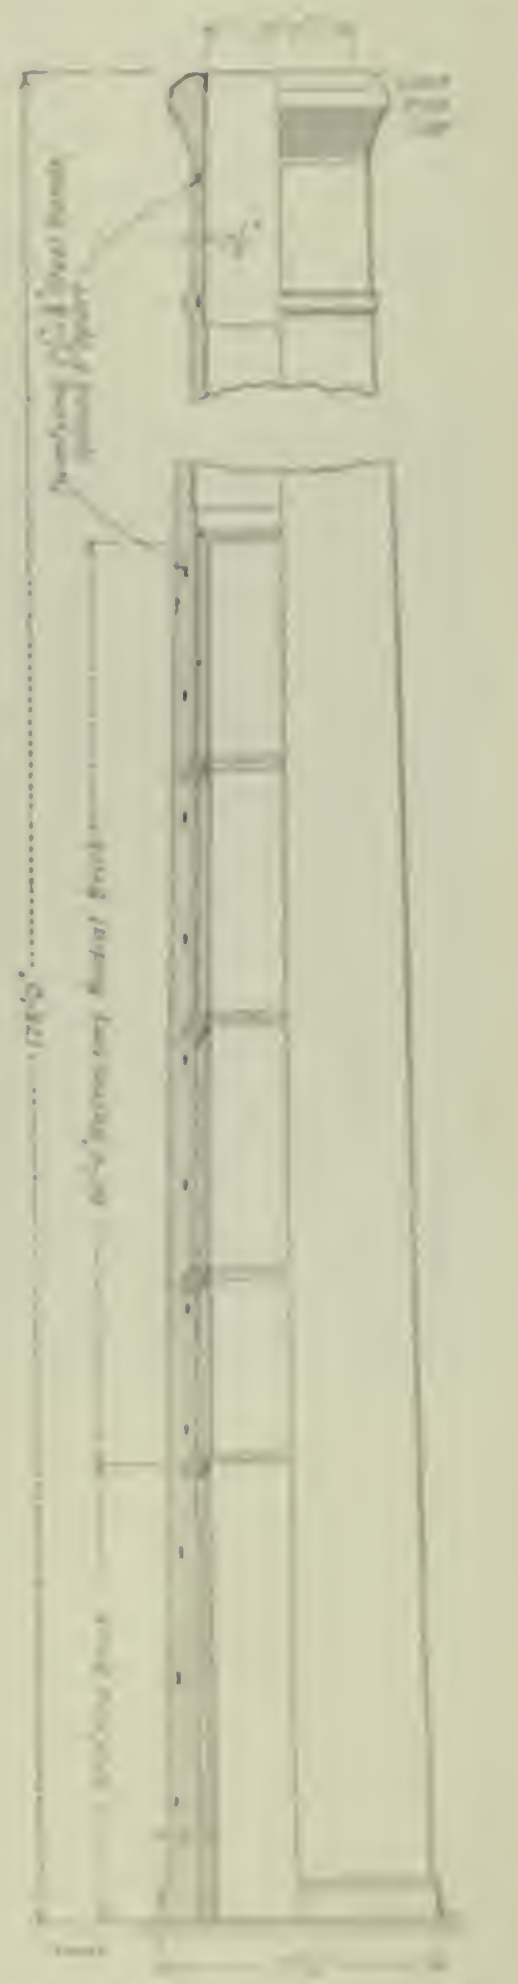

FIG. 6. DETAILS OF RADIAL BRICK CHIMNEY

top diameter is 10 feet. The underground flue which connects the chimney with the stoves and boilers is built of concrete and lined with firebrick. The chimney wall is built in eleven sections. The bottom section is 15 feet high and is inches thick; the ten sections above are each 16 feet 6 inches high, but vary in thickness from 24 inches, the thickness of the lowest one, to 7½ inches for the top one. The head of the chimney is finished with a sectional cast-iron cap which locks the top course of brick solidly in place and protects it from the action of the elements.

The chimney proper is built of perforated, corrugated radial brick laid in cement mortar. The lining is 90 feet high. The lower 30 feet is built of 4-inch firebrick laid in fire-clay mortar. The upper 60 feet is built in 15-foot sections of 4¼-inch hard-burned refractory radial brick. Each section is carried on a firebrick corbel and separated from the chimney wall by a 2-inch air space. The chimney wall is reinforced at 8-foot intervals by 2½x¼-inch steel bands. The M. W. Kellogg Company, New York, which erected the chimney, guarantees it to withstand a temperature of 1500 degrees Fahrenheit.

We acknowledge with appreciation the courtesy of R. H. Rice, of the General Electric Company, in supplying information concerning the centrifugal-air compressor and H. B. Cox, of the Empire Steel and Iron Company, in supplying the other information contained in this article.

The Confessions of an Engineer

By R. O. Warren

In this story the CO_2 recorder is up for discussion, and once more the manager finds that the engineer has failed to apply his knowledge and has missed an opportunity of making good by neglecting to suggest the purchase of a CO_2 recorder.

Manager Wood was about as progressive a man as one would meet in a long time. If I could have absorbed some of his push and hustle I might have occupied a pretty "hefty position" today, and incidentally been better off in dollars and cents.

One day Wood strolled into the boiler room where I was at the time, and, after his usual greeting, said. "What do you know in favor of CO_2 recorders?"

"They are a mighty good thing," said I. "Every boiler plant of any size should have one. A CO_2 recorder shows just what is going on in the boiler furnace, and tells just what percentage of CO_2 gas passes up the stack. Are you thinking of getting a recorder?"

"Not just yet. I never go into a thing before I have a pretty good idea of its value, what it does, how it works and of what use it can be to me. I'll confess I'm a little lame on the finer points of furnace combustion.

"I do know," went on Wood, "that the heat produced in a furnace depends on the completeness of combustion and on nothing else, and that the quantity of heat transferred to a boiler is determined by the state of the escaping gas."

"Yes, that's right," I replied, "and the escaping gas can be burned either to CO or to CO_2, according to the amount of air admitted to the furnace. The difference between the heat values of these two gases would surprise most engineers."

"What is the difference?" asked Wood.

"Well, burn a pound of carbon to CO_2, or carbon-dioxide, and it will yield 14,540 British thermal units. If the same carbon were burned to CO, or carbon-monoxide, it would yield but 4350 British thermal units—a difference of 10,190 heat units."

"Well, what makes the difference? A good deal must be in the method of firing, don't you think?"

"Sure, that has a whole lot to do with it," I replied, answering the last question first. "The reason that CO is formed is because not enough air has been admitted to the furnace. Of course, a furnace has got to be in decent shape, or the best firemen that ever lived can't fire and get good results."

"Most engineers don't really understand what burning flue gases to CO_2 means, but good combustion is simply burning coal to get the best results with the least possible air supply."

You see I was right at home on the CO_2 question, because I had read a good deal on the subject, knew all about the various apparatus on the market; and had a pretty good idea as to just the advantage of a CO_2 recorder. I knew that in the complete combustion of pure carbon there would be 20.7 per cent. by volume of CO_2, which fact I told the manager.

"But," said he, "you don't mean that you can get that amount of CO_2 from the fuel burned in a furnace, do you?"

"I should say not," I answered. "The best that can be got with the regular furnace is about 15 per cent. of CO_2 and that only for short periods. An average of 12 per cent. would be considered good for most plants."

"What saving would that make over, say 3 per cent. of CO_2?" was the next question.

"Well," I replied, feeling considerably gratified that we were considering a matter with which I was tolerably well familiar. "With 3 per cent. CO_2 the loss in coal is about 60 per cent., while with 12 per cent. CO_2 obtained, the loss in fuel is but 15 per cent."

"Whew—quite a difference. That's worth looking into."

"You bet," said I. "Every engineer should know about such things, for he don't know when he will have a chance to use the information."

Wood looked at me in rather an amused-surprised manner, and I, not knowing what was passing in his mind, went on with my explanation.

"The only way that a high percentage of CO_2 can be obtained is by firing at frequent intervals, by maintaining the proper thickness of fuel bed, and by supplying the correct amount of air for the fuel used. This can't be done if a furnace setting is full of cracks through which air can leak. If air leaks into the furnace it simply means that the furnace gases have to heat the excess air before it escapes to the stack, and much of the heat absorbed by the useless excess air is lost."

"There is usually excess air entering into a furnace, I take it."

"Yes, probably about 40 per cent. above the amount theoretically required," I replied. "This excess air dilutes the gases and reduces the percentage of CO_2 in the total volume of gases going up the stack. Under such a condition about 14 per cent. of CO_2 will be shown upon analysis, and the more air admitted to the furnace the lower the percentage of CO_2 and the greater the loss of fuel."

"And you say that this excess air is generally due to imperfect firing, and leaky settings?"

"Sure," I replied. "About nine out of every ten cases are due to these two causes, and it will be found that the flue gases contain only about 5 to 7 per cent. of CO_2, when they should contain at least 10 or 12 per cent.; and this means a loss of about 25 per cent. in coal."

"Then this 25 per cent. loss is a preventable loss. isn't it?" asked Wood.

"That's about the size of it," I replied. "The fact of the whole matter is that the furnace don't want too much or too little air, but just the right amount, for the varying condition of the fire."

"The idea," said I, "is that if the furnace conditions are so bad that the gases and air don't thoroughly mix, or if the temperature of the furnace is so low that the gases won't ignite, or if the boiler plates are cold enough to cool the gases and flame before complete combustion takes place, then CO is present in large quantities and the CO_2 percentage is low.

"About the air," I went on. "If there is too much, then the fire is obliged to heat it before it goes up the stack, and no engineer tries to see how high he can get his chimney gases, or how low he can keep the temperature of a boiler furnace. The whole proposition hinges on the way a fireman handles his fires, providing, of course, that the furnace and grate, etc., are in good condition."

"I suppose then, so long as air plays such an important part, that the draft in the stack must be reckoned with?" said Wood, in a thoughtful tone.

"It certainly must," I replied. "A strong draft eats up coal, and no more draft should be allowed drawing on a boiler furnace than is absolutely necessary to produce a fire of such intensity as to supply the necessary steam to carry the load on the boiler. But the only way to know when the proper draft has been obtained is by knowing what percentage of CO_2 is being obtained."

"And that is by means of a CO_2 recorder of some make," said Wood, in a very positive tone. "Why don't more engineers have these recorders?" According to what you have told me, more steam can be raised with the same amount of coal if a CO_2 recorder is used than without the recorder. Or, in other words, the same amount of steam we are now using can be made with a less amount of coal if a recorder were used. If that is the case, it would not take very long for a recording instrument to pay for itself."

"I guess that is about right," I replied, dimly gathering an idea as to the point Wood was leading up to.

"A good CO_2 recorder would act in three capacities at once," went on Wood. "It would be a simple guide for the fireman and an effective check for the engineer."

"Yes, there's no doubt about that," I answered.

Wood mused for a moment and then said, "It seems strange that so many companies will spend thousands of dollars in building a modern steam plant, pay particular attention to pipe-line design, protect the steam pipes from atmospheric influences, install the best types of boiler and engine, and, in fact, take practically every known precaution against steam losses, and then pay no attention to the loss due to escaping combustible gases."

"It is a little strange," said I, while a slight shiver ran up and down my spine, for I began to see that in not getting after this matter of flue gases I had allowed a good opportunity to slip by unnoticed until the new manager had taken it up.

"The personal element in the boiler room is, in most cases, overlooked as either unimportant or not existing. I think that is what is done here, isn't it?" asked Wood.

"We have a good set of firemen," I answered. "They are careful and ———." Then I came to a halt, for it flashed through my mind that but a few days before the manager had seen a fireman standing lighting his pipe while the furnace doors were open.

Wood evidently recalled the same conversation for he smiled a little and said, "You are not quite sure as to their merits now, are you?"

"Of course, they are men, but when compared with other firemen they are above the average," I protested.

"Yes, they are men, and for that reason they need some means of guidance and control if proper combustion is to be obtained. And that guidance is the CO_2 recorder, because if they are to get the proper CO_2 percentage the proper draft must be maintained and the firing properly performed. A fireman will do his work better if he knows it is being checked. Isn't that so?"

I had to admit that it was.

Then Wood got right down to business and said, "You are a strange proposition, Warren. You know about things, but don't make good."

"How so," I asked, although I well knew what was coming.

"How so! Why you have known all about the losses due to imperfect combustion ever since you have been here, but the only thing I can discover you have done to prevent them is that you have stopped up the cracks in the boiler settings."

"Well, that made quite a difference," I protested.

"Some, but not enough," retorted Wood. "You have told me enough about CO_2 recorders to satisfy me that you knew the full value of such apparatus, but you have never intimated that it would be advisable to have one in our steam plant."

"I know I never have, because they cost so much. I would have been wasting my breath, if I had proposed such a thing," I answered.

"How do you know you would?" demanded Wood. "While most business men don't care to spend money foolishly, there are but few who will not spend three or four hundred dollars if they are reasonably sure of getting the amount back in a reasonable time, because of the saving the expenditure will make.

"And another thing worth remembering. No business man will refuse to at least listen to any sane proposition. From what you have told me, together with the argument of the salesman, I think a CO_2 recorder will be a money saver in this plant."

I HAD ANOTHER INTERESTING SESSION WITH THE MANAGER

Here was another chance gone for making good. Although I knew all along of the advantage of a CO_2 recorder and about what saving one would make in a plant the size of mine, I had made no use of my knowledge, but had waited for the new manager to introduce a recording instrument, and, of course, the saving made would be to his credit.

Although I profited by this experience in after years, the occurrence made but little impression then, for in a few days after the new CO_2 recorder had got to be an old story, I forgot that I had missed one of the greatest opportunities of my life for making good by not applying what I knew in my everyday work.

Aid to Plotting Compression Curves

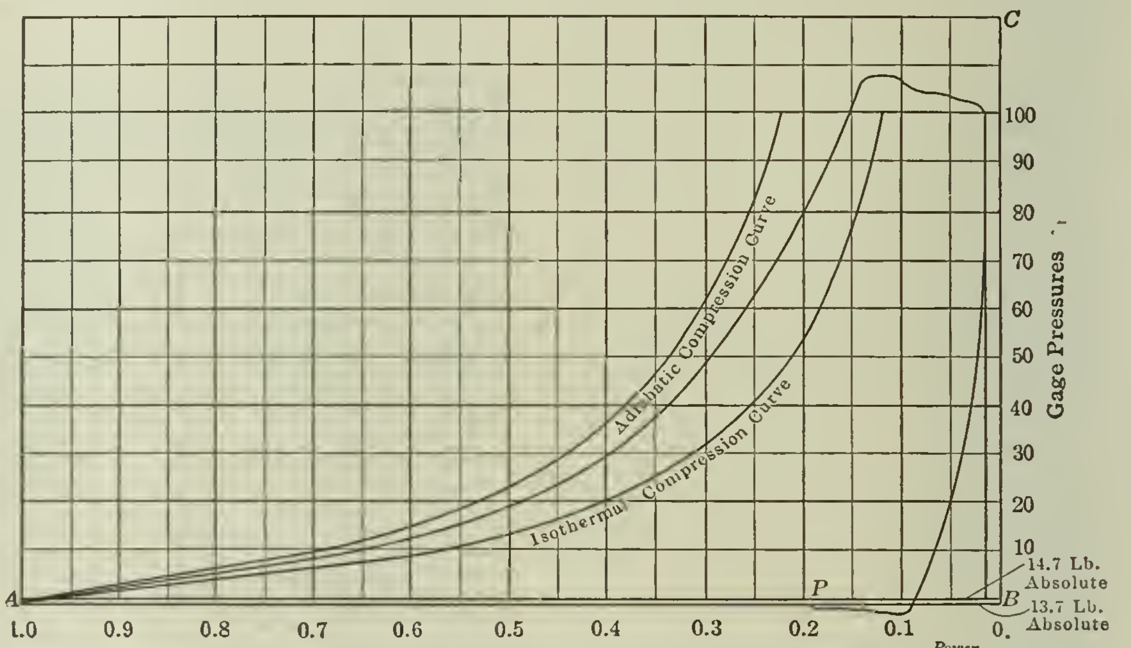
By H. V. Conrad

Tables providing data for conveniently laying out the theoretical isothermal and adiabatic curves on an indicator diagram taken from an air-compressor cylinder.

Indicator diagrams taken from air cylinders always show the compression curve as starting below the atmospheric line, when the compressor is drawing free air. This starting point of compression may range from ¼ pound, in the high-class machine, to 1½ pounds or more, below the atmospheric pressure, in machines having more or less restricted inlet passages.

Tables 1 and 2, provide data for quickly laying out in tenths of a pound the theoretical isothermal and adiabatic curves on indicator diagrams which start their compression anywhere between 14.7 and 10 pounds absolute. To prepare the indicator diagram for applying the tables, (see sketch) draw horizontal pressure lines at 10-pound intervals, to the scale of the indicator spring, using the portion *A P* of the diagram as a base line. Next, increase the length of the diagram by an amount equivalent to the percentage of the volumetric clearance in the cylinder at the end of the stroke, and erect the perpendicular line *B C*. Consider the length *A B* as one and divide it into 10 equal divisions. The tables give the horizontal measurements in percentages of one measured from the line *B C*; these locating the points of the compression curves on the various pressure lines.

As an example, the sketch shows a normal indicator diagram from an air cylinder compressing to 100 pounds, the volumetric end clearance being 1½ per cent., with compression starting at 1 pound below atmosphere at sea level; that is, at 13.7 pounds absolute. The diagram having been ruled with pressure lines and the subdivisions in length marked off, refer to isothermal values in Table 1 for 13.7 pounds absolute initial pressure. In the pressure columns will be found the horizontal measurements to be made on *A B*,



Isothermal and Adiabatic Curves Plotted on Indicator Diagram

10.0	1.250	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]

for the points in the compression curve—on the 20-pound line this is 0.407, on the 40-pound line 0.255, etc. The adiabatic values in Table 2 for 13.7 pounds absolute initial pressure give, on the 30-pound line 0.439, on the 50-pound line 0.336, etc. Thus a sufficient number of points are located to readily and accurately construct the curves.

The tables being worked down to 10 pounds absolute pressure, may be used up to 10,000 feet altitude, provided the inlet pressure does not start below 10 pounds.

The tables also show the approximate position (somewhere between the isothermal and adiabatic curves) of the piston, in percentage of its stroke, for any of the given pressures, and from the isothermal table may be seen the relative volume of air delivered at the given pressures as compared with the original volume, considered as 1, at initial pressure.

Table 3 shows the number of compressions that the initial absolute pressures undergo to reach the given gage pressures, and also represents the number of atmospheres (initial pressure atmospheric) in the given gage pressure.

Old Boilers Doomed by Modern Laws

By William Faulkner

These old vessels which had been moved from the land of the Michiganites to that of the Seattleites were condemned by the wise men of the latter place and a calamity thereby averted.

And it came to pass in the second year of the reign of President Harrison that various artisans, workers in iron and steel, gathered together in the land of the Michiganites and said: "Let us get some earth and turn it with fire and make iron so our craft may be known throughout the land, even from shore to shore." So they made iron and tested it and found it good and were well pleased. And behold, there came a captain of the craftsmen who were skilled workers in wood, and he said: "I am sore distressed because I cannot get sufficient horses to do my work."

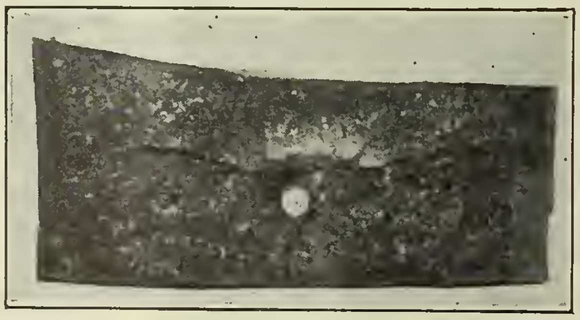
Then called he unto the captain of the workers in iron and steel and said unto him: "Make me a machine the same as James of the Wattites invented, and let it be equal to the strength of two hundred horses. And build me three vessels of iron in which water can be turned into steam."

So the captain of the workers in wood delivered unto the captain of the workers in iron and steel several bags of gold and said "Take this and deliver it to all your craftsmen who work diligently and when I return on the morrow I will pay thee in full." And there was great rejoicing in the land of the Michiganites. Then the captain of the workers in iron and steel sent for a scribe to draw a design for the three large vessels of iron, and he made a design for a vessel 192 inches in length, 60 inches in diameter and 3/8 of an inch in thickness, and he ordered that the sheets should be lapped and held together by two rows of rivets 13/16 of an inch in thickness, spaced 2¼ inches apart. The artisans then built three iron vessels according to the word of the scribe and they tested them with water and ordered that they should carry a working pressure of 100 pounds on every square inch.

Then came the captain of the workers in wood and looked upon the machine and the vessels of iron and he was well pleased.

Then came a great dearth of wood in the land of the Michiganites, so they sent messengers east and west and commanded them to find wood. And a messenger came from afar and he cried aloud and said, "Rejoice with me for I have found great amounts of wood in the land of the Seattleites."

And it came to pass that they journeyed to a far western country and dwelt among strange tribes that they might obtain wood with which to carry on their craft. So the captain of the workers in wood took with him all his machines and



Crack in Boiler Sheet

the three large vessels of iron and set them up in the land of the Seattleites, and they are there even unto this day.

In the second year of the reign of President Taft a number of wise men gathered together in the land of the Seattleites and said, "Behold, there are iron vessels in the country round about us which have been there since the days of our forefathers, and some have gone hence and the noise they made was like unto thunder and the people were much afraid."

So they appointed a number of skilled craftsmen to examine every vessel of iron and every vessel of steel and commanded them to test the vessels with water and with hammer and place their seal on all that were safe, and all that were unsafe they should condemn forever. And it came to pass that one appointed as examiner went to where the captain of the workers in wood had his iron vessels which he had brought from the land of the Michiganites in the year of President Harrison. And the examiner found a crack in one of the vessels of iron and he called unto him skilled workers and commanded them to cut out a piece of the iron vessel around about the crack, and when he measured the piece of iron it was found to be but 1/8 of an inch in thickness, so he condemned that vessel forever.

But the captain of the workers in wood was exceedingly wroth and he called the examiner before him and said unto him, "Would that I had the jaw bone of an ass that I might smite thee." And the examiner answered, "Knowest thou not that thou hast or thou wouldst not carry 100 pounds on each square inch of these old vessels and thereby endanger the lives of your craftsmen."

Then the captain of the workers in wood was much afraid and he shook with fear and said, "I must drink some wine; I pray thee come with me." And the wine softened his heart and he harkened to the words of the examiner and sent for laborers who rent the old vessels to pieces and modern vessels were placed in their stead.

Some week's ago, just after starting up the 13x18-inch engine in the planing mill of the Central Mill and Lumber Company, of Colville, Wash., the 16-inch belt was thrown, catching in the automatic governor and completely demolishing it, also breaking the eccentric and bending the connecting bar. A two weeks' shutdown was the result. The cause of the accident was an open drip from the exhaust. The night watchman was used to "cracking" the throttle early so as to warm up the engine, and on this particular morning neglected to close the drip on which there was an ell pointing toward the belt. Not much steam went out of this ell, but what did condensed and fell on the belt and froze there, where it remained unnoticed in the darkness of the morning until the load from the mill was thrown on. At this moment the belt slipped and did the damage previously mentioned.

Proper Use of the Term "Efficiency"

By A. C. Wilson

Although, fundamentally, the term efficiency represents the ratio of the energy supplied to the work done, it needs qualification in each particular case in order to avoid confusion.

Generally speaking, the efficiency of a machine is the ratio between the energy supplied and the useful work done, the difference between these two quantities being a measure of the waste or the loss of work in the machine. If W is the number of foot-pounds of work per minute required to drive a hoist and w is the number of foot-pounds of work done during the same time in lifting a weight, the efficiency of the hoist is

$$w \div W$$

and the work wasted is

$$W - w.$$

The amount $W - w$ does not disappear but is expended in overcoming friction and, being converted into heat, is consequently not useful work as regards the purpose for which the hoist is intended. There are two ways of measuring efficiency; W and w may be measured directly or either one of them and $W - w$ may be measured. Circumstances usually decide which method is the more convenient. In the majority of cases it is not easy to measure the waste work directly as this appears in the form of heat at the different bearings and the efficiency must be determined by measuring W and w.

It might appear from the foregoing that the efficiency of an engine or other machine is an absolute quantity and requires no further description, but, as a matter of fact, the term is used with reference to any ratio which is a measure of the economical performance in some sense or another and without further qualification conveys little or no information. The efficiency is always a ratio between the actual performance of a machine and an ideal performance, and to use the term without so qualifying it as to convey exactly what ratio is meant is either misleading or useless. Many trade advertisements and catalogs are full of examples of a vague use of the term efficiency. By common usage a number of ratios relative to the performance of steam engines, boilers, dynamos, pumps, etc., are described by prefixing a qualifying term, such as the thermal efficiency of a boiler, or the mechanical efficiency of a steam engine; and if this prefix is used, the ratio is immediately known, but where there is no such understanding it is necessary to state what ratio is meant, if the figures are to convey any meaning at all.

In a steam boiler the efficiency which is ordinarily desired is the ratio between the heat imparted to the water and the total heat in the coal put onto the grate. This ratio is usually known as the thermal efficiency and appears to be a sufficiently simple and straightforward thing to determine. There are, however, several opportunities for ambiguity, even here. The heat imparted to the water is the number of pounds of water evaporated per pound of coal fired, multiplied by the increase in the total heat per pound from that contained in the feed water pumped into the boiler to that of the steam leaving it. If the steam is dry saturated, the latter quantity can be ascertained from steam tables if the boiler pressure is known, but if the steam is wet, the degree of wetness must be measured by a steam calorimeter and if the steam is superheated, its temperature must be known. The total heat imparted to a pound of wet steam at a given pressure is less than that in a pound of dry steam at that pressure by an amount equal to the latent heat of that fraction which is in the form of water; that is, if steam is found to be 2 per cent. wet and the absolute pressure is 100 pounds the total heat per pound is

$$1186.3 - (0.02 \times 888) = 1168.54 \text{ B.t.u.}$$

measured from 32 degrees Fahrenheit. Similarly if steam is superheated in the boiler the total heat per pound is greater than the total heat of saturated steam at the same pressure by the specific heat of superheated steam multiplied by the difference in temperature between the superheated steam and that of saturated steam at the same boiler pressure, which latter may be found from steam tables.

The total heat in the coal is found by a laboratory test in a calorimeter and this may represent the heat in a sample after drying or in the same condition, as regards wetness, in which it was actually used. The amount of wetness in the coal as fired is also determined in the laboratory. If the chemist states the heat value of dry coal it is evident that an additional calculation will have to be made as the boiler test will have determined the evaporation per pound of wet coal. It is usual in scientific tests to give the results in terms of dry coal, and knowing the amount of wetness in the coal the evaporation per pound of dry coal is easily calculated. Suppose the boiler test showed that 7½ pounds of water were evaporated per pound of coal as fired and the chemist's figures show that the coal contained 10 per cent. of moisture; then the boiler really evaporated 7½ pounds of water from 0.9 pound of coal or

$$7.5 \div 0.9 = 8.33 \text{ pounds}$$

of water per pound of dry coal. Another equally correct method would be to calculate from the chemist's figures the heat value per pound of coal as fired as to the heat value of the dry coal and the amount of moisture; that is, suppose the heat value of the dry coal is given out as 13,000 B.t.u. per pound and the wetness of the coal as fired is 10 per cent., the heat value per pound of coal as fired is

$$13{,}000 \times 0.9 = 11{,}700 \text{ B.t.u.}$$

The important thing to look after is, that when the heat value of dry coal appears in the heat balance the evaporation per pound of dry coal must be used in calculating the heat imparted to the water and when the heat value per pound of coal as fired is used the evaporation per pound of coal as fired must be figured.

The available heat value of coal, having in view the conditions under which it is burned in a boiler, is not actually as much as the heat value ascertained by a laboratory test, for the reason that the hydrogen in the coal combines with oxygen to form steam and in a laboratory test this steam is condensed to water and the latent heat is given up. When burned under a boiler, however, the steam thus formed mixes with the other products of combustion and passes away as steam at a temperature above that of condensation; the latent heat in this steam is consequently not available and it is usual to deduct it from the heat value in the coal, calling the result the "lower" heat value. With ordinary coals the lower heat value is about 300 to 400 B.t.u. per pound less than the total heat value. It is customary nowadays to use the "lower" heat value in the heat balance for boiler tests and this, of course, makes the thermal efficiency higher than would be the case were the total heat adopted.

In considering steam-engine efficiency there are a considerable number of ratios each of which may be called the efficiency with respect to some standard of comparison, and it is again obvious that the term efficiency by itself means very little. Taking the general meaning of efficiency to be as stated at the beginning of this article, that is, the ratio between the energy supplied and the useful work done, the efficiency of a steam engine would appear to be the ratio of work done per pound of steam used divided by the total heat in one pound of the steam supplied, both being expressed in heat units. For example: let dry steam be supplied to an engine at 100 pounds absolute pressure and the steam used per horsepower per hour be 20 pounds. The total heat in one pound of dry steam is found from the tables to be 1186 B.t.u. and the work done per pound of steam used is

$$\frac{33{,}000 \times 60}{20} = 99{,}000 \textit{ foot-pounds} = \frac{99{,}000}{778}$$

$$= 127 \textit{ B.t.u.}$$

and the efficiency by this method is

$$\frac{127 \times 100}{1186} = 10.7 \textit{ per cent.}$$

This ratio, however, is not what is generally meant by the efficiency of a steam engine, as even in the case of a thermodynamically perfect engine the ratio would be less than unity. It is more useful, therefore, to compare the performance of an engine with that of the ideal engine working on some assumed conditions, the two most important of which are those known as the "Carnot" cycle and the "Rankine" or "Clausius" cycle. When the term thermodynamic efficiency or simply efficiency is used, the standard of comparison is the "Carnot" cycle, but if an ideal engine working on the "Rankine" cycle is the standard, the term "efficiency ratio" is used. The latter cycle is now generally accepted as the standard cycle for comparison and the "efficiency ratio" alone appears in the Institution of Civil Engineers' (England) standard method of tabulating steam-engine trials where the full formula for calculating this ratio is given.

Another important ratio relating to steam and gas engines but of a totally different nature is the "mechanical efficiency," which is the ratio between the work done on the piston and the useful work given off at the flywheel or the ratio between brake horsepower and indicated horsepower. The difference between these horsepowers represents work absorbed in friction in turning the engine, and the mechanical efficiency is a measure of the loss in obtaining power from the piston to the point where it is actually available for use and has no reference to thermodynamic considerations. To give an idea of the efficiency likely to be obtained in actual engines it may be said that, although the mechanical efficiency of a good engine may be from 85 to 95 per cent., the efficiency ratio lies usually between 0.5 and 0.6.

To turn to other machines it will be found that there is just as great a necessity to define what efficiency is meant when talking about their performance as is the case with engines or boilers. One sometimes sees tests of air compressors quoted where the efficiency without any qualification is given but where the volumetric efficiency is what is actually referred to. This is the ratio between the volume of air drawn through the inlet valves and the volume swept through by the piston of the air cylinder, and relates to the quickness in opening and closing of the valves or the lost motion in the machine and not the lost work. The lost work is measured by the mechanical efficiency and is of a precisely similar nature to the mechanical efficiency of an engine. In a steam-driven compressor the mechanical efficiency is the ratio of the indicated horsepower in the air cylinders to the indicated horsepower in the steam cylinders; and for a motor-driven compressor it is the ratio of the indicated horsepower in the air cylinder to the brake horsepower of the motor.

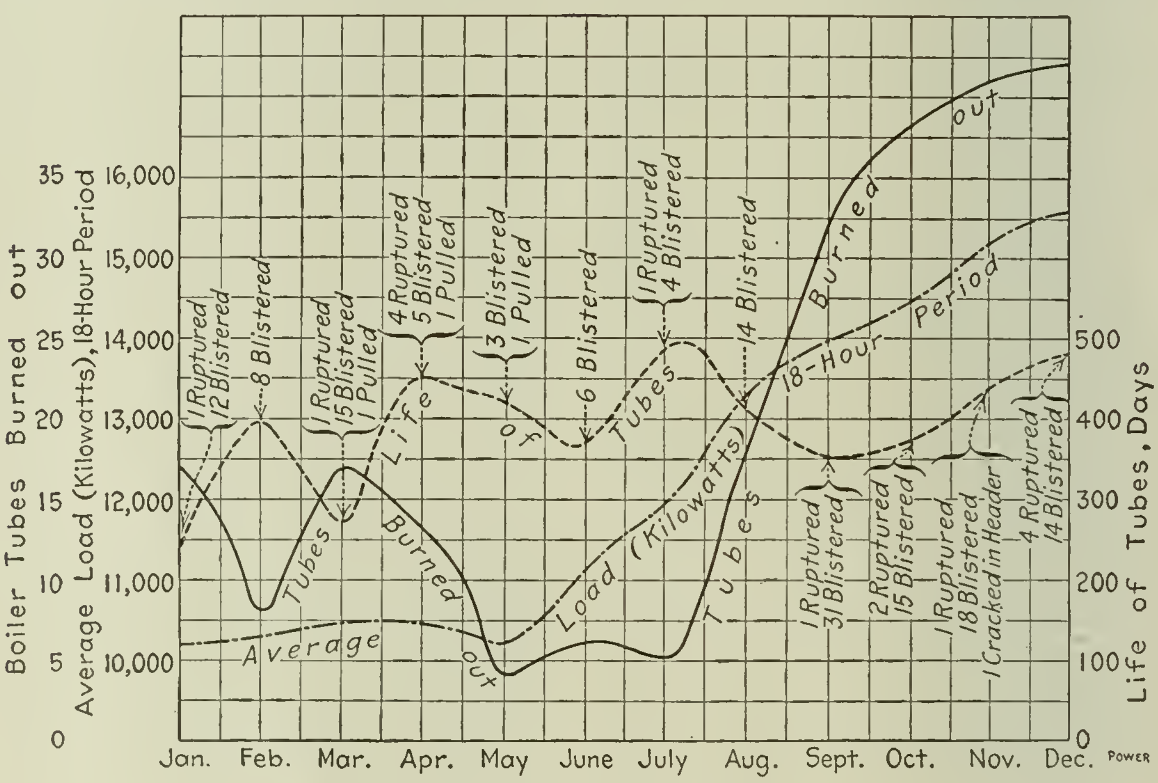
In considering the performance of an air compressor, however, there are other ratios which give useful information and enable different machines to be compared with an ideal standard, and as the term efficiency is often used in connection with these ratios it requires qualification. For instance, the power required to compress one pound of air from one pressure to another pressure when the temperature is maintained constant, that is, isothermal compression, can be calculated readily and is a convenient standard of comparison with the power actually found to be necessary in a compressor working between the same limits of pressure. The ratio of the work required for isothermal compression to the work actually taken is sometimes called the efficiency, but more correctly it is the efficiency compared with isothermal compression. For other purposes the power required to compress adiabatically, that is, without allowing any heat to be abstracted from or added to the air, is taken as the standard for comparison and the ratio obtained should be defined as the efficiency compared with adiabatic compression.

One could easily multiply instances of the various different ratios which are all called efficiency, but enough has been said to emphasize the point that it is a word which cannot properly be used without qualification.

Effect of Heavy Loads on Boiler Tubes

By Leroy W. Allison

Plotted from records of the past year's operation of a 15,000-kilowatt plant, carrying for the most part a railway load, the accompanying chart indicates the effect of peaks upon boiler tubes. The curves are deduced for 18-hour periods and are self-explanatory. The plant contains eighteen Babcock & Wilcox boilers, each rated at 550 horsepower and comprised of twenty-one sections of fourteen 4-inch tubes 18 feet long; the drums are 42 inches in diameter. To supply the three 5000-kilowatt units, the boilers are operated under a working pressure of 175 pounds, in groups of six; five are used for normal load, the sixth being held in reserve. Each boiler is fitted with a Peabody oil-burning furnace equipped



Effect of Load on Tubes

with three burners. These burners fire forward from the bridgewall and steam is used as the atomizing agent. The boilers are provided with Babcock & Wilcox superheaters, designed for 100 degrees superheat, and California crude oil is used as fuel. This ranges in density from 13 to 15 degrees Baumé, and has a value, as fired, of approximately 18,000 B.t.u.

The ingineer at the sawmill wus cleanin' the biler and puttin' a kag of stable manure in the manhed when Parson Goodman kim along and stopped to talk a bit. He watched the manure go in the biler and all of a sudden exklaimed: "I never new before now what was meant by horsepower. I recken if you had a stable of 100 horses you would have a heap more power." An' the ingineer scratched his hed for a while an lowed he would.

Dimensions of Riveted Steel Pipe

By N. A. Carle

Charts showing the thickness of plate for riveted steel pipes of different diameters with various pressures, tensile strengths, factors of safety and efficiencies of joint. Examples are given illustrating the use of charts.

Riveted steel pipe is generally used to carry water from the source of supply to the point where it is to be utilized, at which point the discharge pressure is greater than the inlet pressure, due to the difference in elevation; or it may be used if water under pressure is to be conveyed between two points. The strength of the pipe must be increased as the head increases, and, unless a large factor of safety is allowed, unusual care must be taken in protecting the steel plates and rivets from rust.

The formula for the strength of riveted steel pipe is

$$P = \frac{2\,T\,t\,e}{D\,f}$$

where,

P = Safe working pressure in pounds per square inch;
T = Tensile strength in pounds per square inch;
t = Thickness of steel plate in inches;
e = Efficiency of joint in per cent.;
D = Diameter of steel pipe in inches;
f = Factor of safety.

The accompanying charts show graphically the thickness of steel plate for various diameters of pipe, working pressures, factors of safety, tensile strength of the steel plate and efficiencies of joints.

Fig. 1 is for pipe up to 60 inches in diameter carrying pressures from 50 to 300 pounds per square inch with factors of safety from 2.5 to 6. The tensile strength of the steel plate ranges from 45,000 to 70,000 pounds per square inch with efficiency of the joints from 50 to 85 per cent.

Fig. 2 is for pipe up to 45 inches in diameter carrying pressures from 200 to 1200 pounds per square inch with factors of safety from 2.5 to 6. The tensile strength and efficiencies of joints are the same as for the chart in Fig. 1.

EXAMPLE—What thickness of steel plate of a tensile strength of 60,000 pounds per square inch and an efficiency of joints of 70 per cent. will be necessary using a factor of safety of 5 for a pipe line 42 inches in diameter and carrying a pressure of 100 pounds per square inch?

Using the chart shown in Fig. 1, start with 42 inches diameter of pipe and read up to 100 pounds per square inch working pressure, then across to a factor of safety of 5, then down to 60,000 pounds per square inch tensile strength and across to 70 per cent. efficiency of joint and down to 1/4 inch thickness of steel plate.

EXAMPLE—What pressure will a 30-inch pipe of 1/2-inch steel plate stand with a factor of safety of 4 if the steel plate has a tensile strength of 50,000 pounds per square inch and a joint efficiency of 80 per cent?

Starting with a 1/2-inch thickness of steel plate and using the chart in Fig. 2, read up to 80 per cent. efficiency of joint, then across to 50,000 pounds per square inch tensile strength and up to a factor of safety of 4, then extend a line horizontally across until it intersects the ordinate marked 30 inches diameter of pipe. The value of the working pressure at the intersection will be found to be 500 pounds per square inch.

EXAMPLE—A pipe line 1600 feet in length and 60 inches in diameter has a gradual drop of 200 feet throughout its entire length. What thickness of steel plate of 55,000 pounds per square inch tensile strength should be used if the pipe line is to have a factor of safety of not less than 5 and a joint efficiency as follows:

1/4 inch steel plate	70 per cent.
9/32 inch steel plate	75 per cent.
5/16 inch steel plate	80 per cent.

and what will be the corresponding lengths of pipe made up of 1/4-, 9/32- and 5/16-inch steel plates?

The pressure at any point will be that due to a head equal to 1600 ÷ 200, or 1/8 of the length of the pipe line from this point to the point of supply. Conversely, multiplying the head at any point by 8 will give the length of the pipe line from this point to the point of supply.

On account of the possibility of collapse from external causes, it is advisable that no steel plate shall be less than 1/4 inch for pipes of this diameter and for service of this kind.

Starting with 1/4-inch thickness of steel plate, Fig. 1, read up to 70 per cent. efficiency of joint, then across to 55,000 pounds per square inch tensile strength, then up to a factor of safety of 5 and then horizontally across to its intersection with the ordinate through 60 inches diameter of pipe. This gives a value for the working pressure of approximately 64 pounds per square inch, which is the limiting pressure for 1/4-inch steel plate of 55,000 pounds per square inch tensile strength with a joint efficiency of 70 per cent. and a factor of safety of 5.

This pressure is reduced to an equivalent head in feet by dividing by 0.434, which gives 147.5 feet head. Multiplying this by 8 gives the length of 1/4-inch steel pipe line as 1180 feet.

Starting with a 9/32-inch thickness of steel plate read up to 75 per cent. efficiency of joint, then across to 55,000 pounds per square inch tensile strength, then up to a factor of safety of 5 and horizontally across to its intersection with the ordinate marked 60 inches diameter of pipe. This gives a value for the working pressure of approximately 77.5 pounds per square inch, which is the limiting pressure for a 9/32-inch steel plate of 55,000 pounds per square inch tensile strength with a joint efficiency of 75 per cent. and a factor of safety of 5.

This pressure is reduced to its equivalent head in feet by dividing by 0.434 which gives 178.5 feet head. Multiplying this by 8 gives the length of pipe from the entrance to the end of the 9/32-inch steel plate as 1428 feet.

Starting with 5/16-inch thickness of steel plate read up to 80 per cent. efficiency of joint, then across to 55,000 pounds per square inch tensile strength and up to a factor of safety of 5; then horizontally across to its intersection with the ordinate marked 60 inches diameter of pipe. This gives a value for the working pressure of approximately 91.5 pounds per square inch, which is the limiting pressure for a 5/16-inch steel plate having a tensile strength of 55,000 pounds per square inch and a joint efficiency of 80 per cent. with a factor of safety of 5. This pressure is reduced to its equivalent head in feet by dividing by 0.434, which gives 210.8 feet head. Multiplying this by 8 gives the length of pipe from the entrance to the end of the 5/16-inch steel plate as 1686.4 feet. The entire length of the pipe line is 1600 feet; therefore, no steel larger than 5/16 inch need be used.

The lengths of pipe line for each thickness may be found from the following:

Length of 1/4, 9/32 and 5/16 inch	= 1600 feet
Length of 1/4 and 9/32 inch	= 1428 feet
Length of 5/16 inch	= 172 feet
Length of 1/4 and 9/32 inch	= 1428 feet
Length of 1/4 inch	= 1180 feet
Length of 9/32 inch	= 248 feet

"Casey," says Mike, fr havin' his first visit to the ice factory, "phwat kind of a ingine be that?"

Casey stuck his thumbs in the armholes of his vest and swelled up.

"That do be 'bout a four-cylinder gas ingine," says he.

"'Four-cylinder,'" says Mike, pointin' at the [illegible], "An' many of the cylinders be missin'?"

"Sure," explains Casey, "they're all o' them runnin' right, but wan of them is missin' most o' the time."

Repairing Induction Motors

By R. H. Fenkhausen

Rotor Repairs

After the shaft and bearings have been put in first-class condition, the rotor should be carefully examined to see if the "winding" is damaged. The paper in the slots inclosing the rotor bars should be tried with a knife point, and if so badly charred that it chips off when

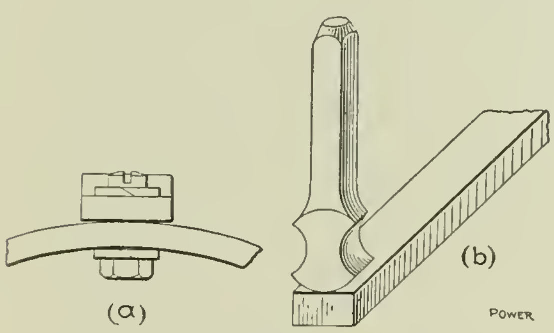

Fig. 14. Bar Connection

touched, it should be renewed. The mere fact that the paper was charred would indicate only a slight decrease in the starting torque, which would not be of any practical harm to the motor. Charred paper, however, is usually the effect of local heating at the joints between the bars and the end rings, caused by loose bolts, and as the repair of this trouble requires the removal of the bars in order that the contact surfaces may be cleaned, the renewal of the paper insulation on the bars entails only a very small amount of additional work and makes a proper job of the repair, instead of a makeshift.

The heating caused by poor contact

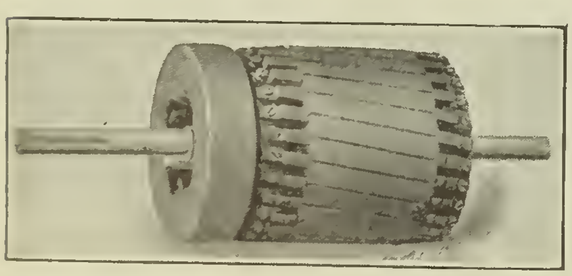

Fig. 15. Rotor with Skewed Slots

between the rotor bars and short-circuiting rings is liable to lead to serious damage to the entire motor if not corrected. The ends of the stator coils outside the slots lie very close to the rotor and are liable to be so badly charred as to necessitate a complete rewinding of the stator.

Squirrel-cage Rotors with Bolted Bars

The bolts should all be removed and the bars taken out of the slots. The short-circuiting rings should then be thoroughly cleaned with sandpaper and the outside circumferences "tinned." The solder should be applied to the ring while the latter is hot, and, after the entire surface has been coated, the "tinning" should be wiped with a piece of cloth before the solder has set. This will insure a coating of uniform thickness all around the ring.

The bars should be cleaned and all charred paper scraped off them and also

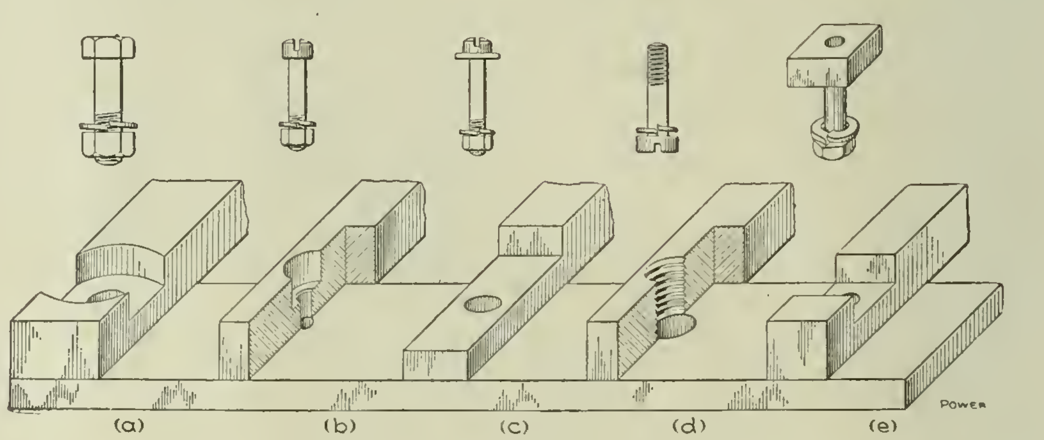

Fig. 16. Forms of Rotor-bar Ends for Bolting

from the walls of the slots in the core. The under surfaces of the bars should then be "tinned" at each end for a distance equal to the width of the short-circuiting ring, and wiped smooth, like the rings. The object of "tinning" the contact surfaces between the bars and rings is to prevent oxidation in case of any subsequent slight heating due to temporary overloads. The "tinned" surfaces tend to unite when heated and form a soldered joint.

Before "tinning" the bars the contact surfaces should be tried on the ring to determine whether the bar is concaved to fit the ring, or flat. Fig. 14 shows at *a* an exaggerated view of the scanty contact found in rotors when the makers do not take the trouble to give the bars the proper shape. Small motors having rotors of small diameter with comparatively few bars are most liable to trouble from this source. Large motors usually have bars of approximately the same size as those used in the smaller motors, but a much larger number of them, and, owing to the large diameter of the end rings, the amount of curvature under a single bar is practically negligible.

If the contact is found to be bad, due to this cause, a steel swedge should be made having a face curved to correspond to the curvature of the ring, and all the bars should be given a blow with this before "tinning," as indicated at *b* in Fig. 14, care being used that the swedge is held level so that the bar will be uniformly indented. For rotors having skewed slots, as shown in Fig. 15, a jig should be made before swedging in order that all bars may be held at the same angle that they will have with reference to the short-circuiting rings when the rotor is reassembled.

Methods of Bolting Bars

There are several methods of bolting the rotor bars to the short-circuiting rings, each of which has its advantages. The four methods in most common use are illustrated in Fig. 16. The method shown at *a* was formerly used on almost all motors. A large bolt with a nut and spring washer inside the ring gave ample clamping power without danger of stripping the threads on the bolt. Later designs of rotors are usually fitted up as shown at *b*, *c* or *d*. On account of the smaller bars now commonly used, there is no room for a large bolt, and a small 10/32 machine screw is usually employed.

It will be noted that the three joints shown at *a*, *b* and *c* are made with the nuts inside the ring and the bolt heads outside. This construction is the most accessible, except on large motors, but is open to the very serious objection that a loose, broken or burned-off screw or bolt will naturally be thrown outward by centrifugal force and will catch on the stator coils and seriously damage them. Cases are on record where a complete set of new stator coils has been necessary as a result of a broken screw. The construction shown at *d* is designed to eliminate this objection and is used on a large proportion of the motors now manufactured; two bolts at each end of each bar are used on the larger sizes of motors. The disadvantage of the latter construction lies in the fact that the thread for the screw is tapped into the bar itself, and as there is no room for a lock nut, reliance must be placed on a spring washer to prevent the bolts from becoming loose.

Fig. 17. Drill Bit

Where there is much vibration, trouble is experienced from loose bolts, which has led one manufacturer to upset the ends of the bolts. This effectually locks the bolt but when it becomes necessary to repair the rotor it is practically impossible to remove the bolts without stripping the threads out of the bars. The screws cannot be drilled out, owing to the difficulty of holding a drill central on a steel screw; it will run off into the softer copper. The limited diameter of the bars makes it impossible to retap them for a larger size of screw when stripped.

Two methods of repairing the rotor are available. The first is to counterbore the bars, as shown at *b*, Fig. 16, and use fillister-headed screws with nuts and spring washers inside the ring. A pin drill for counterboring is shown in Fig. 17; this can be easily turned up in a lathe out of a piece of tool steel. This method of repair, though the easiest, is open to the objection previously mentioned, that a loose bolt can damage the stator winding. A better method is illustrated at *c*, Fig. 16. The bars are sawed or milled out somewhat as shown at *c*, but instead of the screw head being outside it is placed inside and a special square nut fitted into the notch cut in the bar; a spring washer under the head of the screw serves as a lock. As the nut does not carry current it may be made of steel, and may be properly tightened without danger of stripping the threads.

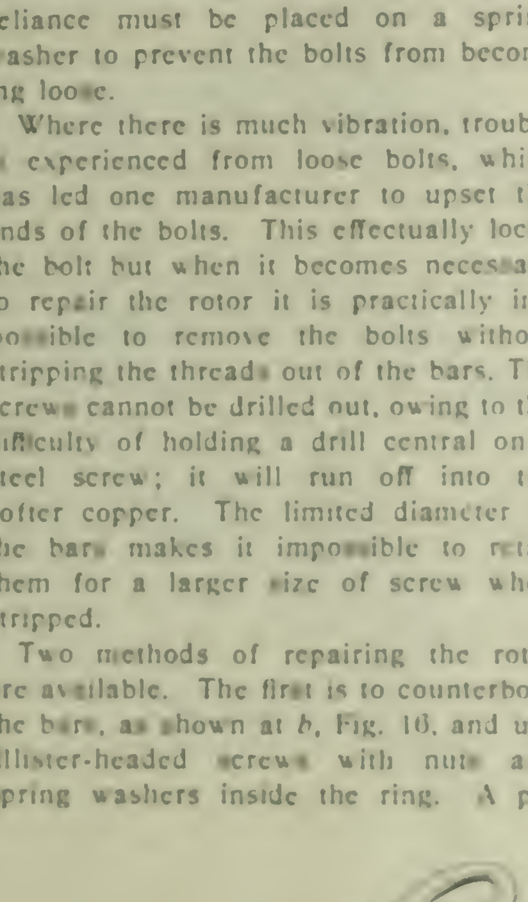

Fig. 18. Insulation Cutter

Paper Insulation

The new paper insulation should be of red rope paper or bond paper, 5 to 8 mils thick. It should be cut long enough to inclose the bar to within 3/16 inch of each end ring, and wide enough to cover five sides of the bar, which will give a lap on one side to allow pasting. The paper should be cut from the roll in strips wide enough to make the length of the individual bar wrappers, with the aid of a straight-edge, and then cut into the proper widths with a photographic print trimmer, such as that shown in Fig. 18.

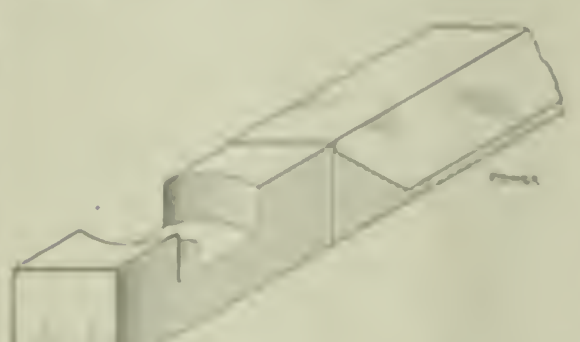

Fig. 19. Paper Sheath

Each paper cell should be creased and folded around the bar, and the corners clipped off as shown in Fig. 19 to facilitate the entrance of the cells into the slots, and prevent the corners of the paper from catching on the laminations of the core.

The overlapping ends of the paper cells should next be pasted into place and the bars inserted in the rotor slots. The double thickness of paper should be on the bottom of the slot to prevent the lapped ends of the paper from becoming loosened by centrifugal force and flying out into contact with the stator winding. This would, of course, do no damage, but would cause a rustling noise, very annoying in most locations.

After the bars are all in place, the end rings should be inserted, and two diametrically opposite bars bolted firmly to the rings at each end. A thin "feeler" should then be tried between the rings and bars to insure that a condition similar to that illustrated by Fig. 20 has not been brought about by too much paper in the bottom of the slots. If trouble from this source is found, the paper cells must be reversed so as to bring the double thickness of paper on top of the bar instead of underneath.

The bolts should then be drawn tight and the spacers which prevent axial movement of the bars inserted at equidistant points around the ring. These spacers consist of small sheet-metal strips clamped under the nuts which hold the bar, as shown in Fig. 21. It will be noticed that the squirrel cage is grounded at these points, but, owing to their location, the effect is negligible.

Fig. 20. A Poor Joint

Soldered Squirrel-cage Rotors

Owing to the soldered joints between bars and end rings, trouble from loose contacts is seldom encountered in this form of rotor, except as the result of extreme overloads such as occur in planing mills or other wood-working establishments, for which service the bolted construction is preferable.

In case repairs are necessary to this type of rotor, the short-circuiting rings must be heated with a gasolene torch until the solder melts and permits the rings to be pried off. The bars should then be cleaned, "tinned," reinsulated, as described in the discussion of bolted rotors, and replaced in the slots. The rings should be thoroughly cleaned and all paint removed before retinning. If this is neglected, the paint or varnish will run into the joints when the ring is heated and prevent the solder from making a good contact. After the rings have been cleaned and retinned all over, they may be slipped into place on the bars.

In the earlier forms of soldered end rings, the openings for the bars were punched out, leaving only a thin edge of metal available for the soldered joint. It is very difficult to make a good joint

Fig. 21. A Good Joint

with these rings unless the entire armature be dipped into the solder. This is best accomplished by the use of a shallow annular trough of clay, or of sheet iron lined with clay. The solder may be melted by means of several torches and the rotor dipped into the molten solder to the required depth, as shown in Fig. 22. Later forms of end rings have the metal only partly punched from the openings and bent back to form lips and spacers between the rings, as indicated in Fig. 23. These lips give a comparatively large contact surface for soldering, and the rings may be soldered with an iron, provided, of course, that one ring be placed at a time, in order to give access to all sides of the bars.

Riveted Squirrel-cage Rotors

In case it becomes necessary to remove the rivets from a rotor of this type, they should not be chipped out, because hammering a steel rivet in a soft copper bar will enlarge the hole and prevent proper contact with the rivet when the rotor is

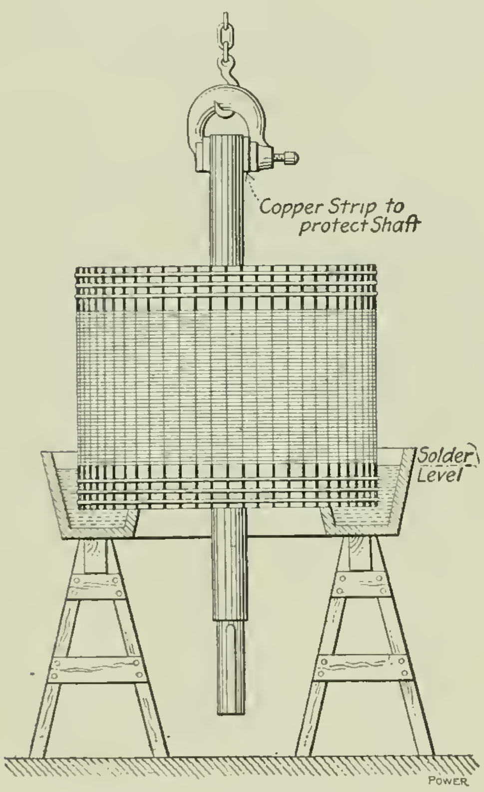

Fig. 22. Soldering Rotor Connections

reassembled. The rivets should be removed by filing off the heads, or by drilling out the countersunk heads if these be used. After "tinning" and reinsulating the bars, as previously described, they should be attached to the end rings by bolting, one of the methods shown in Fig. 16 being employed.

Wound Rotors

Although grounds on a squirrel-cage rotor are of little consequence, two or more grounds on a wound rotor may lead to serious trouble. Rotors of this type are almost invariably equipped with three-phase windings, usually "star" connected. The effect of grounds on a rotor of this type can best be illustrated by an extreme case. Suppose that three grounds should occur simultaneously, at the points *A*, *B* and *C*, Fig. 24; the entire winding would be short-circuited upon itself and run as a squirrel-cage rotor. It is evident that a change in the external resistors R_1, R_2 and R_3 will have no effect on the speed of the motor, which will run at full-load speed irrespective of the position of the controller handle.

Though this is an extreme case, the effect of two or more grounds, wherever located in the rotor winding, is to take the speed control of the motor out of the

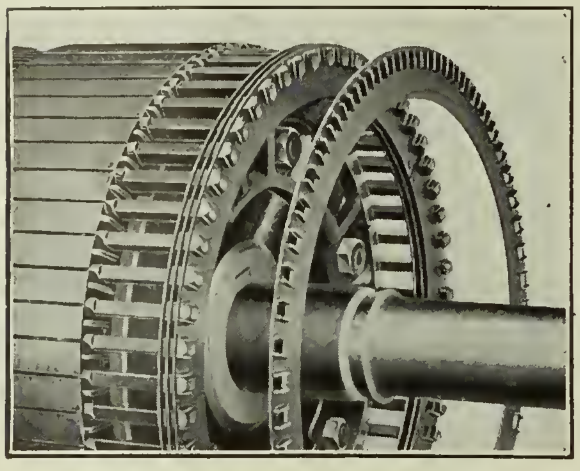

Fig. 23. Bolted Rotor Bars

operator's hands to a greater or less degree, depending on the amount of the winding short-circuited by the grounds. Whenever a motor runs above its normal speed for a given load and controller position it may be taken as evidence of grounds. As the slip rings and brush rigging are more liable to become grounded than the rotor winding, the leads from the winding to the slip rings should be disconnected before testing for grounds.

A short-circuit will produce an effect similar to that of two grounds; but it is a very difficult fault to locate, owing to the extremely low resistance of the wind-

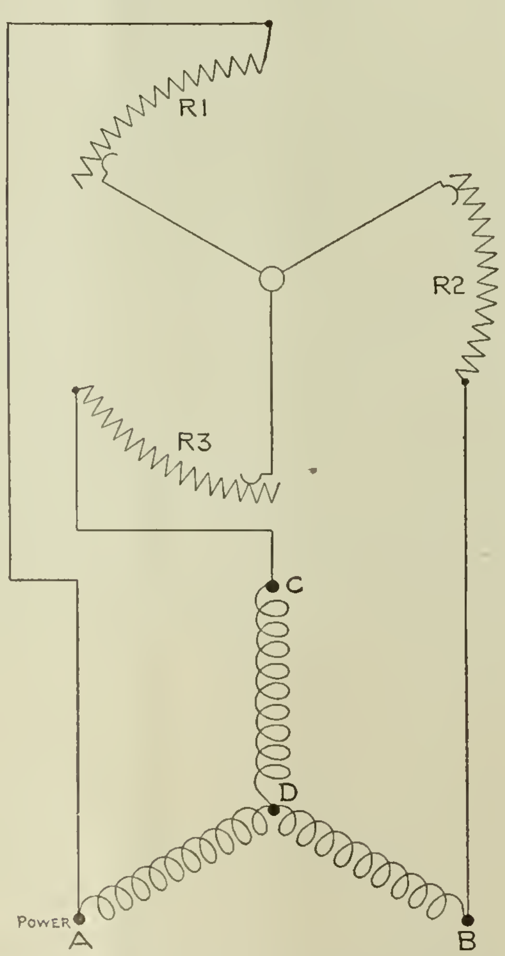

Fig. 24. Wound-rotor Connections

ing. It is most liable to occur between the two bars in one of the slots, where they happen to belong to different phases, and seldom results in a ground.

Open circuits are of rare occurrence, owing to the heavy conductors used, and even should one occur it could easily be located. When a short-circuit is suspected the common junction at *D*, Fig. 24, should be opened to allow testing for crossed phases. By measuring the resistance of each phase with a sensitive Wheatstone bridge, short-circuits can be detected.

Wound rotors for service requiring high torque or where the controlling apparatus is located some distance from the motor are wound with coils similar to those used on the stator, the only difference being that the rotor coils are

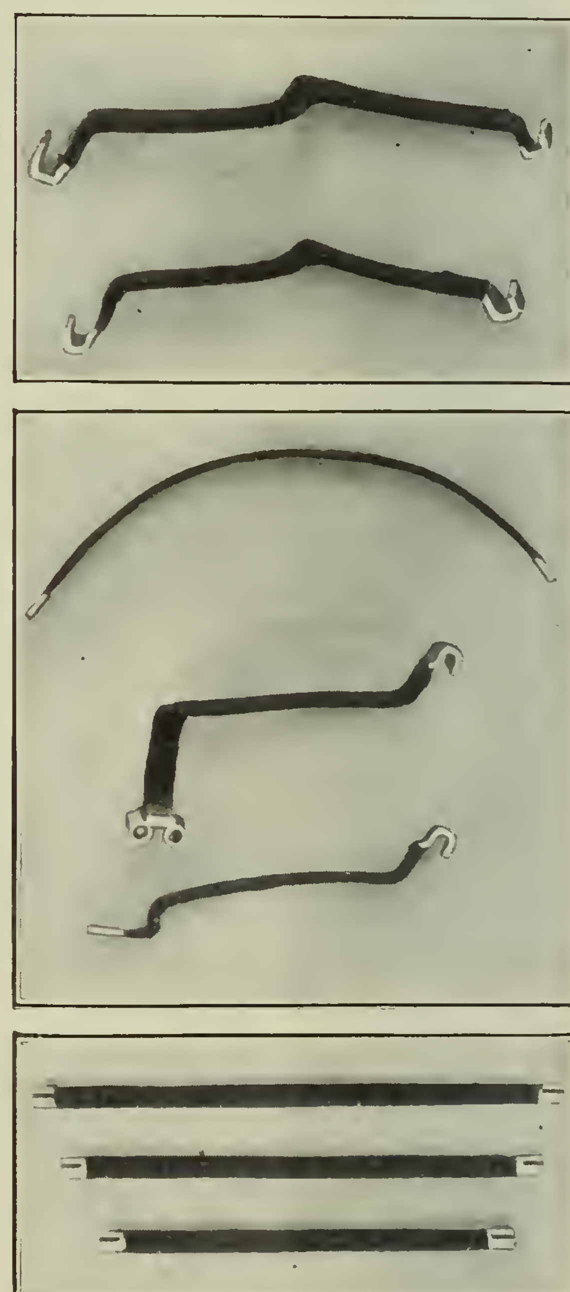

Fig. 25. End Connectors, Winding Terminals and Rotor Bars

placed in slots on the outside circumference of the core, while the stator coils are placed in slots on the inside circumference of the core. Coils of this type are of high resistance and many turns and the rotor voltage is often as great as that impressed on the stator winding. Owing to the similarity between a stator winding and a rotor winding of this character, the repair of such rotor windings will not be treated in this article; the full instructions which will be given in the article on the repair of stator windings will apply equally well to high-resistance rotors.

Bar Windings for Rotors

Most of the wound rotors for multi-speed service now in use are wound with heavy bars or strips similar to those used

FIG. 26. WOUND-ROTOR BAR "COIL"

in a squirrel-cage rotor, but two bars are usually put in each slot. These bars are connected at the ends into regular "coils" by means of pieces of copper strap, known as end connectors. This material is usually only half as thick as the bars which it connects; it is, therefore, made twice as wide in order to get the necessary cross-section. Fig. 25 shows long and short bars and end connectors and also the terminal leads for the winding. Fig. 26 shows the method of grouping two bars and a connector to form a one-turn coil. It will be noted

FIG. 27. A STATOR COIL

that the finished "coil" resembles the involute form of stator coil shown in Fig. 27.

The end connectors are soldered into slots cut in the ends of the rotor bars and the three free terminals of the winding are carried to the slip rings. As the repair of a bar-wound rotor of this type seldom calls for the renewal of anything except the insulation on the bars and end connectors it is merely a matter of replacing things and reconnecting in the original manner.

Balancing

After repairing a wound rotor it should be tried for balance; the less symmetrical character of the winding makes it more liable than the squirrel-cage type to be reassembled out of balance. The most accurate method is illustrated in Fig. 28. Two parallel rails are set up perfectly true and level on stout posts and the rotor is hoisted up and placed on the rails with a large ring slipped over each end of the shaft, as shown. These rings permit far more accurate balancing to be done, as they allow the rotor to revolve much more easily than it would if the shaft were laid directly on the parallel rails.

FIG. 28. BALANCING WAYS

The rotor will roll until the heavy side is at the bottom. A piece of wet clay should be pressed against the inside of the spider on the light side and its weight adjusted and location changed until the rotor shows no tendency to rotate, no matter in what position it is placed. Then the clay is weighed and a piece of metal fastened in its place by means of a tap bolt; the weight of the metal and bolt together must equal that of the clay.

Collector Rings and Brush Holders

Trouble at the collector rings is usually due to defective insulating bushings

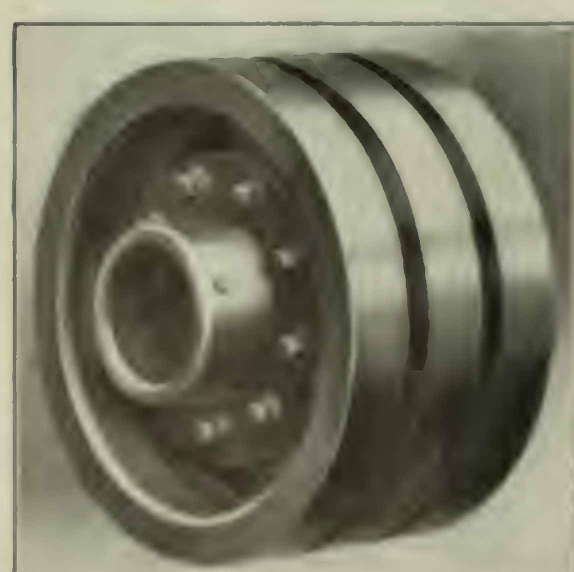

FIG. 29. THREE-PHASE SLIP RINGS

around the bolts which hold the ring structure together. It is usually caused by vibration, which loosens the bolts and allows them to "work," thereby wearing out the insulation. After renewing the bushings the rings should be drawn together tightly and lock washers placed under the bolts. Fig. 29 shows the construction of a set of rings.

Fig. 30 shows a typical set of pivoted brush holders. Flexible copper shunts or

FIG. 30. ROCKER-ARM AND BRUSH HOLDERS

"pigtails" are used to carry the current from the brush box to the terminals. If one of these shunts should be broken, the current would be forced to travel through the hinge pin, which will heat up until it sticks and prevents the brush from maintaining contact with the ring. The carbon brushes used with this type of motor usually have copper-wire gauze molded into the brush to increase its conductivity.

These brushes should be fitted to the slip rings with sandpaper in the same manner as those on a direct-current motor, but, owing to the fact that the long axis of the brush is radial to the shaft, a condition such as that illustrated in Fig. 31 may exist when the sandpaper is removed. If the sandpaper is 1/16

FIG. 31. INCORRECT BRUSH SETTING

inch thick, the hinge edge of the brush is liable to be over 1/32 inch clear of the ring, due to the position of the hinge.

To correct this it is necessary merely to loosen the clamping screw and slide the holder upward on the brush until both edges touch the ring as they must to obtain good contact.

When motors vibrate, hangers will get loose, allowing belts to pull the shaft out of line. This can be prevented by driving in a small lag screw at the heel of one of the hanger.

Gas Power Department

Everything worth while in the gas engine and producer industry will be treated here in a way that can be of use to practical men

Repairing a Broken Engine Frame

By H. T. Melling

The breakdown and repair of a 50-horsepower gas engine came under the writer's observation some time ago. The engine was a single-cylinder single-acting one, working with a similar engine of 100 horsepower, both engines being connected to the same shaft by rope drives off the flywheels.

The engines had been at work about two years, giving entire satisfaction, when the accident occurred. The connecting-rod bolts on the big end of the 50-horsepower engine broke and, the piston being blown partly out of the cylinder, when the crank next came around it lifted the connecting rod so far that it broke through the top of the piston barrel and broke the cylinder liner and the front of the main frame. See Fig. 1.

It was first thought that the breakage of the main frame would necessitate a new casting because the front of it formed a water-tight expansion joint with the cylinder liner. However, it was decided to order from the makers only a new cylinder liner and piston.

The two broken pieces of the main frame were placed in position and a pattern made for a patch to cover the entire surface of the front end of the frame, as illustrated by Fig. 2; the casting was made of brass in order that it might be more elastic. This was bedded down to the surface over the broken part, six ¾-inch machine bolts on each side clamping it down to the main frame. Before the patch was put on, the new cylinder liner

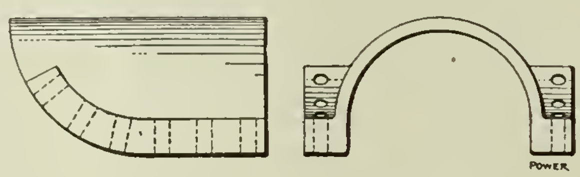

Fig. 2. The Frame Patch

was put in place, with a rubber ring on the end of the liner, which packed the expansion joint. The broken pieces of the main frame were then put in position, a thin coating of red-lead putty was smeared over the entire surface and the patch was drawn down to its place by the bolts.

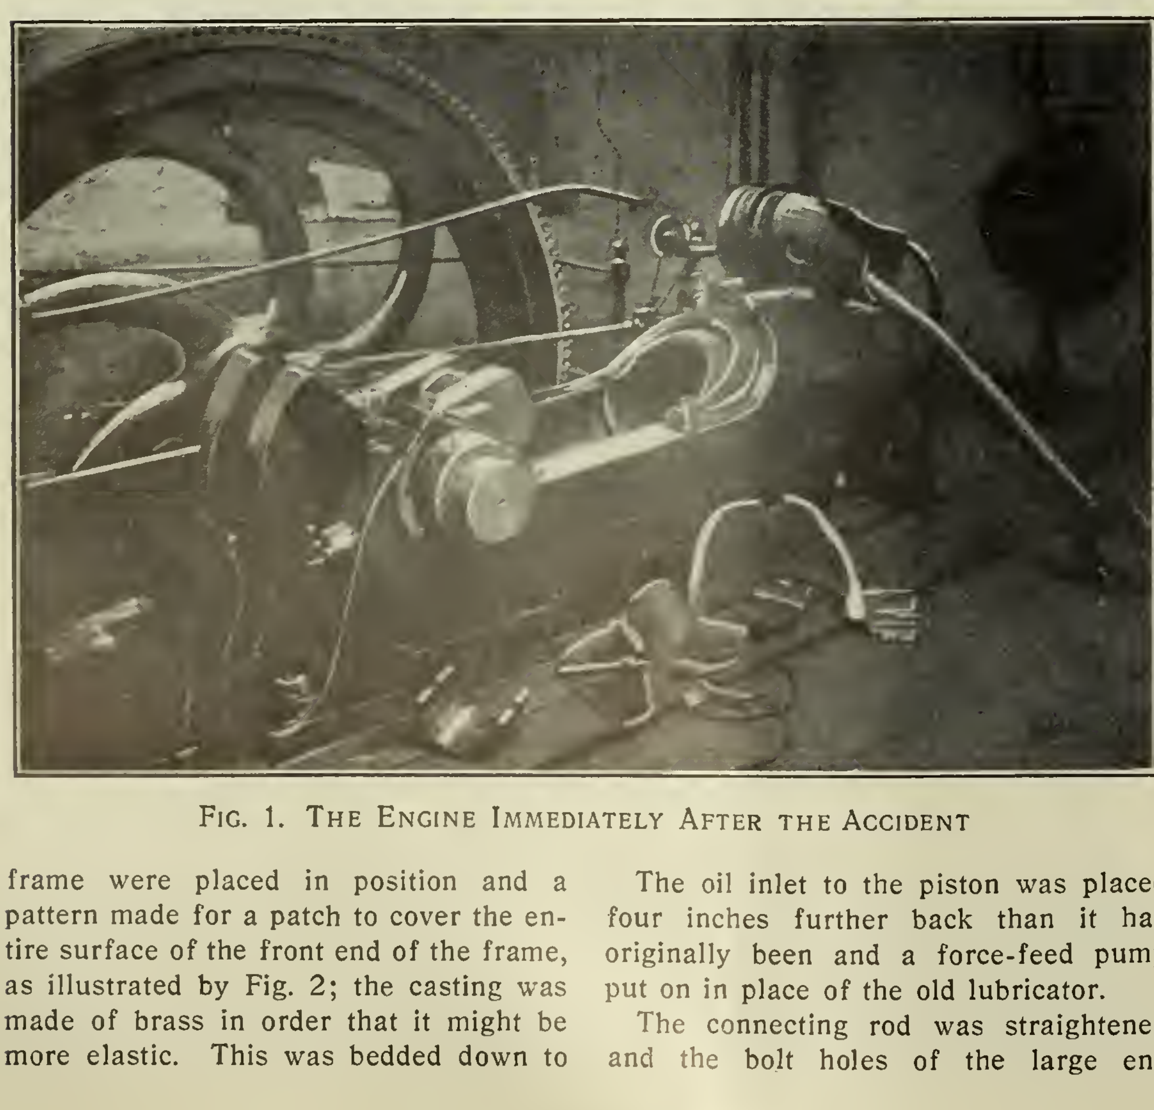

Fig. 1. The Engine Immediately After the Accident

The oil inlet to the piston was placed four inches further back than it had originally been and a force-feed pump put on in place of the old lubricator.

The connecting rod was straightened and the bolt holes of the large end reamed out larger. It was evident from inspection of the old connecting-rod bolts that they had been weakened by the constant knocking of the big end, causing them to stretch to their elastic limit and then broken, after crystallization, at the finish of the thread. The new bolts were made of the best hammered iron and instead of being made of uniform diameter were turned down as shown in Fig. 3 to the diameter of the bottom of the thread, to make them more elastic.

The practice of having both engines drive the one shaft was abandoned and each was given a separate load.

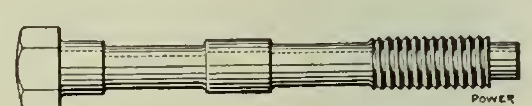

Fig. 3. Connecting-rod Bolt

After the engine had warmed up, the bolts on the patch were thoroughly tightened up and it was found to be a most satisfactory repair.

Rocker Arms for Poppet Valves

By A. M. Levin

Some time ago, upon examining the inlet valve of an 18x24 gas engine in order to ascertain, if possible, the cause for its general bad action and persistent leaking, it was discovered that the bore of the valve-stem guide had become badly worn out of round. Since the valve guides of engines of this class as ordinarily arranged do not usually wear perceptibly, and since everything pertaining to this valve gear appeared to be arranged according to common practice and to be in proper working order, it proved somewhat of a puzzle, at first, to think of a good cause for the abnormal wear. It was promptly observed that the little roller on the end of the rocker arm, which engages with the end of the valve stem in pushing the valve open, had become stalled on its pin; but, as these rollers frequently are and ordinarily can be stalled without bad effects, there was no suspicion at first that this circumstance had any bearing on the case.

Finally, however, after closer observation, it became clear that there might be a right and a wrong way of laying out the valve-rocker motion, or, perhaps more cautiously stated, two right ways, of which one is more liable to go wrong than the other, and that that little roller might have a material influence on the wear of the valve guide. The facts of the matter are very simple and evident, but as it often is the simple and evident things that are overlooked and apt to cause trouble, it may not be waste of time to dwell upon this little kink.

Figs. 1 and 2 indicate two ways for laying out the valve-rocker motion, both of which are apparently good. Fig. 1 represents the way in which the rocker motion was arranged in the case just cited. Observe how beautifully close to the center line of the valve stem is the force acting from the roller, in all positions of the valve. In Fig. 2, however, which represents the more common way of laying out the rocker motion, the force applied on the end of the valve stem shifts between the point *E*, corresponding to the closed position of the valve, and the point *H*, corresponding to its position when fully open. To all appearances the layout in Fig. 1 would be fully as suitable as that illustrated in Fig. 2, but there is a rub due to the friction between the roller and its pivot pin; because if it does not slide at all on the end of the valve stem the roller must, with the first layout, rotate through the angle *A—O—B*.

In estimating the pressure on the roller pin we find that a 8-inch valve, having a spring tension back of it of, say, 7 pounds per square inch of the valve area, calls for a maximum force of 200 pounds to simply open the valve slowly. To overcome the inertia of the valve at full speed there will be added to this force another amounting easily to 5 pounds per square inch of the valve area, or, in total, 125 pounds. We have thus, in all, a pressure of 325 pounds on the roller pin which would not be so bad excepting for the fact that the angle through which the roller rotates is, at best, hardly great enough to allow a proper lubrication of the pin.

The effect of the friction between the roller and its pin in the arrangement of Fig. 1 will be a force *c* or *d*, acting laterally at the end of the valve stem, and, of course, the greater the distance to the valve-stem guide, the greater will be the friction between the stem and the guide caused by this force. It can, therefore, be expected that the guide will wear appreciably if it should happen that the roller got stalled on the pin. Now, in the layout in Fig. 2 it is evident that the roller does not revolve on the pin; it simply rolls on the end of the valve stem. Strictly speaking, it should revolve or slide to the extent of compensating for the versed sine of the angle *A—O—N*, probably not more than 1/64 of an inch each side of the center line of the valve stem; but as that small amount is not much more than the side motion which the freedom of the valve stem in the guide will allow to the stem, there will, practically, be no motion between the roller and its pin.

The difference in principle between the arrangements in Fig. 1 and Fig. 2 is illustrated in Figs. 1-a and 2-a. The forces acting on the valve stem when in its top position resolve themselves, in Fig. 1-a, into the central force F_1, the lateral force *C* and the turning moment T_1T_1. In Fig. 2-a there are the central force F_1 and the turning moment T_1T_1. If, in Fig. 1, it is assumed that the roller, being stalled on the pin, slides on the end of the valve stem, and that the sliding friction becomes as great as 25 per cent. of the normal pressure, with a total valve pressure of 320 pounds, the force *C* normal to the guide becomes 80 pounds and the turning moment T_1T_1 approximately 70 pound-feet. The turning moment T_1T_1 would, under all circumstances, be approximately only 3 pound-feet. Under ideal conditions as to lubrication of the valve-roller pin, the arrangement in Fig. 1 would not be much worse off than that in Fig. 2, but as practical conditions effectively exclude such ideal lubrication, the second arrangement will be by far the safer of the two.

A Satisfactory Plant

By H. T. [illegible]

For the past four years I have been operating gas engines and suction and pressure producers, and my experience has been very satisfactory. The plant I am now running contains a suction producer and a two-cylinder vertical engine rated at 110 horsepower. Previous to the installation of the gas plant the works were driven by an automatic cutoff steam engine of the same rating as the gas engine.

Our load is very irregular. We have an air compressor rated at 48 horsepower working against 100 pounds pressure and it is cut off when the pressure reaches 100 pounds and cut in again at 90 pounds pressure. It goes on and off 200 to 300 times in a day. When the steam engine was driving the plant, the voltage at the switchboard would drop 12 volts every time the compressor went on. This made the lights so poor that we had to install another engine to drive the dynamo. With the gas engine, the voltage does not fall two volts when the compressor goes on, regardless of the other load.

The wrist-pin brasses in this engine have been tightened up only once in the last six months and the crank-pin brasses twice. We have a gage glass attached to the crank case, putting the level of the oil in full view of the operator all the time.

I will admit that it requires a man of more skill and ability to run a suction gas producer and engine than to run a steam plant, but a gas plant does not require as much attention while running as a steam plant. We have not had a breakdown, or even a stop to exceed 20 minutes, in the last 17 months.

The igniters are supplied with current from the dynamos at 110 volts and they run three months without changing.

My experience with the gas engine convinces me that a level head, good, clean gas and the right cylinder oil are all that is necessary to make it the cheapest and best prime mover so far devised.

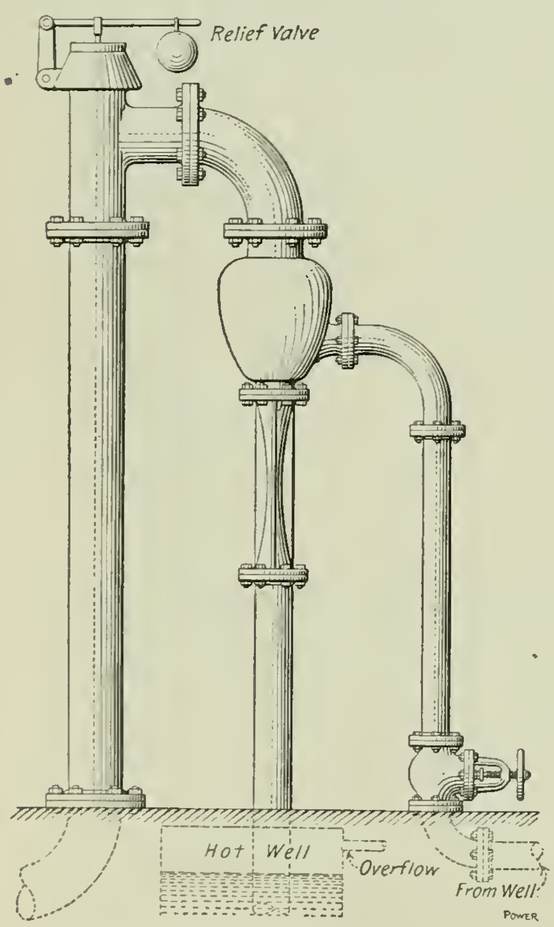
Readers with Something to Say

Practical information from the man on the job. A letter good enough to print here will be paid for. Ideas, not mere words wanted

Pumpless Condenser Installation

In Greenwood, Miss., can be seen a condensing outfit requiring no circulating or vacuum pumps.

It is supplied with water from an artesian well which gives a pressure at the top of the ground of 30 pounds. This water is carried to the supply pipe and is controlled by a valve just above the ground. All that is necessary to start the condenser is to open the valve and start the engines. A vacuum of 23 inches is maintained without any trouble.



Piping of Condenser

I would like to know if anyone else has had any experience with this kind of a condenser arrangement.

H. T. Fryant.

Jackson, Miss.

Filing Power Articles

Various schemes for binding or filing the vast amount of data and information contained in Power have appeared in its pages, but none that I have noticed seem to fill the bill for my use. Binding the different volumes together is open to the objection that the data or information on any subject is difficult to locate. I have devised a system of filing the information contained in Power which is very satisfactory, as any particular article, or series of articles, is easily found.

Each magazine, after being read, is taken apart by removing the binding wires and all information or articles of interest are laid aside, and the remainder of the journal is thrown away. At the office outfitters' I procured an oak letter file about 14 inches square and 24 inches long, provided with drawer, folders to hold the letters and alphabetically lettered division cards, similar to an ordinary card catalog. All information or articles relating to any one subject, as, for instance, "direct currents," would be filed in a folder marked "Direct Current" and filed under "E," for electricity. Should two or more articles on different subjects appear on the same pages, the titles are written or printed on the first page and all held together by a wire fastener; then the group is filed under the subject of any of the articles.

I also keep a card catalog in which appears the complete title and author of every article on file. The different titles are separated under the several subjects as in the main file. The card catalog is necessary on account of numerous articles which do not appear in their proper folders, as explained. For example—there might be an article on fuels, another on heating and ventilating, and still another on refrigeration all on the same page, which could not be separated. These pages would all be fastened together and filed, say, under "Fuels" in "F." On the first page at the top margin would be written the title of the article on heating and ventilating and also of the one on refrigeration; then in the card catalog under "Heating and Ventilating" would appear the title of the particular article with reference to the folder on fuels, and likewise with the article on refrigeration.

The letter file referred to may be obtained at almost any office outfitters' for from $3.50 up, depending upon the finish of the case. The folders are 9x11½ inches, necessitating trimming the pages of Power on two sides.

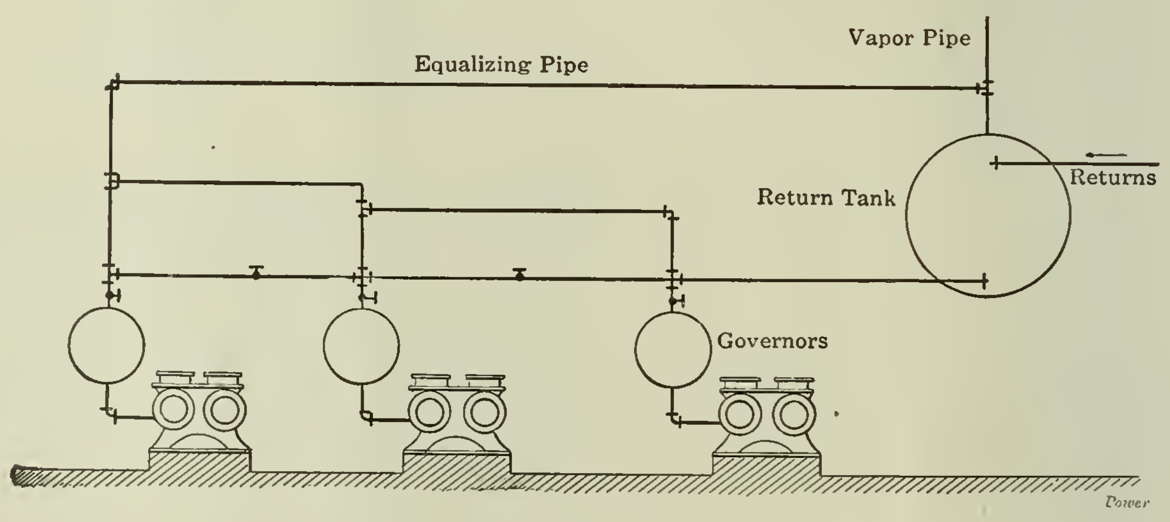
Defective Return System

I was recently called on to remedy a defect in the return system of a large heating installation, the trouble being that the condensation returned intermittently and at times filled the tank and flooded back into the heating returns. The plant is equipped with a receiving tank to which all condensation from the heating system and the various manufacturing processes is returned, and the three feed pumps force the water from the tank to the boilers.



Piping of Return System

Each pump has a receiver containing a float which controls a steam valve by which the speed of the pump is governed and as long as the condensation is returned uniformly one pump would do the work. However, at times the returns came back in large quantities and if the attendant was not near to start another pump an overflow occurred. A larger tank would have solved the difficulty, but this was out of the question for want of room, and the connection shown in the illustration was resorted to.

The valve on each pump governor was left open and those between them closed so that as long as the water returned at a normal rate only the first pump was in operation, but when it was taxed beyond its capacity the water would rise in the tank and pass over to the second pump and, if it continued to rise, would pass on to the third one, each starting automatically in its turn.

By closing the valve to the first pump governor and opening the one between the first and second governors, the last two pumps can be run in tandem, or the valves can be changed to operate any one alone. The piping, as shown, should be as large as the suction pipe out of the tank, but the "equalizer" only serves to prevent an air lock and may be very small.

Bellaire, O.

Topics for Discussion

Is water hammer due to the presence of water lying along the bottom of the lowest part of a line of piping, or is it due to a conflict between the cold air and the inrushing hot steam which causes the violent hammering?

Does air in pipes act as in the air chamber of a high-pressure pump, until equilibrium of temperature is established between it and the steam?

Is steam formed under or above the surface of the water?

How, and by what means, is a very rapid production of a large volume of steam produced after a violent and destructive boiler explosion?

JOHN W. PAYNE.

Detroit, Mich.

Piston Rings

Piston rings cut on an angle are not generally found in a new engine, but rings made at a local repair shop are

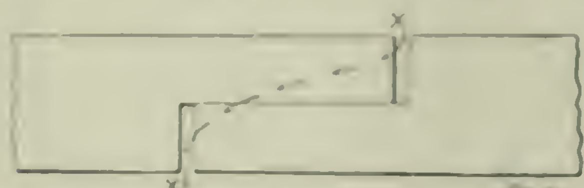

FIG. 1

usually cut in this way. Most engineers prefer the lap-cut ring.

By referring to Fig. 1 it is easy to see that after this ring wears any perceptible amount the joint is broken still more

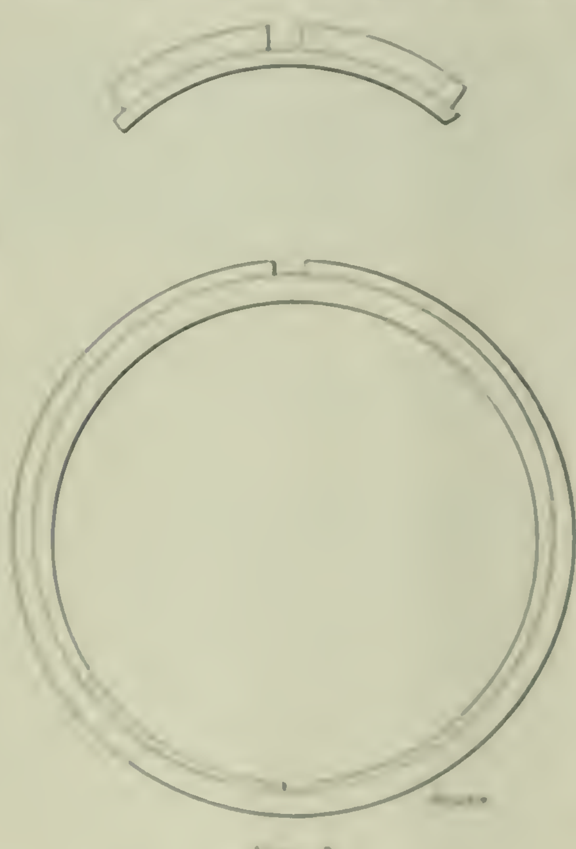

FIG. 2

at the joints X X and that steam will enter at X on one side, as indicated by arrow and, going under the lap, makes its exit at X on the opposite side. The advantage of this kind of a joint over the

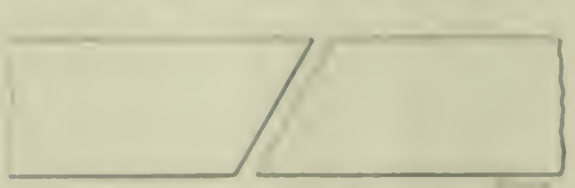

FIG. 3

diagonal joint is that the path of escaping steam is not so direct in the latter as in the former.

In order to remedy this leakage in the lap-cut ring it would be necessary to put a false ring inside with its cut at the opposite side to the cut in the outside ring or a short piece with a curved surface and tensioned, so as to bear against the underside of the joint to make it steam tight, as shown in Fig. 2. I prefer a whole inside ring as it takes care of itself better than a cover piece would.

The leakage of the angle cut cannot be remedied in any way. Fig. 3 shows the angle-cut ring joint open. Some engine builders use a single, sectional, lap cut under the covered ring, as suggested for a single cut ring.

Nashville, Tenn.

Unexpected Happenings in the Steam Plant

One is so accustomed to having certain effects follow certain causes that, when the unexpected happens, a search for a reason or theory to explain it is begun.

In connection with a system of forced draft with which our boilers are equipped, there is a 10-foot piece of 4-inch pipe, capped on each end, the caps being tapped for ½-inch pipe connections. This pipe is fastened to the wall of the boiler room in a vertical position, and steam at boiler pressure enters at the top and is condensed for supplying pure water to operate the blower-regulating valves.

In order to do some repairs, I blew out the water and sediment from the pipe mentioned and disconnected a ½-inch union at the top, but being annoyed by hot vapor I stuck the nozzle of a hose into the hole and turned on the water, expecting it to condense the vapor inside the pipe and create a vacuum. Contrary to expectations, steam was generated in the pipe, which blew out the nozzle of the hose, and steam continued to come with much force and noise for about ten seconds.

All of our furnace-blower pipes take steam from the dome and come down at the front of the boilers, passing through the brick setting of the firebox to the blower jets at the back of the boilers, thence to the ashpit, thus superheating the steam which supplies the forced draft. That portion of extra-heavy iron pipe immediately over the fire was probably heated nearly red hot during the noon hour, and when the valve, which was a new one, was opened at 1 o'clock, the water of condensation which had accumulated above the valve was suddenly let into this hot pipe, and, flashing into steam, broke an elbow, notwithstanding that the jets were open.

Many years ago I ran an engine and boiler in a planing mill, firing with shavings, and sawing logs with full saws and heavy planing sometimes made me work in trying to keep up the steam pressure. At that time I recommended a surface blowoff pipe, but the manager thought that his homemade boiler compound was just the thing. It was formed in the boiler room and contained soda ash, glucose and extract of logwood. These were all boiled in a barrel of water and when the density got beyond a certain point, the concoction would not stop boiling even with the steam shut off, but would go all over the floor.

One day, when firing hard, the compound and mud suddenly got busy inside the boiler, and water and mud choking the engine caused the whole shop to tremble. Then the safety-valve lever flew up, and the valve did not stop blowing until half the contents of the boiler were on the roof, the sight of which convinced everybody that a surface blowoff was needed.

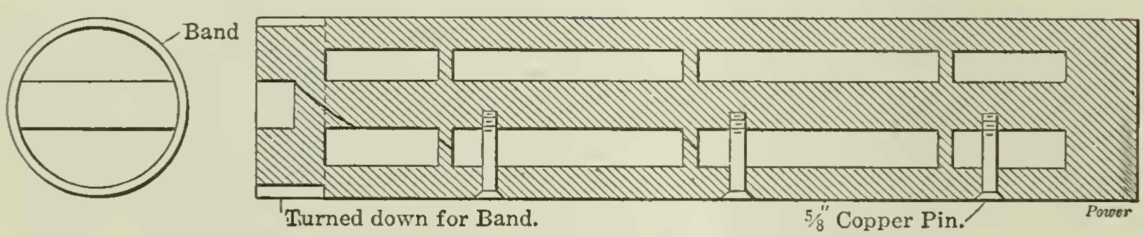
Albany, N. Y.

Repaired Corliss Exhaust Valve

The accompanying sketch shows a sectional view of a double-ported exhaust



SECTIONAL VIEW OF VALVE

valve of a 26x48-inch Corliss engine and how it was repaired. The valve cracked all the way through and nearly across, as shown. This was due to either an excessive flooding of water or the valve being allowed to run with an insufficient amount of oil.

The valve was quickly repaired in the following manner: The exhaust-valve bracket was taken down and the steam head measured, leaving enough play on either side of the valve to allow it to be turned down for a 3/8x3-inch band, which was shrunk on. The valve was bored, countersunk and tapped for copper pins, and turned off to conform with the curvature of the valve.

J. W. DICKSON.

Memphis, Tenn.

Piston Ring Gave Trouble

Some time ago a 26½ and 50 by 33 vertical cross-compound engine was installed and considerable annoyance was experienced, due to the low-pressure piston ring clicking.

The ring originally sent with the engine was made up of six sections and reinforced or held into position by twelve spiral springs, equally spaced.

After many close examinations a new solid ring was sent for, which proved a success.

The sectional ring had ¼-inch clearance between each section, and steam getting into the clearance next to the ports caused a shifting of these sections, which produced a sharp clicking noise, just as the crank passed over the centers, or at the point of steam admission.

FRANK W. BELLINGER.

St. Paul, Minn.

Burning Lignite

I have two horizontal return-tubular boilers set in common brick setting. The boilers are hand fired and the coal used is North Dakota lignite which contains: ashes, 2.47 per cent.; clinkers, 4.23 per cent.; moisture, 39.76 per cent., and 6029 B.t.u. per pound. The factor of evaporation is 1.06, and upon running an evaporation test I found the evaporation to be four pounds of water to one pound of coal and the efficiency 68 per cent.

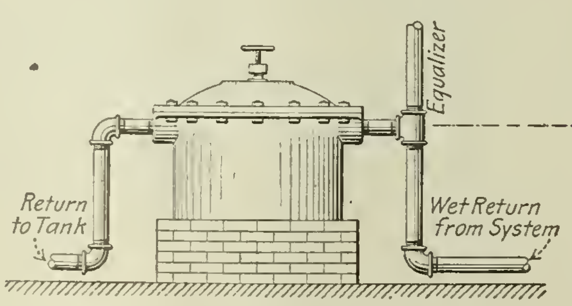
I would like to hear from POWER readers as to what they think of the economy of this boiler plant and if it could be improved in any way.

O. N. BERGMAN.

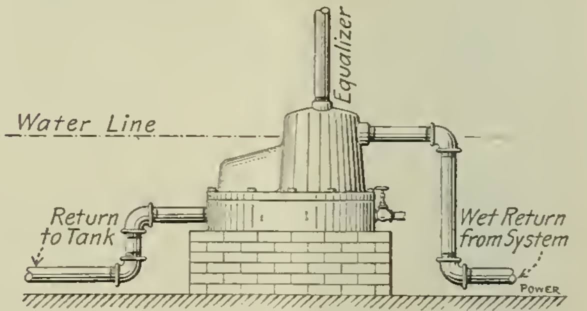
Dickinson, N. D.

Preventing Water Hammer at Trap Discharge

Recently a heating system was remodeled and the traps raised about 3 feet from the floor, and an equalizer pipe was connected from the joint where the return pipe entered the trap up to the steam main and the discharge changed from the sewer to the return line run-



OLD ARRANGEMENT



NEW ARRANGEMENT

ning to the power house, thus saving the water.

As soon as the new layout was put in operation, however, there was a complaint about the rattle made by the water every time the trap discharged, due to the cool water from the wet return meeting and condensing the steam in the equalizer pipe.

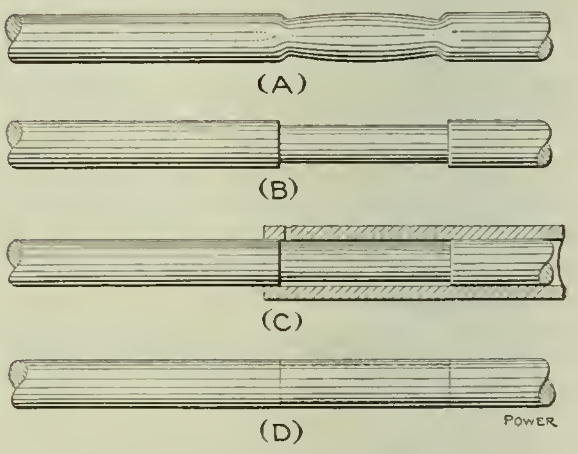
After trying several schemes, the trouble was solved in the manner shown in the accompanying illustration. The system is now operating noiselessly, as the steam comes only in contact with the surface of the water, heating it but slightly, and the discharge is constant.

W. T. MEINZER.

Brooklyn, N. Y.

Repaired Centrifugal Pump Shaft

A great deal of trouble is experienced with worn and grooved shafts which run in packing boxes, as in rotary, centrifugal pumps, etc., and this is especially true of shafts running at high speed, or when running under such high pressure that the packing has to be kept very tight.



SHOWING STAGES OF PUMP-SHAFT REPAIR

After a shaft has run for some time in a tight stuffing box in which hard packing is used, the shaft generally becomes badly worn and the expense of taking it out and replacing with a new one may be saved.

In one instance the shaft became badly worn, as shown at *A* in the accompanying illustration. It was taken out and filed down, as shown at *B*. A tube was then procured of the right size to be slipped over the shaft, as shown at *C*. A hole was bored in the tube, and babbitt poured in, thus filling the recess in the shaft, as shown at *D*.

The tube casing was then removed, and the babbitt finished smooth with emery cloth; the shaft was then ready for use.

If the shaft to be repaired operates under a very high pressure, it is well to sweat it with solder before pouring the babbitt, so that there will be no possibility of a leak starting between the shaft and the babbitt.

Questions Before the House

Comment, criticism, suggestions and debate upon various articles, letters and editorials which have appeared in previous issues

License Laws

The mere passing of a license law will accomplish nothing for, as has been shown by F. E. Albrecht, in the December 6 issue, the value of such a law may be entirely destroyed and, in fact, a state of danger may be created by its improper administration. Evidently, before the existence of the license law in the locality discussed by Mr. Albrecht, the plant owners were previously inclined to exercise some care in their choice of the men they placed in charge of their power plants; but since then these owners have naturally taken the path of least resistance and have accepted without further question the licenses issued by the examiners. Thus, the responsibility has been shifted to the examiners. If they meet it fairly then the results will be good; but if the examinations are farcial, the conditions resulting will be worse than those which existed without a license law.

On account of the good results that have been obtained within the jurisdiction of the Federal inspectors, A. A. Blanchard in the January 10 issue suggests that a Federal law bringing all engineers under its jurisdiction would be the best solution of the problem. It is possible that if a Federal license law for all engineers were placed in operation the results might be all that he desires. Certain it is that such a law cannot be constitutional.

It must be remembered that the United States is a combination of States, once independent, who by adopting the Constitution have delegated to a central authority only those powers in which their interests were identical, retaining all others to themselves. The powers thus delegated to the Federal Government are limited and even though the Supreme Court has generally been very liberal in interpreting the Constitution as applying to laws passed by Congress, there does not seem to be any method of securing a Federal law applicable to all engineers.

Federal jurisdiction over steamboat engineers and that proposed for locomotive engineers is secured through the article in the Constitution which delegates to Congress the power "To regulate commerce with foreign nations, and among the several States, and with the Indian tribes."

License laws, whether Federal, State or municipal, will not in themselves cure the evils from which the engineer is suffering, but they may be the source of some trouble and vexation to him.

The ultimate interests of the engineer can probably best be served by following the path that POWER has been advocating for years, that of the education of the engineer in the safe and economical production and distribution of power, and the education of the plant manager in the knowledge that an efficient engineer in the power house is a safe investment and a large dividend payer.

GUY WEST.

Philadelphia, Penn.

CO_2 Recorder and the Operating Engineer

Of all the interesting and instructive articles that have appeared in POWER recently regarding CO_2 recorders, there is probably as much value to the operating engineer of small plants in the nontechnical article recently contributed by our old-time friend, O. C. Winslow, and published in the issue of January 24, as in any of the very technical articles contributed by our "high-brow" brethren who tell us how much they know rather than tell us how to get results.

While I concede the value of the CO_2 recorder in the hands of a man who can apply the information which it enables him to get, such men are rarely found in the engine rooms of moderate-sized power plants and as it is quite probable that a large percentage of the readers of POWER and kindred publications are of this class, articles of the nature of Mr. Winslow's which they can digest and assimilate are of more value to them than the more technical articles.

I am led to express myself in this way by an occurrence of this morning. An apparent stranger stopped me and expressed his appreciation of an article that recently appeared in POWER on smoke prevention, yet he asked me the meaning of the term CO_2 which was used therein. I learned that this man was "firing" at the factory where the first test of the smoke preventer mentioned in the article was made some thirty years ago. Later on he secured an engineer's license and he has operated moderate-sized plants for the past twenty years or more.

This man is middle aged, perfectly satisfied with his present position and condition, has saved some money and owns his own home. He is sober, steady and reliable, just big enough for the job and the job is just big enough for him. There seems to be no incentive for him to climb. He is interested in reading of the experiences of other engineers of his class and I believe that there are thousands like him. I hope occasionally to contribute leaves from his own experience of over forty years in the belief that they will be interesting and beneficial to the men of this class. I believe that many a fact told in the form which Mr. Winslow used will stick, whereas if told in technical language they would make no impression.

But to return to the question of CO_2 recorders, I am quite sure that Mr. Winslow is in no way opposed to them. I take it that he looks upon them in the same way that I do upon the steam-engine indicator, a very valuable instrument for a special purpose in the hands of the true expert but a snare and a delusion in the hands of the novice.

I suggest that some simple and convenient method of weighing the coal and measuring the water be used. Then, with the quantities of coal and water to check against the output of the factory or mill each week or month, the value of any change made in the engineer's department can be estimated in a more practical manner than by means of any tests of a few hours' duration that could be made by any of our so called experts, unless such tests are made for a special purpose.

If the man in the engine room has the ordinary good sense and a sufficient experience to keep the boiler settings in a good state of repair, the steam-generating surfaces clean from both scale and soot, the fires neither too thick nor too thin, and to see that both pumps and valves are tight without undue friction, and the valves properly set and that all of what might be waste heat is utilized for some useful purpose, he need have no fear of what CO_2 recorders and steam-engine indicators may show, if he uses his ability.

W. H. [illegible]

[illegible], N. Y.

Flywheel Explosions

I have just read the editorial in the January 31 number under the above caption. With reference to the matter of flywheel inspection, I want to say that while an engineer and a piece of waste properly applied to the flywheel of an engine may not be an ideal combination, so far as apparently dignifying the engineer's position is concerned, it is otherwise an excellent one. I have contracts that do not mention work, only supervision, but I very often go over the flywheels and with a piece of waste in my hand make a close inspection of them. In this way faults may be discovered that would not be in any other way. There are too many men engaged in engineering work who are afraid of losing their "dignity" for the good of the profession, or humanity. I do not mean by this that the number is relatively great, but that even a very few are just so many too much.

There is nothing so assuring as to know that you have seen with your own eyes that everything is all right. If you depend upon others there are a good many ways in which you may be ill at ease. The other man may be deficient in knowledge, he might have been careless or negligent and, after all, you feel that you do not really know. If you look after such things yourself, you can feel that you do know, and that affords more satisfaction than the maintenance of any imaginary dignity.

Referring to governor troubles and inspection, I think the editorial "hit the spot" exactly. I recently went into a plant where an ammonia compressor was driven by a Corliss engine. This engine raced badly, and had been behaving erratically for a year or more. Within that year there had been a change of engineers. I started the engine and, true to its reputation, it started off like an impatient race horse. Had I opened the throttle wide, I do not know what would have happened. Although I opened the valve very slowly, the governor got hold of the engine even more slowly. I was suspicious at once from the sluggishness of the governor's action that the trouble lay there, and having had experiences of the same kind before, I went to the governor gag, or dashpot, and found it full of a mixture having a consistency between that of heavy cylinder oil and "taffy." With the bypass wide open it was almost impossible to move the plunger in the pot or cylinder. The only thing to do was to remove the heavy fluid from the dashpot and fill it with a light engine oil. After doing this the action was still too slow, and a part of the engine oil was removed and replaced with kerosene. After this, one could hardly cause racing had he wished so to do, the governor controlled the engine so well.

There can be no question as to the value of many automatic devices, but I can never get rid of the belief that a man with a watchful pair of eyes and an active mind behind them is one of the best safety devices ever invented.

The tendency of some men to overlook small things that give trouble, while looking for something great, deep and mysterious, is hard to understand. There are engineers who can talk engineering Latin and Greek so fluently as to make one feel real small, and yet when you get a chance to pry into their work, you often find such conditions as I have described. On the other hand, you will find some engineers who have so little to say that you are led to wonder how they happened to escape the "cows" so long, and yet when you get an opportunity to go over their work you find ample evidence that they have been more busy with their brains and hands than with their tongues.

WILLIAM WESTERFIELD.

Concordia, Kan.

The Engineer's Wage Problem

I was glad to see that Mr. Morton got his raise in pay (see the issue of January 17). If he had not, I would have half suspected that he was not worth what he was getting to begin with.

Seriously, too many of us compare ourselves with the wrong man. Values are all comparative. Mr. Morton's predecessor was evidently worth a number of dollars a day less than nothing. If he had been worth what he was getting, Mr. Morton would not have been able to get the job. Having gotten the job, it was up to him to give his employer his money's worth of service. To have saved $2 a day would not have entitled him to anything but discharge.

The engine and boiler were adequate in size—Mr. Morton admits it. His employer evidently knew it and would have fired one engineer as quick as another until he found a man who could produce results. If he could have found a man who was able and willing to get results and who was willing to work for 25 cents per day less than Mr. Morton, he would have been glad to do so. Evidently, this particular employer had his mind made up to save about $11 per day by paying $1.75 for the service. If Mr. Morton had saved $15 a day, very likely his employer would have thought twice before he gave him a raise as small as 25 cents.

Here we come to another question. How much did Mr. Morton ask for? Eleven chances out of ten he did not go to the boss and lay out the proposition on paper and prove to him how much he deserved. Probably, it took him a week to screw up his courage to ask if he could have more money. The boss saw that he was afraid to call his soul his own and raised him a "quarter" because it salved his conscience and did not cost much.

It must be conceded that an operating engineer drawing less than $3 a day and with no money in the bank is in little better than a state of slavery, particularly if he has a family dependent upon him. Statistics show that in New England the average family is only two weeks from starvation. A man who asks for more pay cannot usually prove that there is no one more competent who will take the place for the same money. The employer is apt to assume that there is such a man available at least until the present incumbent packs up his kit to go. By that time, if both sides are bluffing, they both are so mad that they have no further use for each other.

They both suffer. The engineer, by loafing until he hits another job at a few cents a day less than he was receiving before and a promise of a raise of 10 cents a day if he saves $10. The employer, by losing $100 a day from his product at a loss to himself of the profit on that amount. The difference is that the employer is usually better able to stand the loss than the worker. Consequently, he has the upper hand.

I wonder if it has ever occurred to other readers that this country's prosperity is absolutely at the mercy of wage earners.

There is, somewhere, about $36 in actual money in circulation for every man, woman and child in the land. Assuming that one person in ten is a wage earner, which is on the safe side, this would be $360 for each wage earner, or approximately 30 weeks' wages for each one. If every wage earner should suddenly decide not to spend any money for 30 weeks and to put it all in the old teapot or hoard it away anywhere, immediately a money stringency would begin and in less than two months these wage earners would have the whole country at their mercy. Of course, the fact that the average family is only two weeks ahead of the game precludes the possibility of this thing being done. Also, men who are in any way thrifty do not hoard away money. They deposit it in banks and the banks put it in circulation again.

The moral of all this is that a bank account large enough to live on for two or three months is worth all the sacrifice it costs. It is all very well to own a house, but it has the drawback of not being edible. The "long green" can be relied on for sustenance at any time or place short of a desert island. The man with a very modest bale of it in cold storage can go to the boss and treat him like an equal when he says, "I am earning more money than I am getting. You cannot get a man to fill my place that will really fill it as I do. I have not bothered to look up another job, because I know you cannot afford to lose me."

That puts the thing on a business basis where it is up to the boss to show cause why the aforesaid service that has been rendered is not worth the money demanded.

After all, why should not the man with something to sell put a price on it? A few years ago the purchase of a pair of boots was a matter of artistic haggling or bargaining. Today, we fight shy of a shoe store where the prices are not marked in plain figures. I am inclined to believe the working people are practically being sold at auction all the time and only for the lack of a supply of money to carry them over a few days of idleness. If a shoe dealer has to raise money he does not sell his shoes at auction, except as a last resort. In the first place, he does not buy shoes up to his last dollar. He saves a little money to do business with. If that is exhausted he borrows, but he does not cut the price of the shoes to raise money. You may think he does by reading his advertisements, but you can safely bet that he marked them up the day before.

Now, a wage earner ought to take example from this. Having set his price he ought to stick to it. In fact, he has no right to come to me and ask me $2.50 a day and then go over to Jones across the street and go to work for $2.25, because Jones scares him into it. He ought to treat us all alike.

E. F. HENRY.

Worcester, Mass.

Handling Men

The discussion in several of the late copies of POWER relative to the chief engineer having "pets" about the plant has been read with interest by the writer. During my experience I have failed to find a chief who was not accused of having pets, especially if he has a number of men under him.

The crew of men never existed that did not have some members who were more ambitious and studious than others. These men the average chief will aid in any way he can; consequently they become more friendly and intimately acquainted. Other members of the same crew do not take as much interest or perhaps think they are too well posted to consult with the chief. Eventually they will become "sore-heads" and think the chief is showing partiality.

Regarding the equal division of work among the men, I think that nine times out of ten the so called pet is willing to do more than his share. The writer does not uphold any tale bearing; on the contrary, it is better to dispense with the services of such men.

EARL E. WEBSTER.

Baseball Problem

Some things are just as clear as mud and that is the condition in which the baseball problem (December 20 and 27 issues), conceived by Prof. A. S. Reeves and elucidated into a state of opaqueness by Uncle Pegleg, now exists.

The high jinks which Professor Reeves, D. E. (Doctor of Entropy) can cause a simple—save the mark—molecule to perform when touched up by a little heat would scatter the brains of a Socrates. He has now invented a "manless something" to hold the stop watch on the earth as it goes round. What next?

But let's to the game and the problem. From the technical terms he uses it is evident that Professor Reeves is trying to qualify as a baseball expert. Uncle Pegleg who—to tell the truth and shame the devil—has more sense than legs, can hardly be expected to play ball, so we will make him umpire.

The pitcher takes his stand on the equator with the ball in his hand and faces east. Earth, pitcher, ball and everything else are going 300 feet each one-fifth second, but no energy is going into the ball. The pitcher now goes down in his "jeans" or his anatomy or some other place of concealment about his person and digs up 18 foot-pounds of energy. In one-fifth of a second, just as he whizzes by the manless something, he delivers the 18 foot-pounds to the ball. Behold! The ball now has 918 foot-pounds of energy more than it had before. Where did the 900 foot-pounds come from? They tell us that it is due to the earth having gone 300 feet in that one-fifth of a second. Well, has not the earth been going 300 feet each one-fifth second ever since we have been talking? It never succeeded in getting 1 foot-pound into that ball before—much less 900. The bug under the chip, and the nigger in the wood pile are not anything to this.

The pitcher picks up another ball and faces the west. Everything going 300 feet each one-fifth second same as before. No energy going into or out of the ball. Down into the "jeans" again and 18 foot-pounds more of energy fished up. Round comes the manless something. Into the ball in one-fifth second goes the 18 foot-pounds. Speed of the ball now, 1440 feet per second. If the curious figure this out, they will find that the ball has lost 882 foot-pounds of energy.

Perhaps these scientific figurers will tell us that *this* was because the earth went 300 feet in *that* one-fifth second. Gain or loss, it is all the same to them. Same old explanation. If the earth was to stop moving it is hard to tell what these figurers would do.

Hold 'em off, Uncle Pegleg!

J. C. MORRIS.

New Orleans, La.

A Mechanical Engineer's Experience with the Cornell System

Natural laws, theory and engineering rules practically proved, demonstrated and accepted by the engineering world have been set aside and declared all wrong and worthless by a modern prodigy from the staid city of Philadelphia, who has convinced some erstwhile conservative business men and mechanics that he has invented and perfected an apparatus which when applied to a boiler at $10 per horsepower will save from 42 to 60 per cent. of the coal used.

Why it will not save 60 per cent. all of the time has not been explained.

Results of tests made by a convert to this wonderful system show a commercial evaporation per pound of combustible on March 10, 1909, of 11.27 pounds and on March 11, 1909, of 11.28 pounds before fitting the boiler with the system.

The same boiler equipped with the *system* produced on March 23, 1909, an evaporation of 15.03 pounds; on March 25, 1909, 16.60 pounds; on March 26, 1909, 18.01 pounds, and on February 10, 1910, 16.14 pounds, a variation of 20 per cent. in the efficiency of the system and a saving of from 42 to 60 per cent. over the original equipment.

A test which I made on the same boiler equipped with the same *system*, fired by the same fireman, on April 28, 1909, showed a commercial evaporation of 10.80 pounds per pound of combustible.

The inventor kindly informed me that the reason for my failure to obtain a higher evaporation was that I followed the rules recommended by the American Society of Mechanical Engineers, which is not the correct way to test boilers and that anyone who could not obtain the same results with his system as his convert had, was not a capable testing engineer.

He also informed me that computations which I made, showing the impossibility of creating heat available for commercial use, by decomposing steam and burning the resulting gases as he claims to do with his system, were not correct, but as he could not point out wherein they were wrong, he would have his consulting engineer analyze the figures and advise me regarding same.

He has had my figures several months now, but I have never had the advice promised.

A partial analysis of the results of one test published for advertising purposes presents claims as follows:

Test of March 26, 1909, using fuel having an actual heat value as determined by chemical analysis, of 14,803 B.t.u. per pound.

B.t.u. necessary to evaporate 18.01 pounds water	17,[illegible]
B.t.u. necessary for loss due to radiation, [illegible]	[illegible]
B.t.u. total necessary to obtain [illegible] claimed	[illegible]
B.t.u. [illegible]	[illegible]

From the foregoing it will be seen that to obtain the results claimed it would be necessary to create heat from steam, available for the evaporation of water, to an amount equal to 56 per cent. of the total amount of the heat contained in the coal used.

George P. Gilmore.

Fall River, Mass.

Automatic Nonreturn Valves

The remarks by E. H. Lane in the January 24 issue regarding nonreturn valves are worthy of note for at least two very good reasons.

In the first place, equipment of this kind in the boiler room makes for the greater safety of the employees; and, secondly, it often obviates the necessity of shutting down the whole boiler plant should one or more tubes blow out in a boiler. The instances which he cites are not the only ones in which valves of this kind have amply justified their installation, for I have heard of a number of others and know personally of one case where a tube was blown out and the nonreturn valve operated instantly, thus cutting out that particular boiler.

A nonreturn valve operates, however, only when there is a break or sudden drop in pressure on only one side of it. While it is perhaps more common to have a tube blown out than to have a break in the header or on the other side of the valve, such things have been known to occur. In a case of this kind a simple nonreturn valve would, of course, be useless.

I recommend, therefore, that a step further be taken in the adoption of a triple-duty valve. With a valve of this kind it would make no difference on which side a break occurred as it would close immediately and thereby cut out the boiler. The reader is, no doubt, familiar with this type of valve; it will operate no matter on which side the break and consequent pressure drop occur, and, in addition, it can be closed by means of a handwheel and stem just like an ordinary stop valve. That is why it is called a triple-duty valve.

In addition to such a valve, it is a good plan to have an ordinary stop valve—perhaps preferably a gate valve—located between the former and the header with a drip cock in the pipe between the two valves so that anyone going into the boiler will be absolutely safe from scalding, due to a leaky valve.

This would be appreciated very much by the boiler inspector. The drip cock, of course, is only intended to prevent any building up of steam pressure between the two valves, should the stop valve leak.

In conclusion, I wish to say that I am heartily in accord with Mr. Lane in wishing to see such installations made compulsory, for the safety of the workmen should be of paramount importance in every boiler plant.

Everard Brown.

Pittsburg, Penn.

Boiler Inspection Laws

The Pittsfield explosion awoke some to the realization that the lap-seam danger is not the only one that confronts us here in Massachusetts. On the other hand, there were those who were not in the least surprised. They may not have been "telling you so"; but they have been expecting it. And, if a few more explosions should happen tomorrow, it would not cause them much wonder. Massachusetts has been getting too smugly complacent. Because it has the best laws of any State in the country, its people have been strutting around with pride, when they should have been treading with circumspection. We have been looking at the disasters abroad and have overlooked the dangers at home. Because we have the best laws is no reason why they cannot be improved; and laws are not sufficient—there must be rigid enforcement. There are too many dangers that yet threaten.

"Agricultural" boilers are outside the law, though one finds no reason for this exemption. An old lap-joint boiler condemned for factory work, may be sold to a florist and set up in a greenhouse within ten feet of a busy highway, and any pressure to suit the ignoramus of a greenhouse man may be put upon it. A road-roller boiler must be inspected and must be under the care of a licensed engineer; but a threshing-machine boiler need have neither. Bring the farmer into line. He needs safety as much as the shop worker.

Not long ago I entered the engine room of a factory and about the first thing that I noticed was that the engine was slowing down. The speed came down almost to a stop, then speeded up again. Upon investigation I learned that the governor was out of commission and that the engine was running with the throttle "set" for the ordinary load. It would have cost possibly $5 to repair the governor and the increased production of the machinery would shortly have paid the bill; but the boss would not see it. The owner holds a license to "cover" the plant and hires a fireman to do the work. One does not enjoy picturing what might happen to that flywheel if several big machines should let go at once when the fireman happened to be out. The treatment that the boiler gets may be imagined from the fact that one day when the waterwheel gave trouble they got up steam from cold water in 45 minutes.

Another "engineer" in another town boasted to the writer of having done the trick in 35 minutes.

In another case, a power plant had been shut down during the winter and was about to be started again. A slow fire was put under the boilers, but as no pressure showed on the gages it was in due time increased and later urged to a good, hot fire. Then, suddenly, the safety valves opened. The gage pointers were still anchored. The engineer claimed that an enemy of his had loosened the gage hands and put them back of the pin. Perhaps that was so, but no real engineer will ever be caught in that way. What if this "enemy" had also seen fit to screw down on the safety valves?

In another plant the engineer frequently leaves his boiler and engine running and goes uptown on a shopping trip or over home for a lunch. I was once requested by my employer to go on an errand to a neighboring factory. This would have left the engine and boiler without an attendant. At another time a request came down to "help clean up the cellar." Of course, I did not do either, but the incidents are cited to show how ignorant some factory owners are of the engineer's duties. There are many engineers who are doing such things nearly every day. Happily, the inspection department is waking up to this danger and is taking steps to abate it. Let us hope they keep at it. The employers need enlightenment and the engineers need starch.

In another case a crack was found in a cast-iron flange of a 12-inch steam header. The chief engineer proposed to cover the thing up again and let it go. He had an assistant, however, who would not stand for such tactics, and the flange had to be replaced. When men will take such chances to save a few cents and make a record, why wonder that accidents happen?

A few days ago in a plant not far from Boston, the safety valve stuck and the pressure ran up far beyond the blowing point. The engineer was in a distant part of the factory. The fireman ran. The superintendent, one of the know-it-all-butt-in type, mounted the boiler and lifted the valve. Luck was on his side; there was no explosion. It was just one more of those many narrow escapes that we all know about. It might be urged that those engineers who know of these things should report them to the State inspectors, and it may be said that they sometimes do. But, too often there are leaks in the office. The "strictly confidential" report is so treated that the guilty party learns the name of the person who made it. Corporations can cause a man considerable inconvenience and expense if they wish, and a man often hesitates to report things against them for fear his name will be turned over to them. This is not right. A man should be able to report dangers without running personal risk.

Here are a few hints of lines along

which progress is possible. Let us quit boasting and do something to boast about. Let us "look forward, not back."

WILLIAM E. DIXON.

Malden, Mass.

Setting Us Straight

C. H. Parson, in the issue of February 7, says that the use of a steam jet under the grates prevents clinker, but says also that his experiments, "absolutely disprove the statement * * * that the temperature of the fire must be reduced in order to prevent the formation of clinker." He gives no reason, however, why the steam prevents clinker, or in what other way it can act, if it does not reduce the temperature. If steam does prevent clinker, there must be a reason.

As a matter of fact, steam does reduce the temperature of the fire to some extent, even if the steam is not decomposed. A formula for the theoretical temperature of the fire is given on page 786 of the eighth edition of my Mechanical Engineers' Pocketbook, as follows:

$$T = \frac{146C + 2200H - 1170\,O - 33W}{f + 0.02W + 0.18H}$$

where, T equals temperature of fire above temperature of the atmosphere and C, H, O and W, respectively, the percentages of carbon, hydrogen, oxygen and moisture in the fuel; f equals pounds of dry gases of combustion per pound of fuel. When steam is delivered with the air under the grate bars, it is practically equivalent to moisture in the coal as far as its effect on the temperature of the fire is concerned. Assuming a dry fuel containing in the combustible portion 0.90 C, 0.05 H and 0.05 O, the formula gives an elevation of temperature of 3107 degrees Fahrenheit, but if 10 per cent. of water is added, making the analysis 0.81 C, 0.045 O and 0.10 water, the temperature elevation is only 2710 degrees, or about 13 per cent. less. Even if allowance is made for the heat carried in by the steam, about 100 B.t.u. for 0.1 pound of steam, the temperature would not be raised 100 degrees.

A greater cooling takes place, however, at the bottom of the fire, close to the grate bars, if any of the steam is decomposed into oxygen and hydrogen. The dry coal used in the illustration has a heat value of 15,800 B.t.u. per pound of combustible. The hydrogen in 0.1 pound of steam is 0.0111 pound; the unburning of which absorbs

$$0.0111 \times 62{,}000 = 690\ B.t.u.,$$

or over 4 per cent. of the heat value of the fuel.

That it is possible to decompose steam when it is mixed with, say, 20 times its weight of air, by blowing the mixture into white-hot carbon, I do not think has been satisfactorily shown by experiment. If carbon at a very high temperature has a greater affinity for hydrogen than it has for the oxygen in the air, it may decompose the steam and form water gas,

$$CO + H_2$$

which will burn to $CO_2 + H_2O$, reforming the same amount of steam just as quickly as the gases CO and H become mixed with enough oxygen from the air, and generating again the heat that was absorbed in the decomposition. If it takes some appreciable time for the sequence of reaction to take place, then there may be a cooling of the fire by the decomposition of the steam immediately above the grate bars, and a recomposition higher up in the fuel bed or above it. This possible action was pointed out many years ago by Dr. R. W. Raymond, in the *Transactions* of the American Institute of Mining Engineers.

WILLIAM KENT.

Montclair, N. J.

Somewhere, someone has written something about consistency being a jewel.

In the February 7 issue, under the above heading, Mr. Parson makes a number of the most inconsistent statements that could well be imagined.

He first objects to a suggestion that the flue doors be opened to check the draft through a horizontal return-tubular boiler when it is banked, on the score that doing this would cause cold air to be drawn through the tubes. Anyone who knows the difference between a horizontal return-tubular boiler and a cross-compound steam engine, must know that there is no more certain way of preventing cold air being drawn through the tubes when banking the fire than by closing off everything else and opening the flue doors.

Mr. Parson suggests that the flue doors be left closed and a part of the grate bars; this would certainly be about the best way to pull cold air through the tubes, and could only be exceeded in this respect by opening the fire doors. He also objects to opening the flue doors at night because this will cause them to leak during the day; he certainly must have gained his experience with flue doors constructed along very peculiar lines.

His principal objection to the leaky flue door is that it is a great detriment to the economical production of steam where natural draft is used. The only result that can be produced by a leaky flue door is an impairment of the draft and if there were sufficient draft, notwithstanding such leaks, there could be no practical effect on the efficiency.

The second grievance of Mr. Parson is in regard to the use of steam under the grates. In the third column of his article he shows his inability to render consistent his objecting strenuously to the editor's statement that steam admitted below the grates reduces the temperature of the fire and then immediately admitting that he tested with a pyrometer and found that steam does reduce the temperature. A little further on he states that the steam does not materially reduce the temperature of the fire but in many cases improves it. It is difficult to tell what Mr. Parson really believes about this matter, but it appears that what he wants is to make himself and others believe something which experience indicates is not correct. Steam admitted under the grate is one of the most effective and most used methods of preventing clinkers.

It would seem that Mr. Parson should at least have struck it right in one out of his three criticisms, but the third one is apparently as far off as the first two. To show just what was stated, the question and answer will be repeated.

"What is the correct number of square feet of heating surface to be reckoned for a horsepower in different types of boilers?"

Answer. "Ten square feet of heating surface per horsepower has always been the standard used by the makers of water-tube boilers, and from 12 to 15 the standard of the makers of other types. But recently the opinion has prevailed that the heating surface in other types is as efficient as that in the water-tube, and 10 square feet of heating surface per horsepower is now the rating for all types of boilers."

Mr. Parson objects to the rating given for a horizontal return-tubular boiler on a basis of 10 square feet of heating surface per horsepower because the inquirer was talking about a boiler which was already built and states that it should not be rated like one that was being made at the present time.

If there is any valid reason why horizontal return-tubular boilers of the same size and number of tubes built during the spring of 1905 and the fall of 1910 should be rated on different bases, the engineering fraternity would doubtless be under lasting obligations to Mr. Parson for an explanation of the reasons. The New England boiler manufacturers adopted a basis of 10 square feet of heating surface per horsepower for rating horizontal return-tubular boilers about 1907 and there is no reason why it is not perfectly proper.

J. L. JONES.

New Haven, Conn.

The Parliamentary Commission, which was appointed some time ago to consider the expediency of holding a universal exposition in Paris in 1920, has presented a report to the Government in favor of this project. The proposed date of the exposition will coincide with the completion of the extensive program of works for embellishing Paris.

Inquiries of General Interest

Questions are not answered unless accompanied by the name and address of the inquirer. This page is for you when stuck—use it

A Catch Question

A boiler has been made using tool-steel rivets with extra large heads so that they will not pull through and it is not possible for them to shear. The plate must fail by crushing in front of the rivets. If, after this boiler had been tested it was found that the metal in front of two of the rivets had disappeared, what became of it?

T. T. P.

Boiler rivets are made of soft steel or iron and never, even for a test, of tool steel, and the question is one to discover how much is known of the character of the materials used in boiler construction. The reference to the supposed disappearance of a part of the sheet is inserted to draw the attention from the main question, which, put in plain English, would be: Of what material are boiler rivets made?

Stress on Boiler Stays

Figure the stress between the stays and give proper pitch of 1-inch stays, 54,000 tensile strength for a working pressure of 155 pounds.

S. B. S.

Staybolts $1\frac{1}{4}$ inches diameter or less are allowed 6500 pounds per "net section." The area of a 1-inch staybolt having V threads 12 to the inch is 0.575 inch

$$6500 \times 0.575 = 3738 \textit{ pounds}$$

allowable stress on one bolt. For 155 pounds pressure

$$3738 \div 155 = 24.24 \textit{ inches}$$

of surface to be supported by the bolt. To find the pitch extract the square root which gives 4.923 inches pitch. In this the area of one staybolt hole has not been deducted.

In close calculations the area of the hole may be deducted, but Massachusetts rules do not require this. In practice the pitch woud be either $4\frac{7}{8}$ or $4\frac{15}{16}$ inches. As the stress on the plate would be supported by the stays, it would not enter into the calculation.

The plate for 155 pounds pressure and above pitch should not be less than $\frac{3}{8}$ inch thick, whether flat or circular furnace.

Weight of Castings

How can I estimate the weight of iron and brass castings?

I. B. C.

An approximation may be made by weighing the patterns and multiplying the weight by 19 for brass and by 17 for iron if the patterns are made of pine.

Equalizing Piston Clearance

How is the piston clearance in an engine cylinder equalized?

E. P. C.

By disconnecting the connecting rod and pushing the piston to one end of the cylinder until it strikes the head; make a mark on the guide at one end of the crosshead and then move the piston to the other end of the cylinder and mark the guide as before. Lengthen or shorten the distance between the connecting-rod brasses until the crosshead travels equally between the marks on the guide.

When the piston rod screws into the crosshead, the total clearance may be found, and with the crank on the back center the piston rod may be screwed in or out until it is equal at both ends.

Inspection of Boiler Plates

Suppose the owner of a power plant came to an engineer and said in regard to a new boiler that had been ordered, "I have been talking to the boilermaker about that boiler and he says he has some plates that are all right. I have told him that if you said the plates were all right he could build me the boiler." Now, what would the engineer look for? The plates are all right in regard to tensile strength and chemical tests and are rolled nice and smooth and free from blisters and so forth.

B. P. F.

If in Massachusetts, the engineer would look for nothing at all, as the boiler to be installed must comply with the requirements of the Board of Boiler Rules and any observation or investigation on the part of the engineer would be supererogatory. In any other State he should measure each plate with a micrometer at various points on the four edges to ascertain the exact thickness and reject all plates of less than the proper thickness; require mill-test affidavit of chemical and physical tests and check the heat number of each sheet.

Safety Valve Calculations

Please give in plain English without algebra or formulas the rules for calculating the pressure, length of lever, weight of ball, distance from fulcrum, etc., of lever safety valves.

L. S. V.

To find the pressure per square inch which will balance a valve with a given weight at a given distance from the fulcrum, the effective weight of the valve, valve stem and lever being known.

RULE: Multiply the weight by its distance from the fulcrum. Multiply the weight of the valve and the effective weight of the lever by the distance of the stem from the fulcrum, and add this to the former product. Divide the sum of the two products by the product of the area of the valve multiplied by its distance from the fulcrum, and the result will be the pressure in pounds.

To find the distance from the fulcrum at which the weight must be placed to balance a given pressure per square inch.

RULE: Multiply the area of the valve by the pressure, and from the product subtract the effective weight of the valve and lever. Multiply the remainder by the distance of stem from fulcrum, and divide by the weight of the ball. The quotient will be the required distance.

To find the effective weight of the lever, valve and valve stem.

RULE: Multiply the actual weight of the lever by the distance between its center of gravity and the fulcrum, and divide by the distance between the fulcrum and the stem. To the quotient add the actual weight of the valve and the stem.

Engine Running Under

What are the advantages, if any, of running an engine "under"?

R. U. E.

When an engine runs "over," the lower guide bears the weight of the crosshead, part of the weight of the connecting rod and one-half the weight of the piston rod in addition to the pressure due to the diagonal thrust of the connecting rod. When the engine runs "under," the diagonal thrust of the rod forces the crosshead against the upper guide with a pressure which is reduced by the weight of the crosshead and rods, which reduces the friction load of the engine.

Graft

The practice of accepting considerations from salesmen of engineering supplies for influencing the purchase of their goods is belittling and corrupting to the man who does it.

Amos Skeg, whose communication upon this subject appears in Power for February 14, is a good engineer and an upright man. We do not believe that he would buy or recommend the purchase of any machinery or supplies because the sale meant a commission to him, and we do not believe that, having recommended a thing because he thought it was the best and cheapest, he would demean himself by accepting a tip for which he had rendered no service.

The waiter, or porter, or barber has an excuse for the tip which is given him in supposedly special personal attention and extra service. The engineer has no justification for accepting gratuities for which he has rendered no service, even if he is willing to put himself into the tip-receiving class.

No amount of sophistry or argument will justify the practice and we deplore the aid and comfort which those who practice it will derive from Amos Skeg's communications.

It may be true that there is more temptation to find a justification for grafting on the part of a man who, as Mr. Skeg says, views the subject from the edge of a coal pile while cogitating on the dismal fact that the grocery bill will have to go over another week in order that the kiddie may have a new pair of shoes, than on the part of one who considers it from an office chair with the assurance of a comfortable income; but the fact that one needs the money is no justification for a practice otherwise questionable.

The fees and commissions of a professional engineer are not graft when he earns them. He may undertake to do the planning and oversee the installation of a plant for a fixed fee or for a commission or percentage of the cost. So long as this is the agreed method of payment and is abided by, there is no graft. But, if he abuses the power of recommendation and purchase with which the commission endows him by accepting commissions from the sellers of apparatus in addition to the fee or commission which he is accepting from the purchaser, he is a grafter, and he is just as much a grafter if he leads himself to think that his judgment is not influenced by the commission, or that the purchaser is paying no more than the market price and that the commission would stay in the "bulging pockets of the salesman" if he did not collect it.

When we mentioned the high ideals of the professional engineer, however, we had in mind the operating, not the consulting class. Society orators will harp upon the manifold attainments, the highly specialized knowledge, the weighty responsibilities, the executive ability which raise the man in responsible charge of the modern steam plant to the professional plane, and go behind the boiler the next day and sell themselves to an oil peddler for a two-dollar bill.

Two good tests to apply to a transaction are to ask if it will stand daylight, and what would happen if everybody did it. You, who are taking tips from your supplyman, would you be perfectly willing for everybody to know it? Do you let your employer know how much you got for dealing out his patronage? And, if he, trusting in you so absolutely that he believes these tips make not a bit of difference in the cost to him or the quantity or quality which he gets, is willing for you to accept them, do you make the salesman understand that the orders would come just as promptly and just as regularly whether you got the tip or not? Do you let your friends, who look upon you as a responsible salaried man, know that a part of your income is composed of gratuities from supplymen? If you earned an extra twenty-five dollars by indicating the engine of a neighboring factory or by testifying in court upon some mechanical question, you would be rather apt to talk about it. Is your reticence concerning your gratuities induced by an unadmitted sense of shame?

Mr. Skeg asks if the acceptance of the premiums offered for the securing of subscribers to Power or the premiums offered by advertisers for the purchase of their goods or the acceptance of a consideration for writing an article, consigns him to the blacklist.

The premium for getting a new subscriber is legitimate pay for a legitimate service, as is the money which is paid for accepted articles. If you purchase goods with somebody else's money for the purpose of getting the premium for yourself it is graft.

On the B.t.u. Basis

An old gentleman in a Western city had invested his savings in a power building and for years had lived comfortably upon the rents, given his girl a good education and sent his boy to the State university. Upon graduating, the boy set out to administer the property in accordance with the latest developments of the art. One of his first moves was to summon the coal man.

The latter knew what was coming, and had come prepared. "Now, look here," he said, "I know we sell you a lot of coal but we sell it to you right. Your father was one of our first customers and we've always looked out for him like a friend of the family. He gets the best there is and at a price that won't stand talking about out loud. Now, you just let the thing run along and don't go to stirring things up or you'll break up a deal that it will be hard to get back into."

"That's all right," returned the young fellow, "but we are going to run this thing on a business basis. We want to know what we're getting. What per cent. of moisture is there in this coal that you're giving us?"

"What's that —?"

"How much moisture does it contain? How much water is there in it?"

"Water! There ain't no water. It's good, dry coal—dry as a cracker."

"What per cent. of ash has it got?"

"Ashes? There ain't no ashes in it. It's good, clean coal I tell you; the prettiest there is mined."

"How many B.t.u.'s are there in it?"

"Not a d——d B.t.u."

Publicity of Operating Costs

In everyday life there is little which, if viewed abstractly, conveys much meaning, but when compared with some familiar object or incident its value and significance assume definite proportions. This is particularly true of engineering practice.

To one unfamiliar with the performance of steam engines the mere statement that a certain engine has a water rate of fourteen pounds conveys little information, although the definition of the term "water rate" may be thoroughly understood; but when it is known that this figure very closely approaches the best performance of engines of this type and size, its significance is at once apparent.

Similarly a person having access to no test data would fail to differentiate between a boiler efficiency of seventy-six per cent. and a generator efficiency of ninety-six per cent.; and, taking the higher figure as a standard, would class the performance of the boiler as poor, whereas it would be exceptionally good.

In engineering, theory and mathematics are useful, but they serve principally as a guide or check to empirical rules. The real foundations of engineering practice are based upon experience.

Developments along engineering lines are so rapid that the standards of practice are constantly changing; but, in order that widespread benefit may result, it is essential that everybody concerned shall contribute his own experiences, whether success or failure, to the common cause.

The managers of plants making exceptionally good records often refuse to give out any figures for fear that the public will think they are making too great a profit. On the other hand, many plants that are making a poor showing will not disclose any facts concerning their operations for fear of being criticized. Both are assuming an attitude tending to impede progress; the former by refusing to aid its neighbor, and the latter by practically refusing to accept aid.

Speak Up

Human nature is composed of a peculiar mixture. Many people have such an ingrained fear of being criticized or ridiculed by their fellows and associates that they are deterred from expressing their opinions no matter how sure they feel of being correct. To every question there are two or more sides, and in the words of Wendell Phillips, "He does not really believe his opinion who dares not give free scope to his opponent." Once, during a "dinner-pail" talk, a certain operating engineer's veracity was seriously questioned because he stated that the shaft of the De Laval turbine rotates at thirty thousand revolutions per minute. The expressions of disbelief were even more forcible when he stated that this was a moderate speed when compared with that used in grinding small holes.

The recanting of Galileo at the command of the Inquisitators did not stop the rotation of the earth upon its axis, but the fear of the derision of his fellows has deterred many a man from that development and progress which was within his grasp. It is an extremely fortunate thing that the great minds which now stand symbolized by certain human names did not bow their necks to the storm of derision expressed by their contemporaries.

As it is in the large and grand arena of a world entire, so it is within the circumscribed limits of the workshop. Success comes, not at the beck and call of one's fellows and associates, but at the demand of the mind of the individual who has the will to be responsible for himself. The man with a message to his fellows is, fortunately for the world, in most cases the one who is determined to deliver it. It is to be regretted, however, for their own sake as well as the world's, that many fail.

"Be sure you are right, then go ahead"—and let them howl!

American Institute of Boiler Inspectors

Among the many organizations born during recent years there are few which will be watched with keener interest by those engaged in the generation and transmission of power than the Institute of Boiler Inspectors.

When the responsibilities resting on the boiler inspector are considered, the value and the possibilities for the accomplishment of good by a society of this nature become apparent. On him devolves the duty of deciding the ability of a boiler to withstand the effects of the pressure of the confined steam which with the stored energy in the highly heated water is productive of such destruction when an explosion occurs. This demands on the part of the inspector a thorough knowledge in detail of all types of boilers, besides the technical training that is absolutely necessary to enable him to decide constantly arising questions of strength of materials, of methods of construction and operation.

With education along lines leading toward increasing and spreading the social and technical advantages resulting from coöperation as its keynote, the society is bound to succeed in placing itself in the front rank of beneficial organizations.

It would seem to be a simple matter to weigh the coal fed to a battery of boilers, and the water which they evaporate, and determine how much water is evaporated per pound of coal. There are a lot of ways that one can fool himself, however, in this apparently simple operation. Try it under similar conditions and see how careful you must be in order to get consistent results.

Officials of several boiler-insurance companies have told us recently that their losses from "safety" water-tube boilers exceed those from all other classes, even taking the number insured into account. The failures seldom attain to the importance of an explosion, and usually escape notice in the press, but the aggregation of losses from tube rupture is becoming serious.

Have you had any trouble with boiler tubes? If so, how do they fail? Do they open in the weld, thin out and burst, or do pieces drop out of them?

If all of the little things about a plant are given "first aid" when needed, there will be no large one to add to life's burden.

Usually a man's reputation is good until he gets into trouble. Bluff does not count for much when an emergency arises.

Congratulations to San Francisco. Now show them what a real exposition is like.

A New Boiler Feed Water Treatment

Several months ago it was announced in the Australian technical press[1] that a revolutionary method of treating feed water had been discovered in that country. The treatment consisted simply in allowing the water to flow over inclined aluminum plates in the presence of sunlight. Under these conditions the molecular or intermolecular conditions of the scale-forming elements are so changed that instead of forming a hard crystalline scale on the boiler tubes, the deposit is a powdery amorphous mass which can either be washed out of the tubes, or is blown out of the mud drum when blowing down the boiler.

The Australian Apparatus

As used at the Broken Hills Proprietary Company, the apparatus consisted of two aluminum sheets, each 2x4 feet in size, fixed in a frame at an angle of 59 degrees and facing the sun. The water to be used in the boilers was then flowed over these plates from a perforated pipe along their upper edge. As the process was only supposed to be effective during the daytime, storage was provided for the water to be used at night.

In all 197,750 gallons of water were treated and used in a specially cleaned boiler, the test lasting 54 days.

The boiler was then opened, and instead of the hard adherent scale which is normally observed after a run of this length there was either simply a whitish powder or a brittle loose scale, while a portion of the boiler had no deposit in it.

The time of cleaning was reduced from 3½ days to eight hours.

American Installations

Several somewhat similar installations have been made in America recently. In these installations, however, a corrugated plate, or a series of aluminum channels has been used. The equipment is being tried by several important industrial organizations; for example, at the Long Island City plant of the Standard Oil Company, and an installation by the West Shore Railroad at Newark, N. Y., the water in this instance being used by the locomotives. These installations have not been in use long enough to give a definite opinion as to the value of the operation, but the important character of these two corporations indicates that the matter may be worth following up.

It may be noted in this connection that the Watson-Stillman Company, of New York, is putting on the market a compound claimed to be a natural mineral product "consisting mainly of iron, alumina and silica," which is fed into the boiler in suitable quantity at each stroke of the feed pump. It seems to be the general assumption that aluminum hydroxide is partly responsible for the results obtained, as suggested under the idea of protective colloid below.

On Feb. 23, 1911, Thomas R. Duggan, of London, lectured on this new process before the Society of Chemical Industry, adding somewhat to the information already made public. The form of the apparatus shown was that with corrugated aluminum plates, but the corrugations are apparently more to insure thorough distribution of the water than for any other reason. There is a hopper at the top, from which a number of small nozzles, one to each trough, feed the water to the plate. The hopper is furthermore provided with a screen to keep large pieces of dirt and grit from choking the nozzles.

The plates should be open to the air and although more active by day, have some activity at night, apparently due to the small amount of ultraviolet radiation even at that time. The plates in the northern hemisphere should face south; in the southern hemisphere, north. It is essential that the pipes and storage tanks used after the water is treated should be, as far as possible, of nonconducting material, and the water should be used as soon as possible after treatment, and should be used by the seventh day, as a maximum. It is also essential that the plates should be given a rest occasionally; where hard water is being treated, every plate is allowed to rest one day per week.

It is stated that the plates become positively charged and the water negatively, and this, when considered in conjunction with the fact that the plates should face either north or south, and that a nonconducting material should be used for the storage tank, leads to the belief that some fundamental change in ionization is responsible for the results. However, a minute amount of the aluminum dissolves, and researches with the ultra-microscope show that it remains in colloidal solution, though whether as a mixture of aluminum and aluminum hydrate, or the latter only, seems open to question. Whichever of these it may be, the explanation of protective colloids seems also possible.

The apparatus is made in units about 6 inches wide, one 6-inch unit having a capacity of about 1000 gallons per hour. The advantages claimed for the treatment are: It is automatic, continuous and uniform; no chemicals or heat used, hence low treatment cost; it has no action itself on the boiler, and by a deoxidizing effect on the water is a preventer of corrosion; hard scale is prevented and the time of cleaning the boiler much lessened, thereby getting more hours' work from a given plant; by the elimination of hard scale the efficiency and life of the boiler are claimed to be increased.

Any water is amenable to this treatment except that containing ferrous sulphate or carbonate. With saline waters the length of the plates is increased beyond the usual 5 feet, or the water run back over the plates several times. Boilers under this treatment must be blown off frequently, particularly during early stages, as old scale often loosens and settles into the mud drum during the first few weeks.

The process is the invention of Herr Brandes, and is patented in most civilized countries, the rights for the United States being held by the Luminator Water Company of America, with offices in New York.

[1]Aust. Min. Std., Sept. 21, 1910.

Congress of Technology

A congress of technology will be held in Boston on April 10 and 11 in celebration of the fiftieth anniversary of the granting of the charter of the Massachusetts Institute of Technology. In line with this idea, the fifty or more papers which will be presented at the congress will be written by graduates of the institute, and will thus serve to record the part the alumni of the institution have taken in the development of scientific industry.

As the titles of these papers are sent in by the writers, it is becoming evident that the managers of the congress will succeed in their effort to make the proceedings show from another point of view the general industrial advance that has taken place during the past fifty years under the guidance of trained engineers. The papers will cover a wide range of subjects, from architecture to sewage purification, and the names and professional standing of the writers show that they will together discuss authoritatively every important problem of modern industrial technique and management. It is already clear that this record is not limited to any narrow activity within merely technical lines, but that it covers the broader problems of the relations of science to industry, and the place of the engineer in creating a more efficient type of industrial management.

The point is made that by a slight change in the arch of a furnace under a tubular boiler much can be done to prevent smoke. The proper length and form of the combustion arch depends upon many variable factors and perhaps is best determined by experiment under the given conditions. A station was equipped with a pair of [illegible] boilers, and it was thought they were installed exactly alike. One was making smoke and the other did not. On taking measurements it was found one arch was 8 inches higher than the other. The high arch was lowered 8 inches and the smoke stopped. If the draft had been a great deal more the arch might have had to go up.—F. S.

New Power House Equipment

What the inventor and the manufacturer are doing to save time and money in the engine room and power house. Engine room news

Samson Transmission Rope

This rope is composed of a special crucible cast-steel wire rope coated with a rubber compound over which is braided, under heavy tension, a cotton cover comprising about four-fifths the area of the rope. The compound in the rope is vulcanized, which causes it to expand and harden into the interstices of both the cotton and wire ropes, firmly binding them together, also waterproofing and lubricating that portion of the rope most subject to deterioration. A final operation is to treat the cotton with a penetrating finish, binding its fibers together and increasing its resistance to wear. Fig. 1 shows the construction of the rope.

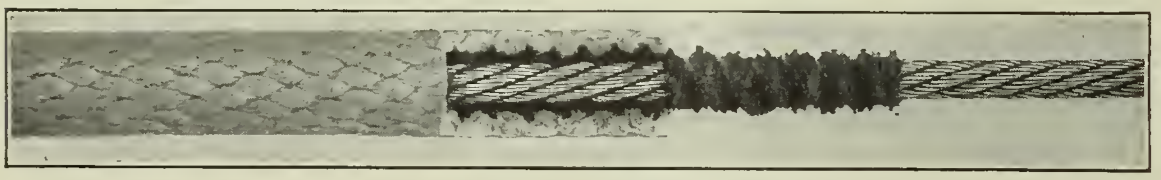

Fig. 1. Details of Construction

The method of splicing this make of rope is such that every wrap can be fitted with a coupling to exact length, by any mechanic at any convenient bench, and then coupled or uncoupled in working position on sheaves. This makes it possible to cut spare ropes at the exact length required and fit them with the coupling ready to be attached. Unlike rope that requires splicing, it is not necessary to make each rope endless in working position while the drive is idle, nor is it necessary to shorten it up after installation.

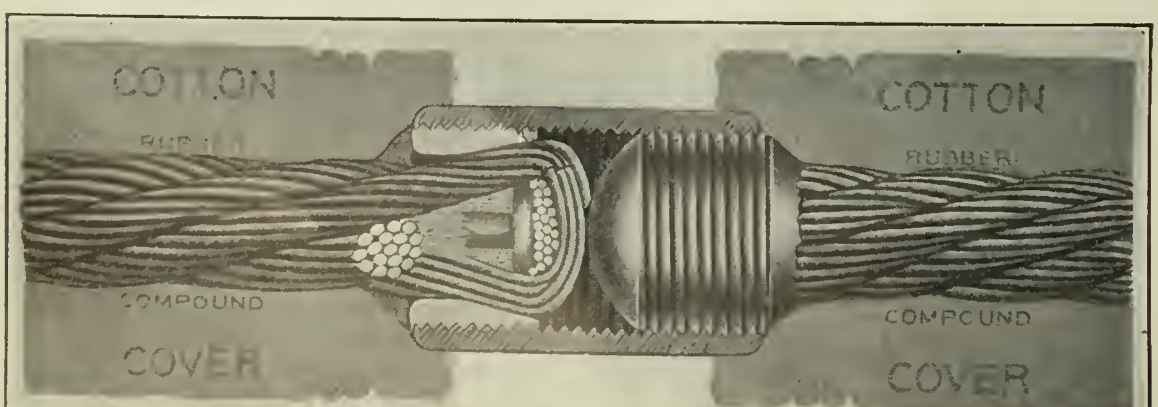

Fig. 2. Coupling Joint

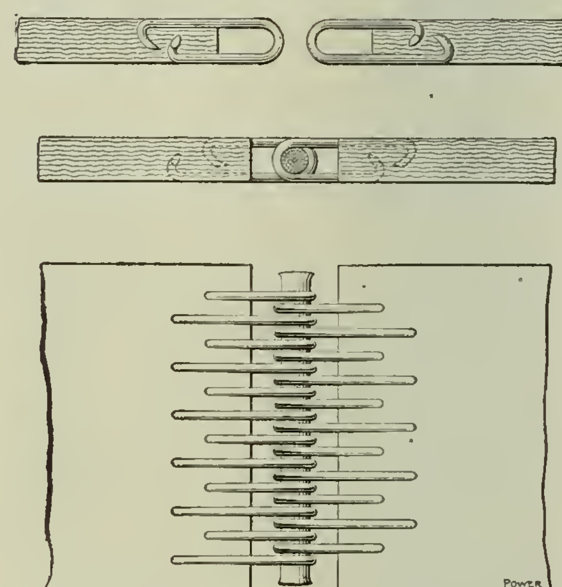
The rope coupling is composed of two thimbles and a connecting sleeve, as shown in Fig. 2. Each end of the rope is cleaned bright, then passed through a thimble and expanded by driving a rivet, and turning the wire ends into the socket, after which all space between the wires is filled with solder. It is claimed that a ¼-inch coupling will resist a ton strain. The coupling and wire center, which carry the strain, never come in contact with the sheaves, as the cotton cover protects them.

This transmission rope and coupling is made by the Samson Cordage Works, 88 Broad street, Boston, Mass.

Clipper Belt Lacing

This lacing constitutes a simple and effective means of fastening belts, and is easily and quickly applied. The lacing is done with a series of hooks of a size corresponding to the amount of power to be transmitted, these hooks hinging on twisted rawhide pinions. The lacer itself consists of a solid steel base and anvil, with lacer part of bronze metal, and a solid lignum vitae mallet. The advantages claimed for this lacing are that both sides of the belt are perfectly smooth, it uses hooks having a long and short side, thus equalizing the strain, the joint is flexible, with no chance of crystallization of the hooks if they are properly driven into the belt flush with the surface, and no short ends of belts are wasted in making the lacing. Any width or thickness of belt may be laced with the same tool and as it is portable it is easily taken to the point where the work is to be done, making it unneces-



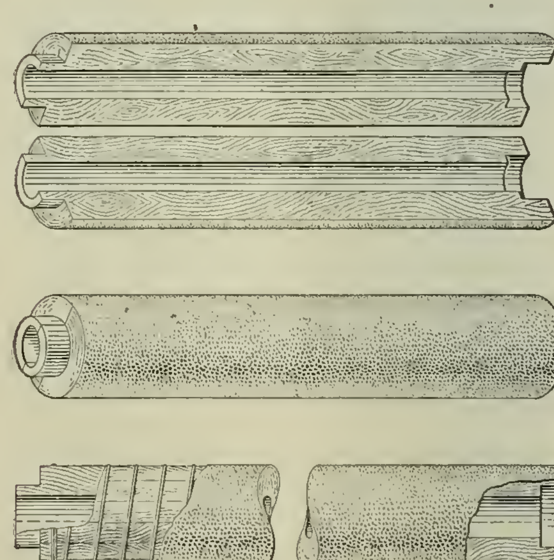
Clipper Belt Lacing

sary to take the belt off the shaft or pulleys.

The Clipper belt lacer is manufactured by J. B. Stone Company, Grand Rapids, Mich.

Improved Steam Pipe Casings

An efficient nonconducting covering is made by the Michigan Pipe Company, of Bay City, Mich. The casings are made of staves, which it is claimed have



Steam-pipe Casing

proved successful in every respect. The stave casings, which are illustrated in the accompanying drawings, are made in sections up to 12 feet in length, of Michigan pine and tamarack. The inner and outer surfaces of the staves are curved to conform respectively with the inside and outside circles of the pipe and the sides are fitted with a double tongue and groove, running the full length of the pipe. The staves are thoroughly inspected, and assembled in a cylindrical form, after which the sections are spirally bound with galvanized wire from end to end, under heavy tension, with a double wrap at each end, thus making them of uniform strength and as rigid as the solid log. A mortise is then put in one end and a tenon on the other, after which the outer surface is heavily coated with an imperishable cement.

Smaller sizes of casings are made of solid logs which are bored and then finished the same as the stave casings.

The Kilgour Boiler Setting

Barristers hall in Boston is so situated that its smokestack is one of the prominent features of the view from the smoke inspector's window. As a consequence Dwight Kilgour, the mechanical engineer in charge, made numerous involuntary excursions to the court where violations of the smoke ordinance are tried, each entailing considerable unpleasantness, not to mention the expense incurred in the shape of lawyer's fees and time. Convinced that the only way to stop the arrests was to stop the smoke, he directed his activities to the production of a smokeless furnace.

If one sits in a room with a lamp having a chimney like that shown in Fig. 1, he will soon be sensible that the lamp is there. If the chimney is extended into the usual converging nozzle, the combustion will be complete and the flame bright and steady. Mr. Kilgour compared his smoky furnace with the smoky lamp and concluded that it needed its chimney lengthened, not the tall brick stack beyond the boiler which carries off the products of combustion, but the firebrick inclosure in which the combustion should be completed before the gases

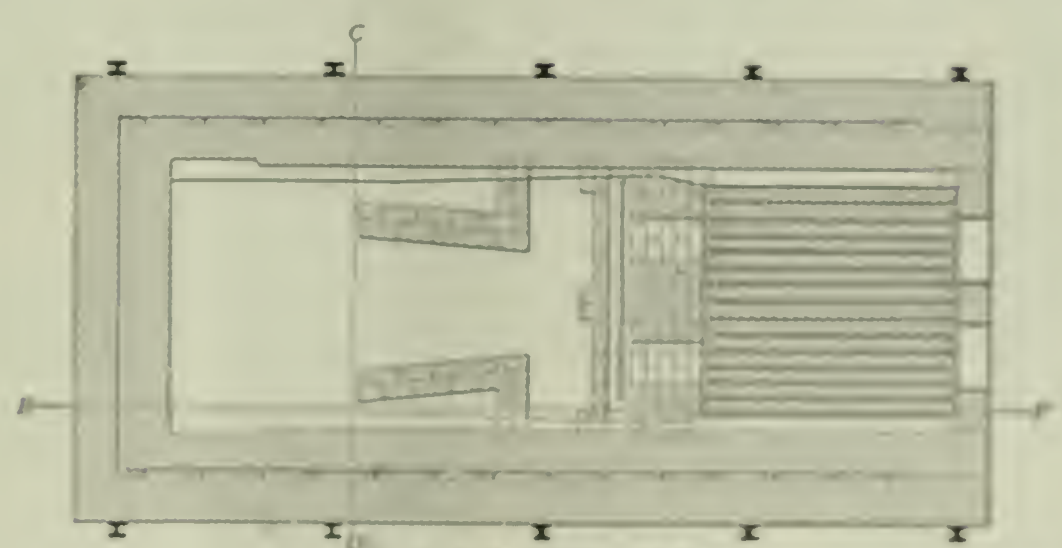
FIG. 1. A CASE OF CHILLING THE FLAME

reach the cool boiler plate and tubes.

He therefore threw up a firebrick curtain *M* behind the bridgewall and led the converging firebrick tube or arch out of it as shown in the views of Fig. 2. The bridgewall was made hollow, and cast-iron ducts *N* with perforations pointed toward the rear of the boiler discharge finely divided streams of highly heated air into the gases as they stream over the bridgewall.

One observer said that he had simply changed the ordinary brick arch from the furnace to the combustion chamber. Even so, he gets away from that disadvantage of the furnace arch that it radiates heat upon the firebed with such intensity that it accelerates the throwing off of the volatiles which already come off from freshly fired fuel faster than they can be burned. With the arch located back of the bridgewall, all the products of the furnace, including the volatiles, have to pass through it; and, if they are hot enough, if there is oxygen enough present and if the mixture is sufficiently intimate, the combustion will be complete.

After the furnace has been running for a while the mass of brickwork becomes incandescent. The gases coming directly from the furnace and with no chance of losing heat except to the shell directly over the furnace, can easily be kept above the point of ignition while passing through the passages of red-hot brick. The presence of sufficient oxygen may be secured by the admission of air above the bridgewall, and as this comes



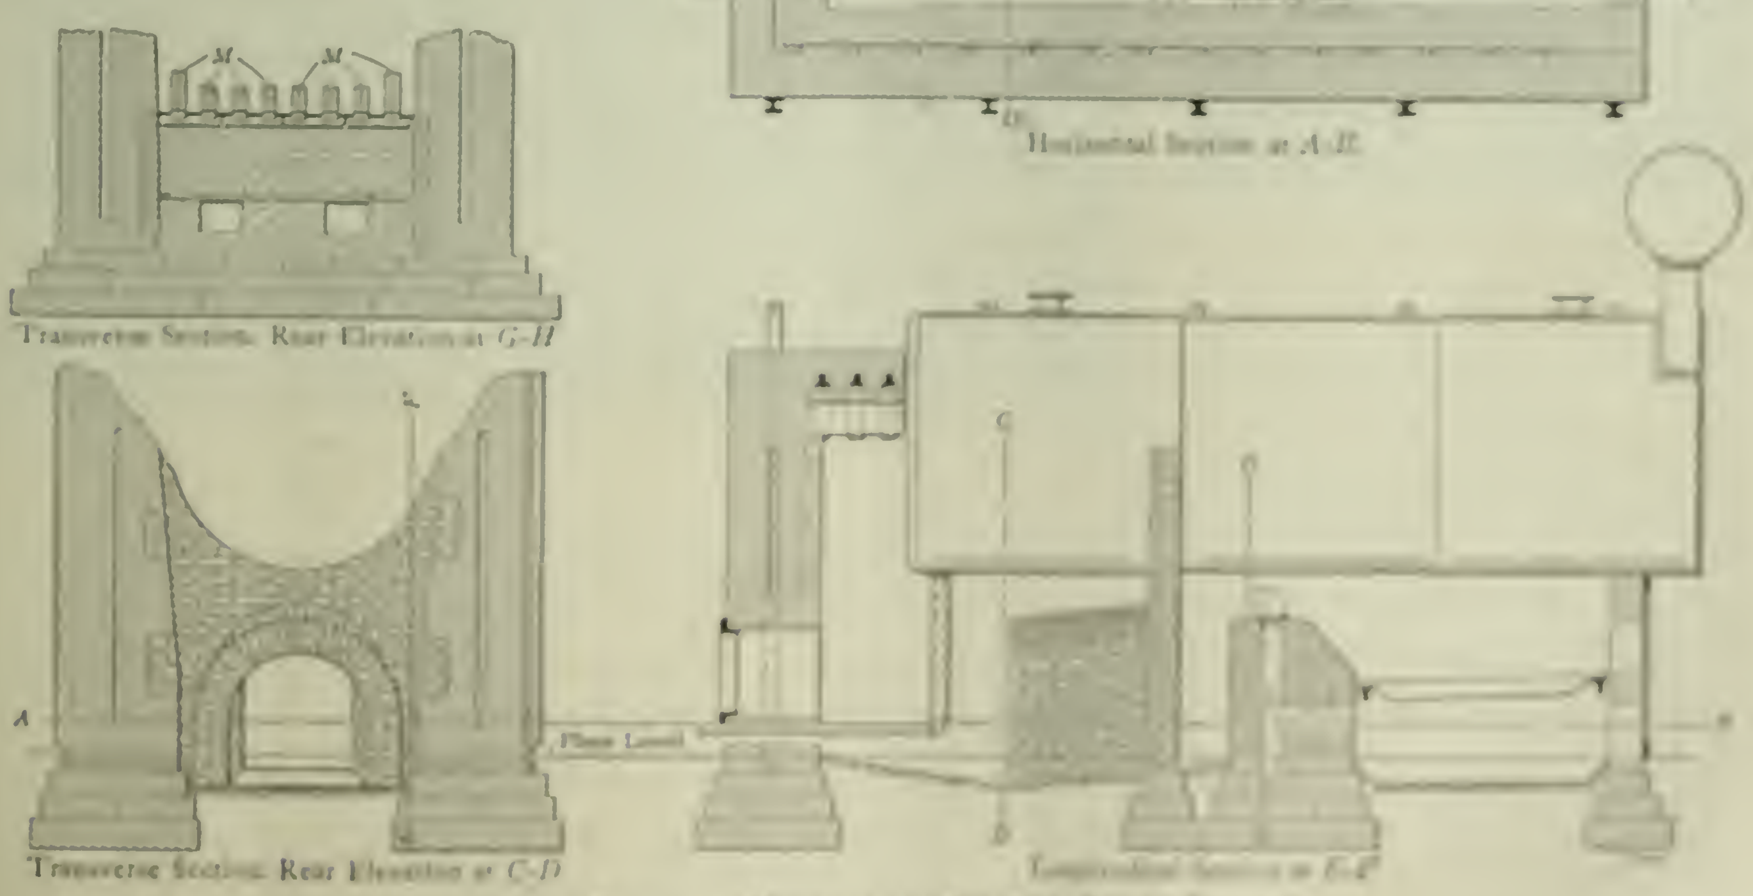


FIG. 2. SECTIONAL VIEWS OF THE KILGOUR BOILER SETTING

in a highly heated condition its introduction does not cool the gases below the temperature at which they will unite. The diffusion of the air in numerous jets tends to an intimate mixture, which tendency is enhanced by turning the sheet of gases which is flowing over the bridgewall in a sheet the width of the furnace, so that they pass out through a passage which is quite some higher than it is wide. This change from a horizontal to a vertical plane produces a swirl in the current which is very pronounced as their combustion in the extension tube is watched from the rear. There is no impingement of the flame upon the shell, and yet no loss of efficiency in the heating surface, for the shell above the arch receives radiant heat from it as it would from an equally hot mass of glowing coal.

C. E. Cotting is the trustee of numerous estates owning large buildings, and Mr. Kilgour is his mechanical engineer. He has therefore had an exceptional opportunity to try out his ideas under various conditions. I saw them at the Exchange building carrying fires of soft coal piled nearly to the top of the fire doors. I watched at the back connection while they put on fresh fuel and sliced the fires. Each shovelful of coal as it was fired produced a rush of flame in the arch as though a jet of gas had been turned on momentarily. The slicing filled the whole back connection with a roaring mass of flame, which, however, cleared up instantly. The stack showed a very thin gray smoke at intervals, evidently when the fires were disturbed.

They have burned as high as 25 to 30 pounds of coal per square foot of grate, and after three years of use the arches are in good condition with no rebuilding or repairs. The perforations in the iron retorts require drilling out from time to time. The brickwork becomes covered with a black vitreous crust to which clusters of slag attach themselves, which may, however, be picked off with the fingers. The furnace has been patented and adapted to water-tube as well as to shell boilers. Henry W. Buhler, 251 Causeway street, Boston, is licensee of the Kilgour patents and controls the manufacture and erection of the setting.

Annual Banquet of the Combined National Association of Stationary Engineers Associations of Manhattan and the Bronx, New York City

New York Engineers Hold Annual Dinner

Saturday night, February 25, at the Broadway Central hotel, a gay scene was presented when about two hundred ladies and gentlemen sat down to the second annual dinner given by the general committee of the combined associations of the National Association of Stationary Engineers of Manhattan and the Bronx.

John Mahr acted as toastmaster and introduced each speaker and singer in turn with words both pointed and pertinent.

Edward H. Kearney, national vice-president, was the first speaker. He dwelt on the history, aims and triumphs of the National Association, ascribing a good measure of the success attained to the coöperation of the wives, sisters and sweethearts of the members. So eloquently did he portray the effect of this influence that few, if any, of his audience realized that his experience in feminine coöperation had been conducted entirely on the absent-treatment plan.

Charles A. Wilhoft, president of the Supplymen's Association of Manhattan, read letters of regret and of felicitation from prominent members of the national association from various parts of the country, and made a few brief remarks as to the history, aims and scope of the supplymen's organization.

Past National Presidents Carney and Reynolds added gems of mixed wit and wisdom to the occasion and very considerately cut their parts short in order to give all the time possible to Billy Murry and Jack Armour.

Promptly at 12 o'clock dancing began and was continued far beyond the usual "wee sma' hour."

It was the consensus of opinion that the event was both pleasant and profitable and the best ever.

The Newly Elected President of A. S. M. E. for 1911

On May 30, 1841, Edward Daniel Meier, who is now president and chief engineer of the Heine Safety Boiler Company, was born in St. Louis, Mo. A scientific course at Washington University in St. Louis and four years at the Royal Polytechnic College in Hanover gave him a solid foundation on which to build his engineering career. After seeing much active service in the Civil War, Colonel Meier entered the Rogers Locomotive Works, at Paterson, N. J., remaining one year. From 1867 to 1870 he was associated with the Kansas Pacific Railway, first as assistant superintendent and then as superintendent of machinery, leaving there to become chief engineer of the Illinois Patent Coke Company. In 1872 he became manager of the Meier Iron Company, building its blast furnace, and from 1873 to 1875 directed the machinery department of the St Louis Interstate Fair. During this time he became actively interested in the St Louis cotton industry and designed machinery for baling cotton, first with the St. Louis Cotton Factory and then with the Peper Hydraulic Cotton Press. In 1884 he organized the Heine Safety Boiler Company for the development in the United States of the water-tube boiler of that name, and has been its president and chief engineer ever since. He was also responsible for the introduction of the Diesel motor into the United States and until 1908 was engineer-in-chief and treasurer of the American Diesel Engine Company.

Col. E. D. Meier

Colonel Meier has been active in a number of professional organizations. From 1881 to 1884 he was treasurer of the St. Louis Engineers Club and president from 1890 to 1891. During the latter period he was also secretary of the American Boiler Manufacturers' Association, and in 1898 to 1900 he was president of the association and also of the Machinery and Metal Trades Association.

In the American Society of Mechanical Engineers, Colonel Meier has been active on many committees and has been twice elected vice-president, serving his first term from 1898 to 1901, and beginning the second in 1910, so that he was still holding this office at the time of his election as president.

Low Water Caused Explosion on the "Delaware"

It is reported by the daily press that the boiler accident on the battleship "Delaware" on January 17, which killed nine men, was caused by low water in the affected boiler. According to the findings of the court of inquiry, appointed by the Secretary of the Navy, the water tender, who was killed, was responsible for the condition of the water in the boiler. At the Navy Department it was said that the findings will result in an attempt to devise a plan by which the responsibility for maintaining the water at a proper hight will not be intrusted to water tenders alone, but will be shared by others of the boiler-room force.

Steam Boiler Inspectors Organize

On the evening of February 21, following a dinner at the Victoria hotel, New York City, the steam-boiler inspectors employed in and around the city, organized a society which adopted the name of the American Institute of Steam Boiler Inspectors. The dinner was attended by a large number of inspectors employed by the several insurance companies, railroads, etc., in and around New York, together with representatives from a similar society of Boston, Mass., including its vice-president, J. F. Mullen, who outlined the value of the society and the good work that is being done. James G. Shaw read a paper defining the purposes and aims of the institute.

After an informal discussion a constitution was adopted and the following officers elected: President, T. T. Parker; vice-president, J. N. Wixted; secretary, Robert A. Thomson; treasurer, T. McGowan.

An executive committee of five was chosen, and the organization will be completed at an early date. The list of charter members contains thirty-six names, but it is expected that when the purposes of the society are fully understood by the inspectors not present, the membership will be greatly increased and embrace practically all those in the immediate vicinity of New York.

The society is for steam-boiler inspectors employed by Federal, Dominion, State and city governments and the insurance companies of the United States and Canada, but the charter list is open to actual boiler inspectors only.

The object of the institute is to promote the educational and social interests of its members, and, to this end, meetings for presentation and discussion of papers will be held at regular intervals.

This is the second society of this nature formed in this country, but owing to the success of the Boston organization, steps are being taken to make the institute one which shall include in its membership all of the reputable boiler inspectors in North America.

The address of the secretary is 1 Madison square, New York, N. Y.

SOCIETY NOTES

The Oregon Society of Engineers has been organized with a charter membership of 160. All branches of the engineering profession are included in the membership. The territory has not been limited to the State of Oregon, but includes all the Greater Northwest. D. C. Henny, 605 Spaulding building, Portland, Ore. (consulting engineer for the United States Reclamation Service), has been elected president, and G. L. Bliven, 407 Buchanan building, secretary. The present headquarters of the society will be located at 407 Buchanan building, Portland.

The ninetieth meeting of the National Association of Cotton Manufacturers will be held at the Massachusetts Institute of Technology, Boston, Mass., April 12 and 13, 1911. These dates have been selected because they immediately follow the Congress of Technology which will be held on the preceding days, in celebration of the fiftieth anniversary of the charter of that institution, and it is expected that many of those present will remain to attend the meeting.

President Maclaurin, of the Massachusetts Institute of Technology, will speak at the opening session and during the meeting papers are expected on the following subjects: "Arbitration on Cancelation of Orders," "Byproducts in Cotton Manufacture," "Doffing Machines and their Relation to Child Labor," "Electric Power Transmission to Cotton Mills," "Executive Management of the Textile Plant and its Relation to the Market," "Gas Producers and Gas Engines for Cotton Mills," "Illumination," "Law of Moisture in Cotton and Wool," "Methods of Cost Finding in Cotton Mills," "Moisture in Cotton," "Renaissance of the Waterfall," "Rewinding Weft Yarn," "Sandwich Island Cotton," "Textile Education from a Manufacturing Standpoint," "Weaving Shed Roof Construction."

Also reports on standard specifications and other subjects by special committees.

NEW INVENTIONS

Printed copies of patents are furnished by the Patent Office at 5c. each. Address the Commissioner of Patents, Washington, D. C.

PRIME MOVERS

INTERNAL COMBUSTION ENGINE. Geo. F. Murphy, Jersey City, N. J., assignor to Fuel Oil Engine Company, Providence, R. I., a Corporation of Rhode Island. 984,695.

ROTARY ENGINE. Ambrose Everts Greene, Pueblo, Colo. 984,901.

ROTARY ENGINE. James Henry Watson, Riverton, Wyo. 984,983.

ROTARY ENGINE. Karl Wittig and Emil Wittig, Zell, Wiesenthal, Germany. 985,091.

BOILERS, FURNACES AND GAS PRODUCERS

WATER-TUBE BOILER. John E. Bell, New York, N. Y., assignor to the Babcock & Wilcox Company, New York, N. Y., a Corporation of New Jersey. 984,880.

FURNACE. Joseph Harrington, Riverside, Ill. 984,910.

SMOKE-CONSUMING FURNACE. William E. Ludlow, Washington, and Henry J. White, Augusta, Ga. 984,979.

POWER PLANT AUXILIARIES AND APPLIANCES

BOILER-TUBE CLEANER. Thomas S. Waller and John V. Carr, Detroit, Mich., assignors to Raphael Herman, Detroit, Mich. 984,622.

LUBRICATOR CUP. Robert M. Stevenson, Olean, N. Y. 984,713.

FINE FUEL-FEEDING APPARATUS. Geo. L. Swift, Chicago, Ill. 984,715.

VALVE. William Gavin Taylor, Waterbury, Conn. 984,718.

ENGINE INDICATOR. Max Arnot, Aix-la-Chapelle, Germany. 984,732.

VALVE MECHANISM. John W. Ledoux, Swarthmore, Penn. 984,820.

LUBRICATOR. Oscar H. Neiman, Freeport, Ill. 984,839.

PISTON-PACKING EXPANDER. George Christenson, Nevada, Mo., assignor to H. W. Johns-Manville Company, a Corporation of New York. 984,888.

NOISE MUFFLER FOR EXHAUST PIPES. Daniel W. Dudderar, Mount Airy, Md. 984,890.

BOILER FLUE-CLEANER SYSTEM. De Los E. Hibner, Dubois, Penn., assignor to the Vulcan Soot Cleaner Company of Pittsburg, Penn., Dubois, Penn., a Corporation of New Jersey. 984,919.

SAFETY DEVICE FOR STEAM ENGINES. Walter B. Kollar, Lansing, Mich. 984,935.

SEPARATING GRATE. Nicholas Colgen, St. Charles, Minn. 985,007.

BOILER FEEDER. George C. Miller, Fitchburg, Mass., assignor to the Leominster Machine Supply Company, Leominster, Mass. 985,050.

PISTON HEAD. Frank Pienie Roesch, Douglas, Ariz. 985,065.

ELECTRICAL INVENTIONS

ELECTRIC HAMMER. Hilary F. Whalton, Key West, Fla. 984,984.

ALTERNATING-CURRENT MOTOR. Burton McCollum, Lawrence, Kan. 984,582.

ELECTRIC WELDING MACHINE. Lafayette M. Pryor and Jesse L. Trapp, Frankfort, Ind. 984,603.

VAPOR ELECTRIC APPARATUS. Max Von Recklinghausen, New York, N. Y., assignor to Cooper Hewitt Electric Company, a Corporation of New York.

ELECTROMAGNETIC APPARATUS. John P. Coleman, New York, N. Y., assignor to the Union Switch and Signal Company, Swissvale, Penn., a Corporation of Pennsylvania. 984,748.

VARIABLE SELF-INDUCTION COIL. Allyne Clark Hovey, Pittsburg, Penn., assignor of thirty-one-hundredths to Walter Rosenbaum and thirty-one-hundredths to Herman S. Heymann, Pittsburg, Penn. 985,009.

POWER PLANT TOOLS

WRENCH. Hiram Mendenhall and Bertel R. Wonsmos, Audubon, Iowa; said Wonsmos assignor to John Weighton, Audubon, Iowa. 984,691.

WRENCH. Eugene Green, San Marcos, Tex. 985,028.

Engineering Societies

AMERICAN SOCIETY OF MECHANICAL ENGINEERS

Pres., Col. E. D. Meier; sec., Calvin W. Rice, Engineering Societies building, 29 West 39th St., New York. Monthly meetings in New York City. Spring meeting in Pittsburg, May 30 to June 2.

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS

Pres., Dugald C. Jackson; sec., Ralph W. Pope, 33 W. Thirty-ninth St., New York. Meetings monthly.

NATIONAL ELECTRIC LIGHT ASSOCIATION

Pres., Frank W. Frueauff; sec., T. C. Martin, 31 West Thirty-ninth St., New York. Next meeting in New York City, May 29 to June 2.

AMERICAN SOCIETY OF NAVAL ENGINEERS

Pres., Engineer-in-Chief Hutch I. Cone, U. S. N.; sec. and treas., Lieutenant Commander U. T. Holmes, U. S. N., Bureau of Steam Engineering, Navy Department, Washington, D. C.

AMERICAN BOILER MANUFACTURERS' ASSOCIATION

Pres., E. D. Meier, 11 Broadway, New York; sec., J. D. Farasey, cor. 37th St. and Erie Railroad, Cleveland, O. Next meeting to be held September, 1911, in Boston, Mass.

WESTERN SOCIETY OF ENGINEERS

Pres., O. P. Chamberlain; sec., J. H. Warder, 1735 Monadnock Block, Chicago, Ill.

ENGINEERS' SOCIETY OF WESTERN PENNSYLVANIA

Pres., Walter Riddle; sec., E. K. Hiles, Oliver building, Pittsburg, Penn. Meetings 1st and 3d Tuesdays.

AMERICAN SOCIETY OF HEATING AND VENTILATING ENGINEERS

Pres., R. P. Bolton; sec., W. W. Macon, 29 West Thirty-ninth street, New York City.

NATIONAL ASSOCIATION OF STATIONARY ENGINEERS

Pres., Carl S. Pearse, Denver, Colo.; sec., F. W. Raven, 325 Dearborn street, Chicago, Ill. Next convention, Cincinnati, Ohio.

AMERICAN ORDER OF STEAM ENGINEERS

Supr. Chief Engr., Frederick Markoe, Philadelphia, Pa.; Supr. Cor. Engr., William S. Wetzler, 753 N. Forty-fourth St., Philadelphia, Pa. Next meeting at Philadelphia, June 5-10, 1911.

NATIONAL MARINE ENGINEERS BENEFICIAL ASSOCIATIONS

Pres., William F. Yates, New York, N. Y.; sec., George A. Grubb, 1040 Dakin street, Chicago, Ill. Next meeting at Detroit, Mich., January, 1912.

INTERNAL COMBUSTION ENGINEERS' ASSOCIATION.

Pres., Arthur J. Frith; sec., Charles Kratsch, 416 W. Indiana St., Chicago. Meetings the second Friday in each month at Fraternity Halls, Chicago.

UNIVERSAL CRAFTSMEN COUNCIL OF ENGINEERS

Grand Worthy Chief, John Cope; sec., J. U. Bunce, Hotel Statler, Buffalo, N. Y. Next annual meeting in Philadelphia, Penn., week commencing Monday, August 7, 1911.

OHIO SOCIETY OF MECHANICAL ELECTRICAL AND STEAM ENGINEERS

Pres., O. F. Rabbe; acting sec., Charles P. Crowe, Ohio State University, Columbus, Ohio. Next meeting, Youngstown, Ohio, May 18 and 19, 1911.

INTERNATIONAL MASTER BOILER MAKERS' ASSOCIATION

Pres., A. N. Lucas; sec., Harry D. Vaught, 95 Liberty street, New York. Next meeting at Omaha, Neb., May, 1911.

INTERNATIONAL UNION OF STEAM ENGINEERS

Pres., Matt. Comerford; sec., J. G. Hannahan, Chicago, Ill. Next meeting at St. Paul, Minn., September, 1911.

NATIONAL DISTRICT HEATING ASSOCIATION

Pres., G. W. Wright, Baltimore, Md.; sec. and treas., D. L. Gaskill, Greenville, O.

POWER

NEW YORK, MARCH 14, 1911

SOME months ago there was a cartoon on this page showing that while the engineer was dozing over his work the central-station solicitor was busy and succeeded in getting public-service wires into the building.

To those who saw the picture it was just as evident that the heating company had also got a foothold, and its steam-supply pipe was just as ready for service as the electric wires.

But the picture told more than this.

It told how the wires from the central station and the pipe from the steam heating company found an opening through which the building could be entered. It was made by the engineer himself while asleep on duty.

He walked about in his sleep, attending to the routine work of the plant and nothing else. Neglect and mental indolence so clouded his brain that the invasion of his field was not noticed until it was too late. Another engineer went out into the world to enter the ranks of the unemployed and by his competition help to force still lower the standard of wages and living of that class of skilled workmen whose remuneration should be the highest paid to any workers in the country.

But he slept. His obvious duties were perfunctorily performed, while the more important factors of his vocation were neglected.

He knew how to shovel coal enough into the furnace to generate what steam was wanted. But he did not know whether he was using too much for the work or only enough.

He knew when he saw the switchboard how much current was being used at that moment. But he did not know how much that current cost per kilowatt-hour.

He knew how to read the water meter through which the water went to the feed pump. But he did not know whether leaking steam valves and pistons in pump and engine were wasting a third of the water that went to the boiler.

He could attend with apparent skill and intelligence to every detail in the operation of the plant. But when the proprietor showed him the central-station and the heating-plant figures, and asked if he could meet them with the present equipment, he was dumb.

He had been sleeping on the job in fancied security, while the men who wanted his plant were awake and busy.

They knew how much coal was burned, the amount of the water bill and the size of the payroll for this department. It was all, every item, on the tips of the solicitors' glib tongues. They could tell the owner everything; he nothing.

It is certain that the immediate interests of a greater number of people will be better served by the use of isolated plants for heat, light and power in a great majority of modern office, store and apartment buildings. But to continue in service those already installed and add to their number as buildings are erected, the engineer must be the character implied by the name: alert, intelligent, courageous, aggressive and, above all, a master in his vocation.

Everybody is ready to help the bottom dog in a fight if he fights. While but few have either respect or sympathy for a "quitter."

New Power Plant of Amoskeag Mills

By Warren O. Rogers

This plant contains sixty-four 300-horsepower Manning boilers set in a single row in a boiler room 500 feet long. The boilers consume 130,000 tons of coal per year and supply steam to 42,300 horsepower of engine equipment and for manufacturing purposes.

The Amoskeag Manufacturing Company, Manchester, N. H., employs 15,000 men and women, and uses 50,000,000 pounds of cotton and 15,300,000 pounds of wool per year. This requires 65,700 nominal boiler horsepower and 42,300 engine horsepower, of which 17,500 horsepower is developed by steam turbines. The steam necessary to operate these engines in addition to that used in the process of manufacture demands an annual consumption of 130,000 tons of coal.

When present plans are completed, the power necessary to drive the machinery in these mills, and the steam used for other purposes, will be generated in three central power plants, dividing the mills into three sections, each section having its own central station. Two of these power plants have been running for several years, but the third is just being put into use.

The initial idea, when the new plant was proposed, was to furnish power for the new Coolidge mill, built on the opposite side of the river. This mill requires about 4000 horsepower; the machinery is motor driven and the electrical current is carried across the river by means of wires supported by towers placed on an island in the center of the river and on the two banks. The wires start from the wire tower above the switchboard.

Steam Turbines

This new power plant contains two of the first horizontal type of Curtis turbines made, each of 3500 kilowatts capacity. They are set side by side at one end of the turbine room, as shown in Fig. 3, on a concrete foundation that is built on a solid ledge base. There is room enough between the turbines and the end wall of the building for the switchboard gallery, and enough floor room has been provided for several more turbines, should they be required. The turbines under a steam pressure of 175 pounds per square inch run at a speed of 1200 revolutions per minute.

Fig. 1. Cleaning Side of the Manning Boilers. The Hand Lever in Front of Each Boiler Controls the Air Supply in the Air Duct

Although rated at 3500 kilowatts, each unit will be made to develop 6000 kilowatts continuously, or nearly double the rated capacity of the machne. Each generator is kept cool by means of a fan blower attached directly to the turbine condensing nozzles arranged as shown in Fig. 4. No circulating pump is used, as the condensers are started and operated by the condensing water itself and a vacuum of from 26 to 27 inches is maintained.

priming pipe. As the lift of the condensing water is but 2 feet, the water in flowing from the priming pipe to the discharge pipe of the jet head creates enough vacuum to lift the condensing water, which, when once started, main-

Fig. 2. The Sixty-four Manning Boilers Equipped with Jones Stokers

shaft. Air is taken from the turbine room and discharged into the room again through the top of the generator casing.

Condensers

Each turbine is piped to a Bulkley type of condenser, and each head has three

A 52-inch flume conveys the condensing water from a point above a dam in the Merrimac River to the basement under the turbine room, and the drop of the pipe provides of a 33-foot head at the lower end. Each discharge tube of three jet nozzles is fitted with a starting or

tains a steady flow to the condenser. The water of condensation and cooling water is allowed to go to waste by the river, there being no necessity in saving it. The feed water is heated by the exhaust steam from the feed pumps and auxiliaries in a closed heater after which it passes through economizers. The condensers are set outside of the turbine room and discharge into a hotwell from which the water runs to the river.

There is fitted, at the top of each condenser, an atmospheric exhaust pipe. When first installed these condensers gave trouble at starting, because of water backing up in the cone chamber and flooding back into the turbine exhaust pipe. The cones were removed and bored out from 6½ to 7½ inches in diameter, which increased the opening in them 40 per cent. A piece of 48-inch pipe, the size of the exhaust pipe leading from the turbines, 6 feet 6 inches long, was inserted between the top head of the condenser and the main riser pipe. A similar length of pipe was also inserted in each of the pipes leading from the head to the nozzles. These changes eliminated the trouble as the water must now lift 11 feet before it can overflow into the exhaust pipe. Fig. 4 shows the former and present arrangement of the condensers. The cooling water is controlled by three valves in the supply pipes which are located in the turbine room.

Piping

The steam pipe leading to each turbine is 12 inches in diameter, and branches from a 20-inch main leading from the boiler room. All steam pipes are placed in the basement under the turbine room, the 20-inch main rising to a level with the top of the boilers after it has passed to a point under the pump-room floor. Owing to the large exposed surface of the exhaust pipe of each turbine, considerable condensation takes place at light loads of 1500 kilowatts or under, and in order to keep these exhaust pipes free of water a Strong vacuum trap is used on one and a receiving tank and duplex steam pump on the other. Fig. 6 is a cross-sectional view of the turbine room and also shows the arrangement of the condensers.

Exciters

On the switchboard platform there are two motor-driven exciter sets of General Electric make and on the ground floor is a turbine-driven set which is used as an emergency unit. There is also a motor-driven direct-current generator which supplies current at 250 volts to the motors operating the coal-hoisting and conveying machinery.

The switchboard is of slate and contains the necessary apparatus to control the electrically operated oil switches, which are placed on the turbine floor directly beneath the switchboard. The feeder cables drop from the switches to iron-pipe conduits, suspended from the ceiling of the basement, and are carried to the various points of distribution through iron-pipe conduits set in concrete piers. These iron conduits, after they leave the cement piers, are encased in concrete work, which extends from the power plant to the nearest factory building.

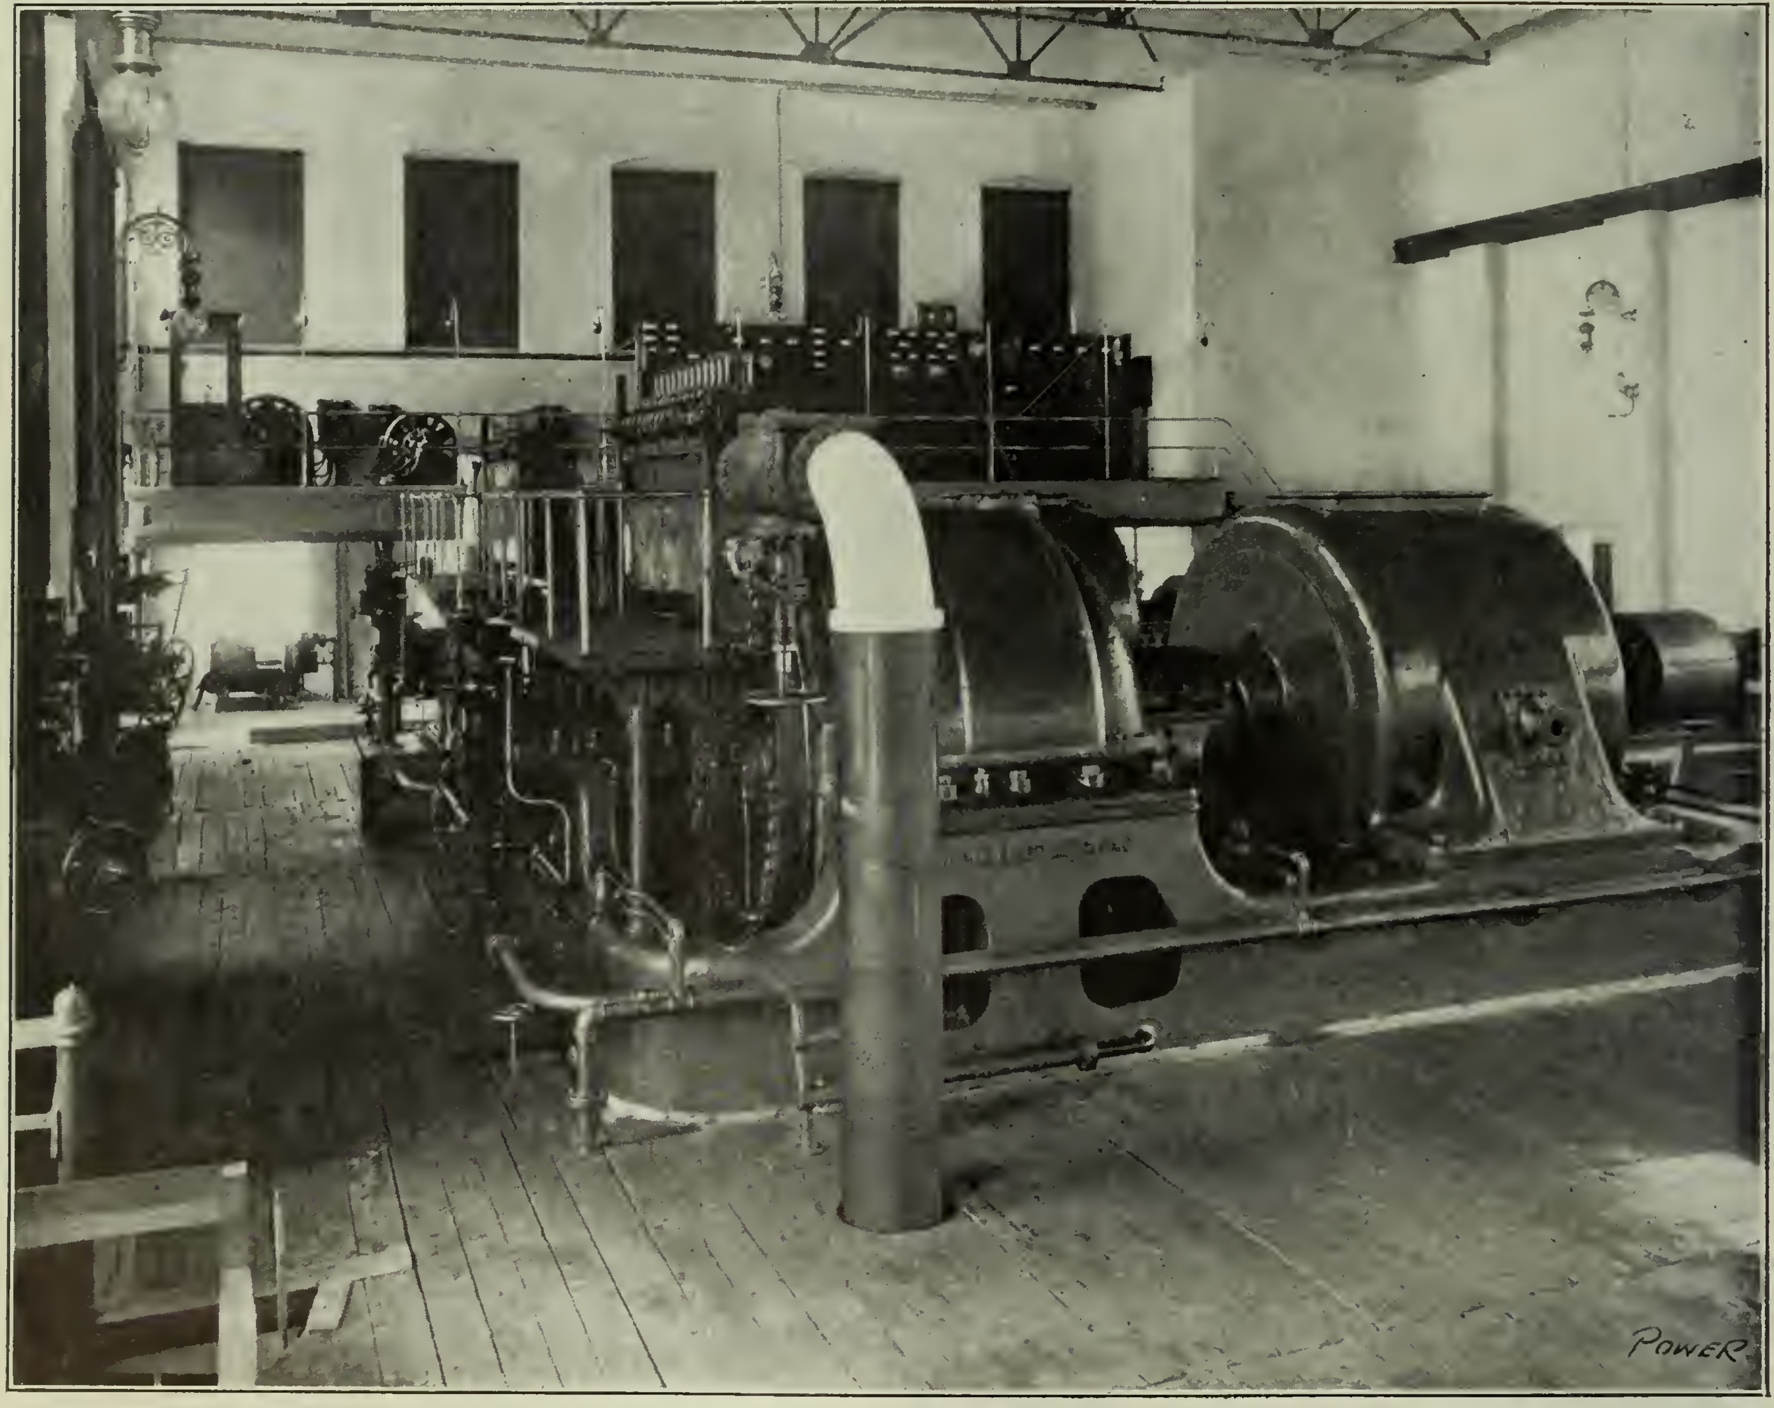

Fig. 3. View of the Two 3500-kilowatt Horizontal Curtis Turbines. The Permanent Floor Has Not Yet Been Laid

Boiler Room

The boiler room is worth going some distance to see, for it is not often that one can view 64 boilers set in a single row in a boiler room 500 feet long. These Manning boilers are each of 300 horsepower capacity, or a total of 19,200 horsepower. They are set in four batteries of 16 boilers and each battery is connected to a separate smoke flue. Figs. 1 and 2 show the cleaning and stoker sides of the boilers.

Beginning at either end of the boiler room, the brick-lined smoke flue extends the length of the first battery of 10 boilers and at a hight that will permit the smoke connection from each boiler to be made above the center line of the flue. The flue from each end battery then rises to permit the flue from each middle battery to form the lower half of a double smoke flue, which carries the gases to the stack, located outside and midway of the building. The smoke flue from each boiler is provided with a damper which is kept open while that boiler is in operation.

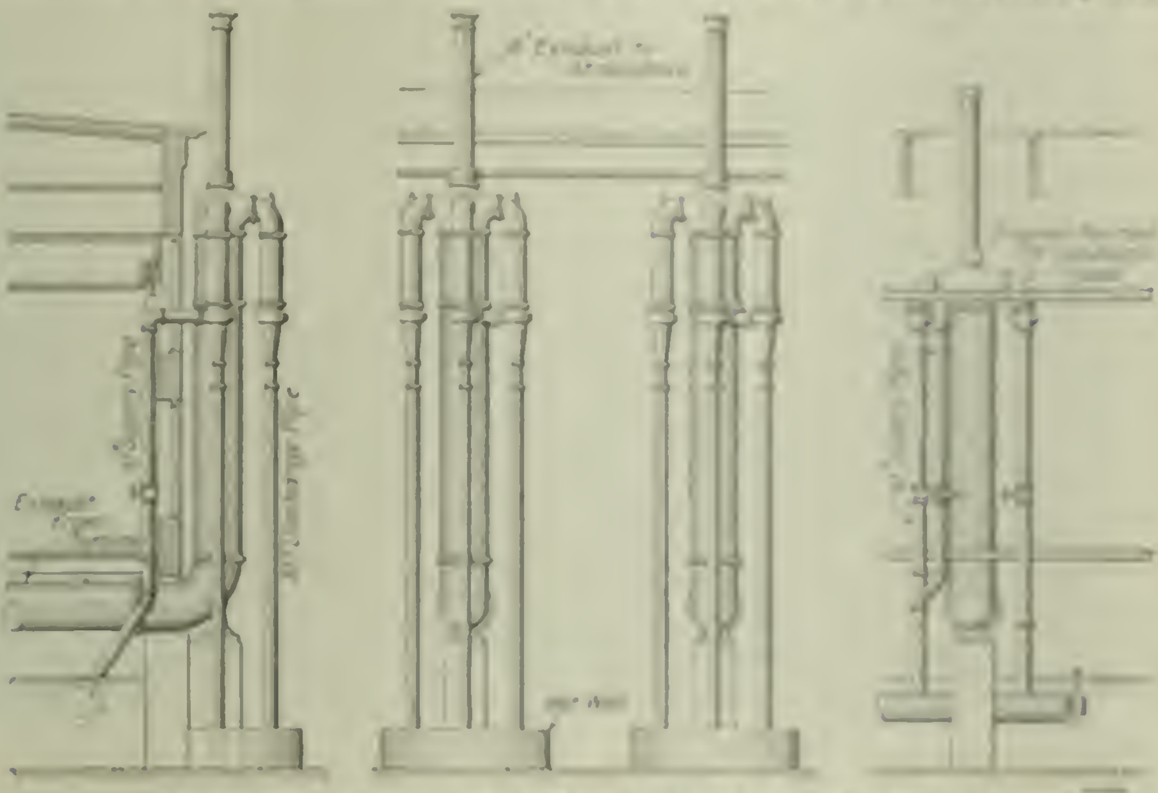

Fig. 4. Showing How the Condenser Head Was Altered

Forced Draft

Forced draft is used, and each battery of boilers is supplied with air by an 8-foot 8-inch fan blower driven by an 8x10-inch Sturtevant engine. The air is driven through a duct to the main air duct that extends the entire length of the battery which the blower is serving. A branch duct conveys the air to each boiler. The air is controlled by a swinging damper, one for each boiler, which is regulated by a hand lever attached to an extension rod and placed convenient for the fireman to operate.

The steam pipe of the blower engine is fitted with a Foster reducing valve to control the speed of the engine, shutting off the steam as the pressure in the boilers increases and admitting the steam as the pressure decreases. With this means,

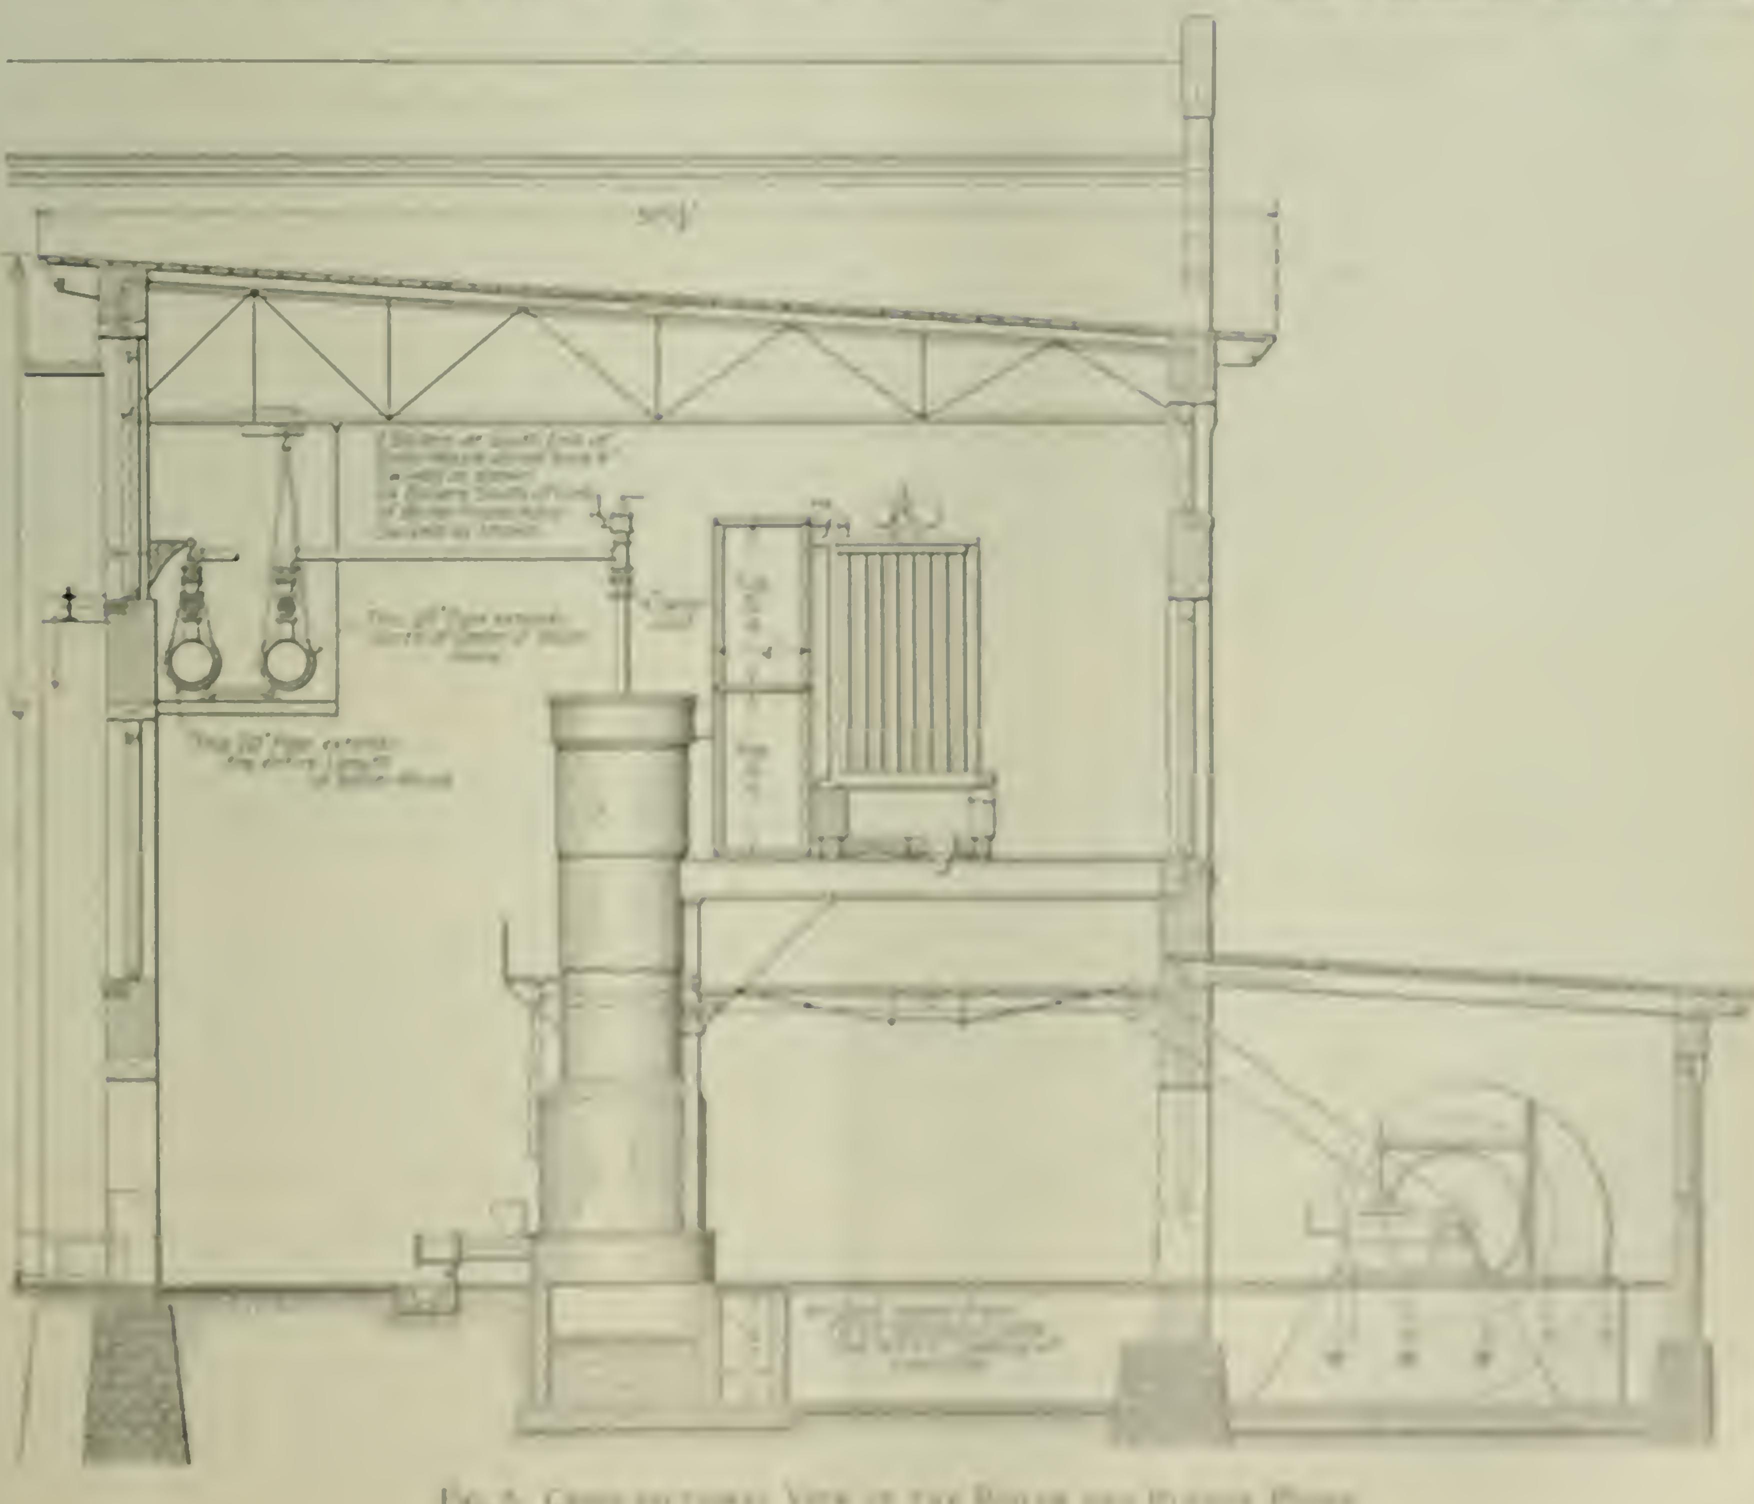

Fig. 5. Cross-sectional View of the Boiler and Blower Room

of draft regulation, the variation in steam pressure is between three and four pounds.

Stokers

The apparatus controlling the steam valves that admit steam to the cylinders of the Jones stokers for each battery of boilers, is driven from a cam shaft by means of sprocket wheels and a chain belt. As the speed of the fan decreases the speed of the stoker apparatus is decreased; when the pressure drops the speed of fan and stoker increase. With the blower engine running at full speed the stokers feed once per minute, but with a slow-speed and high-steam pressure the stokers feed but once in four minutes. Usually the stokers do not feed at all during the period that the blower engine is running at reduced speed.

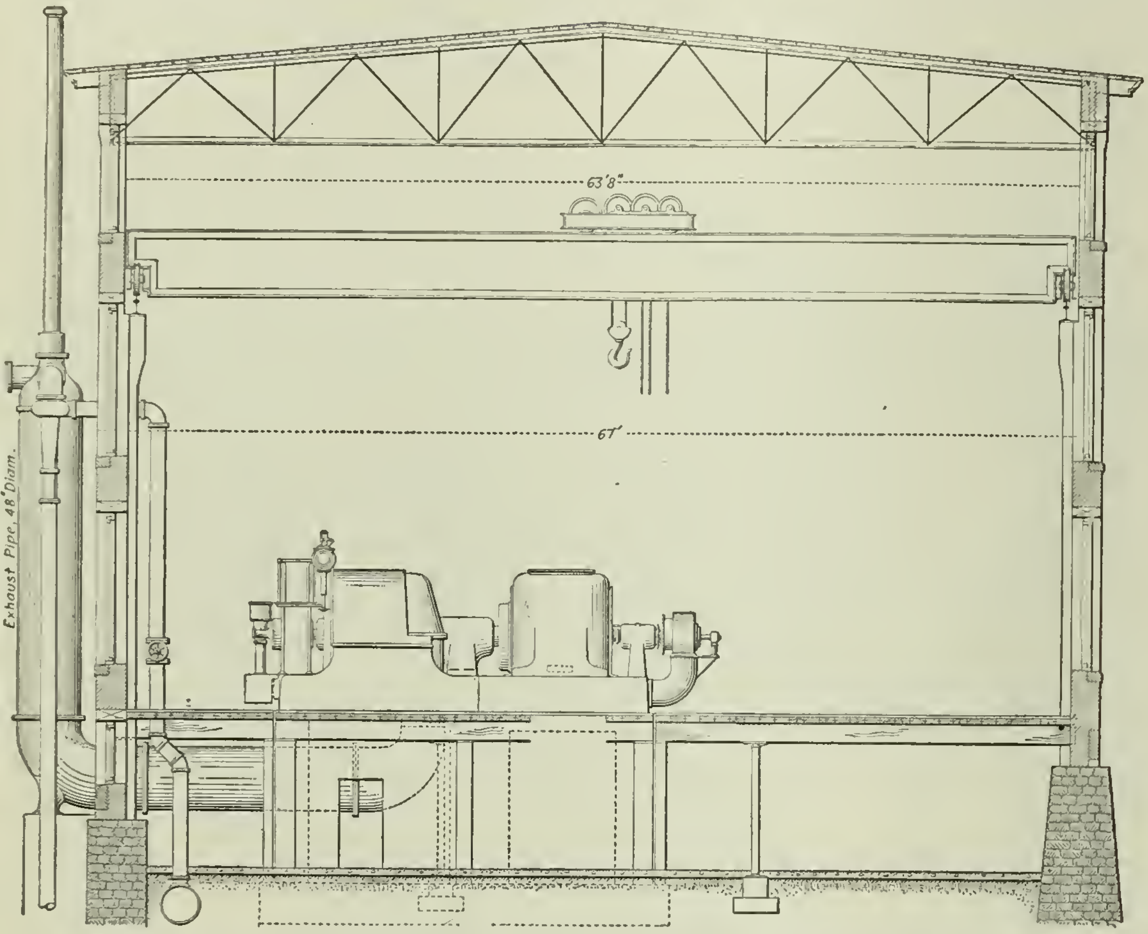

Fig. 6. Sectional Elevation of the Turbine Room

A Jones stoker is fitted to one side of each boiler furnace; the other side of the furnace is fitted with a cleaning door through which the fires are cleaned and kept in proper shape. One man handles six stokers, the work being that of keeping the hoppers filled with coal. One man cares for four fires on the cleaning side and one man wheels coal for eight boilers. When the entire boiler room is in operation, one man will be required per boiler, which includes the hopper man, the day and night boiler-room attendants and coal passers. A passage way has been left between each set of eight boilers, making it convenient for the men to pass from one side to the other without walking the length of sixteen boilers to do so. The boiler room has a concrete floor sloping toward the side wall so that after cleaning fires the fine ash and dirt can be washed to a trench next to the wall and out through a drain pipe into the river. Fig. 7 shows a plan and elevation of the boiler room. Fig. 5 represents a cross-sectional view of the boiler and blower rooms.

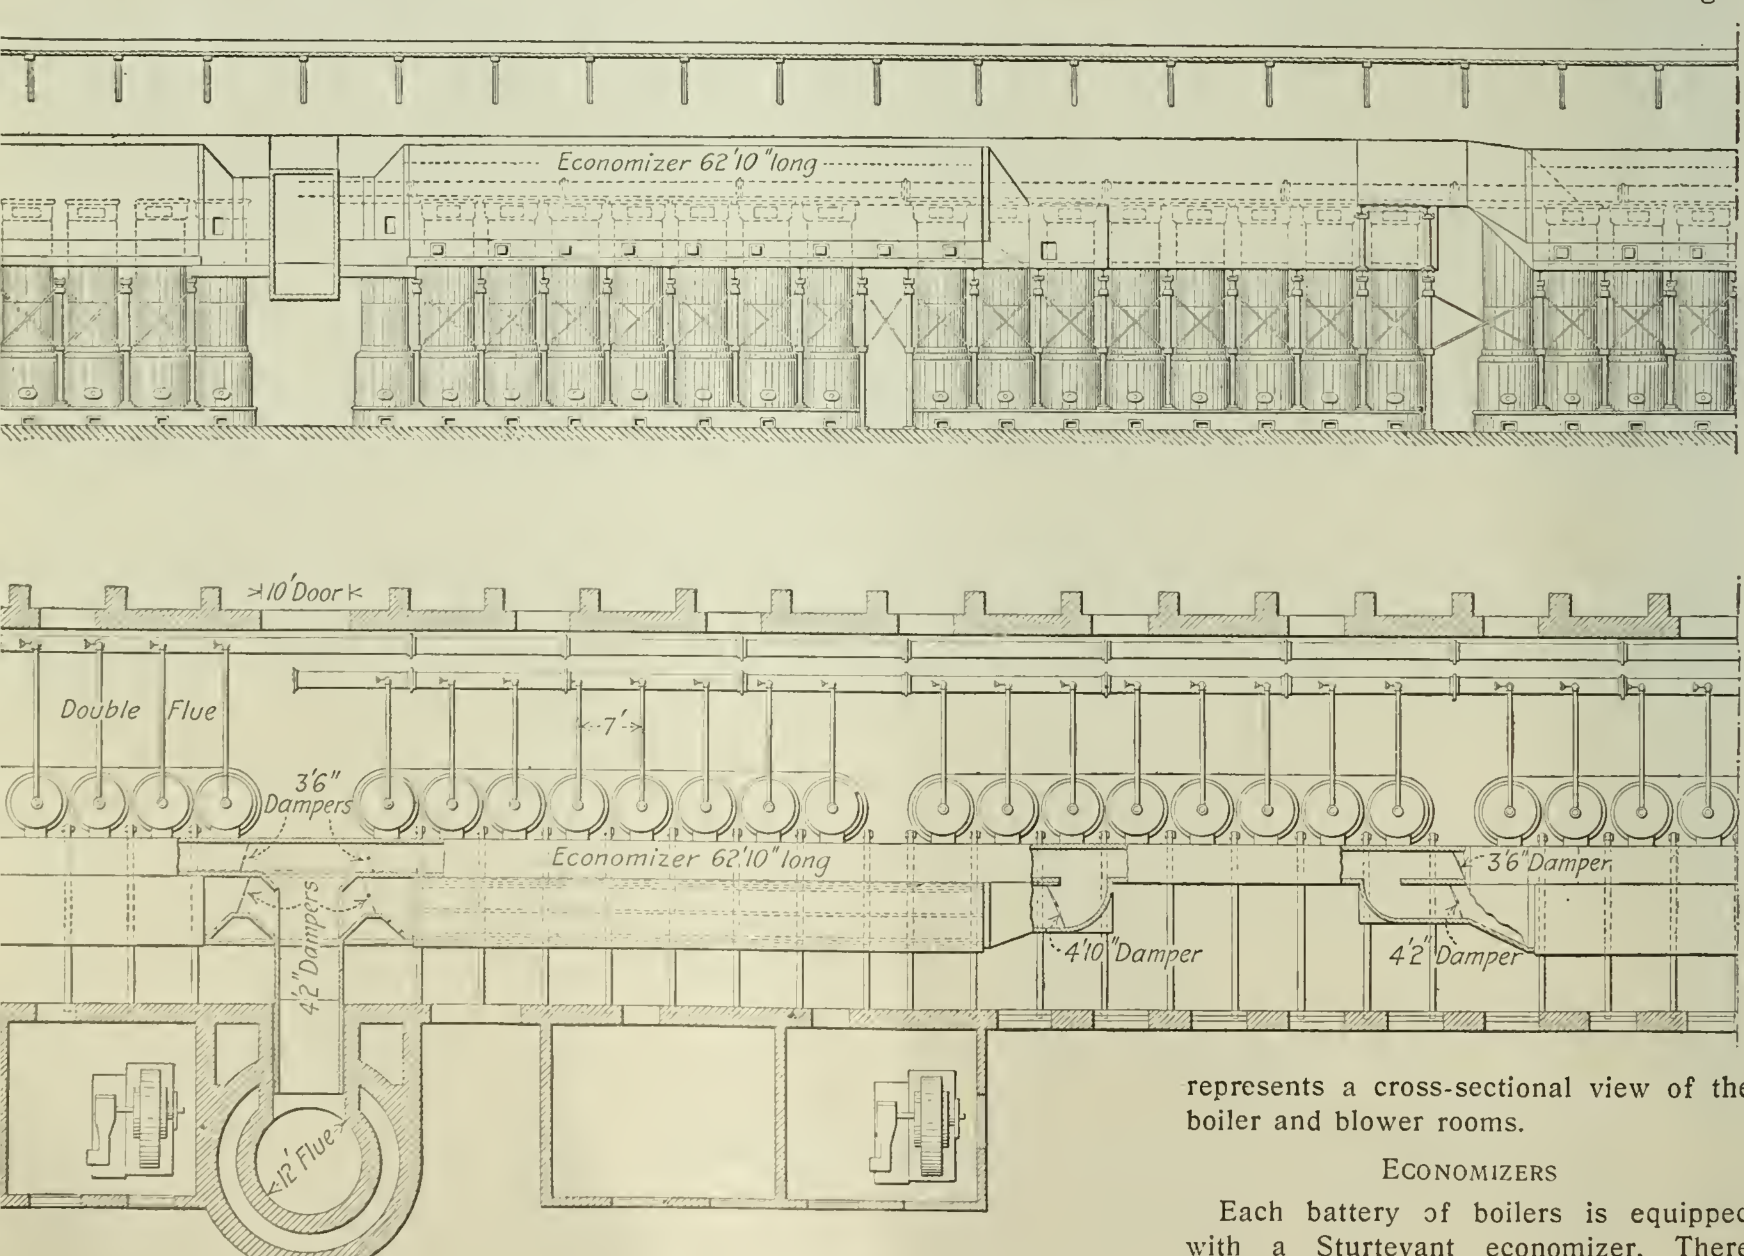

Fig. 7. Plan View and Elevation of Left Half of Boiler Room.

Economizers

Each battery of boilers is equipped with a Sturtevant economizer. There are four in all and the scrapers are driven by one motor from a shaft attached to the side wall of the boiler room. These economizers can be cut out from the main smoke flue by means of suitable dampers, and the water passing through the tubes can be bypassed direct to the boilers, entering them at the temperature obtained in passing through the feed-water heater; this is about 130 degrees, and passing the water through the economizer raises its temperature 70 degrees.

Fig. 8. Partial View of the Pump Room

Pump Room

In the pump room, which is located between the boiler and turbine rooms, and illustrated in Fig. 8, are two Worthington 14, 20 and 12 by 15-inch duplex boiler-feed pumps, pumping against a pressure equal to 190 pounds. There is also one 12 and 7½ by 10-inch duplex pump, which is used when but few boilers are under steam. The exhaust from these pumps and the blower engines go through a Reilly multicoil feed-water heater and then through an open heater. The feed water passes through the heaters in a direction opposite to the flow of the steam, so that the hottest water receives the heat from the hottest steam.

Boiler-room Piping

All overhead pipes throughout the boiler and the pump rooms are suspended from wall brackets by means of chains and hook bolts, as shown in Fig. 7. In some instances two pipes are suspended from the same bracket by means of an extension piece, as shown in Fig. 8. This method of pipe suspension is very flexible, as the hook bolt can be adjusted so that a pipe may have any desired pitch. It also allows the free movement of the pipe when under expansion or contraction stresses. The two main steam pipes expand 1 foot in their 300 feet of length. Both are anchored about 30 feet from the end next to the turbines and the expansion is all toward the other end. In order to overcome undue stresses in the pipes leading from the boilers to the main steam pipes, swivel joints are used on all of the boiler connections with the exception of the first nine boilers nearest to the pipe anchor. The swivel joints consist of a sleeve having a flange the size of the pipe connection at one end and a smaller flange at the other. Over this flange a two-piece gland is fitted, and this is followed by a collar. Square packing of suitable make is placed between the split gland and the ring washer which fits over the smaller gland on the sleeve. One section is secured by means of flange bolts to the outlet pipe of the boiler, the large flange of the sleeve is secured to the pipe leading to the main by means

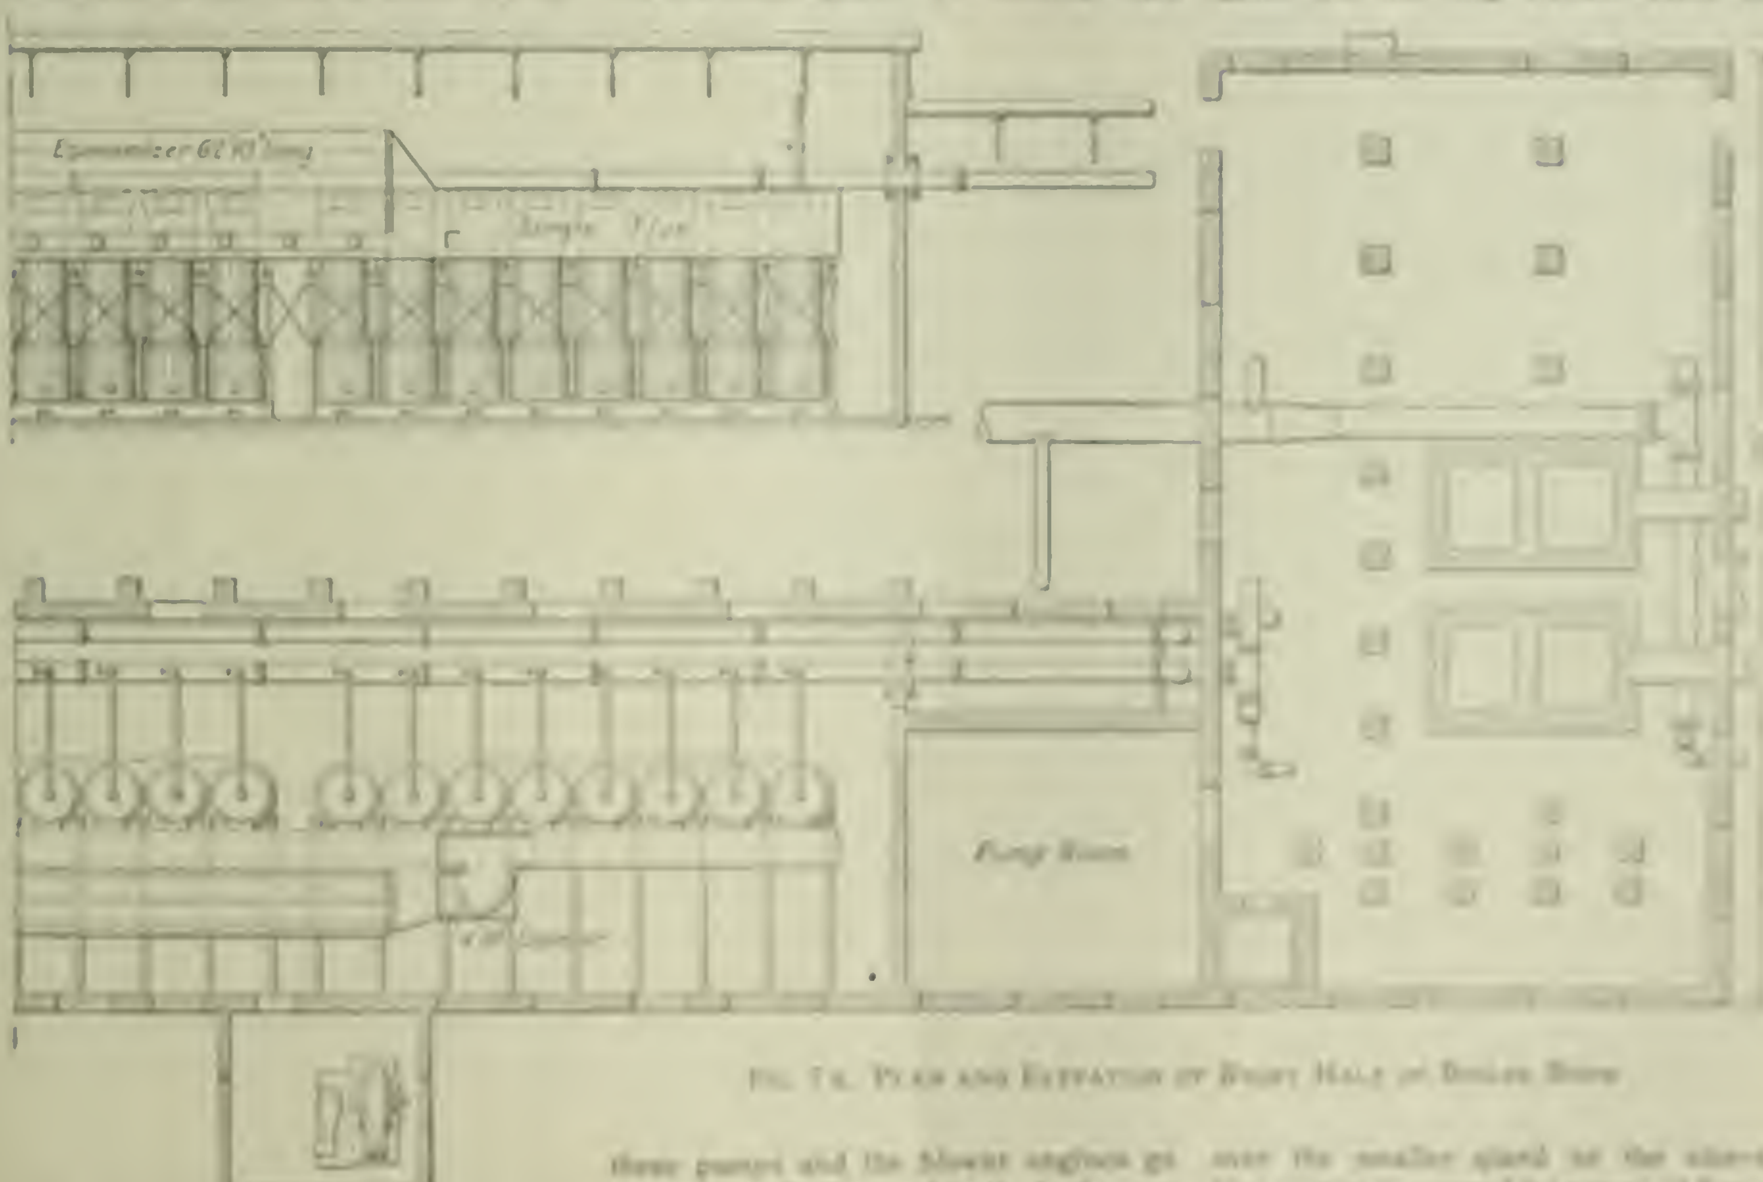

Fig. 7a. Plan and Elevation of Right Half of Boiler Room

of bolts, while the two-piece gland and washer is secured to the upper gland. This allows the pipe and sleeve to turn in either direction. The first set of thirty-two boilers is connected to one steam main and the second set is connected to the other steam main. In order to permit steam to be used in either main in case of accident, the first eight of the second set of thirty-two boilers are connected to both steam mains, the upright pipes of each boiler being fitted with two of these expansion joints. This allows the top pipes to turn in one direction in case the main is cold, and the lower pipes to turn in the other direction when the other main is hot.

The feed pipes are divided into four sections, one for each battery of boilers, and are placed on brackets on the rear side of the boilers; the live steam and exhaust pipes from the stokers are also suspended from these same brackets. The live and exhaust steam pipes from the blower engines are suspended from brackets running along the outside wall of the boiler room. At a convenient point on the stoking side of the boilers, an iron walkway is provided for the water tender. Hand regulation of the feed water is maintained.

Handling the Coal

One idea in having the boiler room of such length was to make it convenient for handling the coal from the storage bins to the boilers. These storage bins have a capacity of 16,000 tons. The coal is brought to the plant by rail and is unloaded to the bins by means of a clam-shell bucket, which is operated from a traveling coal conveyer. This runs on a track, one rail of which is supported by concrete piers and the other rail by the brick piers, forming a part of the boiler-room wall. This bucket is capable of handling one ton of coal each lift and besides being used for the unloading from the cars to the coal pile it is also used to convey coal from the outside edge of the pile close to the boiler-room doors in case the coal supply becomes low. All the coal consumed in this plant is wheeled in coal cars, each having a capacity of 500 pounds. The ash is also handled in the same manner.

Stack

Midway of the building and on the outside, is a 200-foot brick stack which has a 12-foot flue. Owing to the forced draft, considerable fine coke and ash is carried to the base of the stack through the smoke flues, it being too heavy to go out at the top. It is necessary to remove this about three times a week, the total amount of accumulation being about 15 cubic yards per week. A rather unique idea has been worked out for removing this ash. An 8-inch pipe is built into the base of the chimney, extending level with the concave bottom. In this pipe a small ¾-inch air pipe is inserted with a U-bend on the inner end. When it is necessary to remove the accumulation of fine coke and ash, air is turned on this small pipe at a pressure of 100 pounds per square inch. The air passes to the U-bend, where its direction of travel is reversed, and as the air escapes from the end of the pipe, a partial vacuum is formed, which draws the accumulation to the base of the stack and discharges it through the outlet of the large pipe into the river. This eliminates the necessity of handling the fine ash deposits by means of manual labor.

This power plant was designed by and erected under the supervision of Capt. Charles H. Manning, mechanical engineer of the Amoskeag company, from which the foregoing data and accompanying illustrations were obtained.

Engine Room Mismanagement

By Hubert E. Collins

Several instances in which outside help had to be called in to solve difficulties which could have been overcome by the exercise of common sense on the part of the engineer.

In a certain hospital in New York City the operating conditions were very bad. Investigation showed that all high-pressure drips led through leaky traps into the sewer. About half these traps were not working at all and the steam was bypassed direct into the sewer. The cylinder and steam-chest drips on each of the engines were connected together and led to a leaky trap. One of these engines was operated continuously and the other two were operated during the winter from four to six hours each evening. The engineer in charge operated the engines with these drips wide open all the time. The steam from the steam chest leaked into the cylinder drips and alternately from end to end of the cylinder. The engineer claimed that it was necessary to operate with the drips open, as water sometimes came over from the boilers. It was true that the boilers were dirty and foamed at times, but he ran more chance of wrecking his engine by leaving all the drips open while running, connected as they were, than by closing them. Upon examination the boilers were found to be coated with scale from $\frac{1}{32}$ to ⅛ inch thick.

The exhausts from two feed pumps and one large house pump, in continuous operation, were piped to the atmosphere, and the hot-water supply was heated by live steam. The low-pressure drips were trapped and led with the returns from the house-heating system into an open heater, from which the water was drawn to feed the boilers. The fact that the hospital was free from water tax gave the engineer the impression that it did not matter how much water was used. But all water in the building was taken from the large house tanks on the roof, to which it was first pumped by the house pump. The low-pressure drips which entered the open heater with the heating returns were found to be bypassed by the traps and created enough pressure in the heater to cause all the water to siphon out into the sewer; consequently the cold water from the mains poured into the heater almost continuously, to supply the makeup to the boilers. This necessitated burning more coal in order to get up steam; but the worst feature of the arrangement was that the house pump had to be in continuous operation to keep the tanks full, and at times this pump could not supply all the water needed.

The passenger elevator was in bad condition, having poor contacts in the controlling box and on the magnets; the counterweight cables were too long and some contact springs were broken. Also, the freight elevator was shut down because many of the push buttons were out of order.

The fire service, which is so important in a hospital, was not in operation at all. The standpipes had no water in them, as the valves connecting them to the house tanks were closed. The hose had never been tested, the porters had never been drilled for fire service, and when the fire gongs were tried the wiring was so defective that they would not ring.

The engineer had been in charge of the plant for four years, having taken charge when it was new, and had not inquired into a single feature of operation tending toward its betterment. When anything broke down he was accustomed to send for outside help, and had allowed the plant to become a menace to the safety of the occupants of the building.

The board of directors finally called in outside aid, and when these defects were pointed out to the engineer he declared they could not be helped, and that he was operating as well as anyone could under the circumstances.

The first changes that were made were to stop all leaks past traps and to connect all pump exhausts to the heating coils in the hot-water tanks. This saved the use of live steam for heating water, and, by saving all of the drip returns from the heating system, it cut off entirely the use of cold water for boiler feed, while at the same time, the house pump was not required to operate more than one-third the time.

All these changes to effect economy and give uninterrupted service on the elevator and lighting service required about two months, but in the first month the coal bill was cut from $710 to $590 on the same output, and during the second month so much saving in steam consumption had been effected that only one boiler was required, whereas two had formerly been in constant service. This boiler steamed so easily after having been overhauled that a low grade of coal was used, with the result that the second month's bill was $280; at which figure it kept during all the winter months.

A Lack of Ordinary Judgment

An instance where the man in charge did not use ordinary judgment in locating a simple cause of trouble is shown in the following.

At a certain summer resort a hotel stands on piling out over the bay. The lighting is furnished by a small isolated plant located in a separate building, and the equipment consists of a locomotive boiler, a small high-speed engine and a dynamo. The engine has combined relief and drip valves, with a star wheel having a rising stem. When the stem extended through the wheel, the operator knew that the drips were open, and when the wheel was loose on the stem he could tell that they were closed.

The drips from the cylinder led through these valves and in this instance were piped together into a tee, as shown in Fig. 1. From the tee the drips led outside the building and discharged into the bay. The water supply to the hotel and the feed water for the boiler were taken from one tank.

The complaint was made that the engine ran badly, that the exhaust made so much noise as to annoy guests and cause them to leave; furthermore, that the engine used so much steam that it had to be shut down by 9 or 10 o'clock in the evening, leaving the place in darkness as the hotel was not piped for gas.

An expert was called in and discovered the cause of the trouble immediately upon entering the engine room. It all lay in the engineer's misconception of how the drip valves looked when open. When the expert looked at the engine he casually remarked that the drips were open, as was not unusual, for the engine was standing idle. The engineer said that they were all right, as he had set them that way when he first took the job and they had remained so all the time.

Questioning confirmed the fact that the engine had been running with the drips wide open all the time. The cylinder was 7 inches in diameter, with 1/2-inch drips, which were wide open for steam to flow from end to end of the cylinder, the surplus exhausting in a steady roar

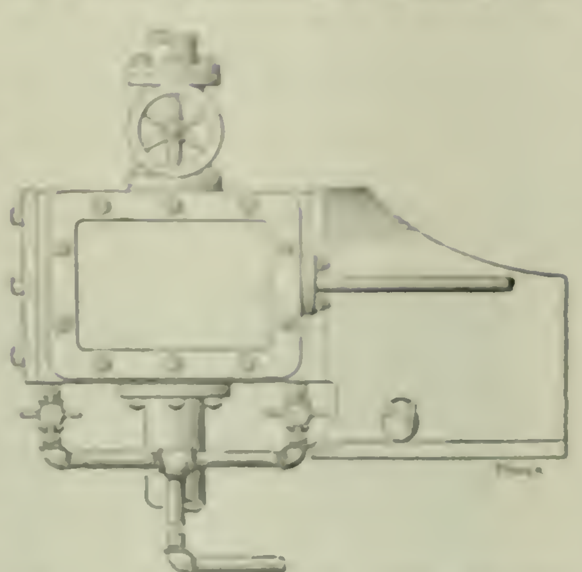

Fig. 1. Showing Drip Pipes Together

out of the drip line. Here was the cause of all the trouble and the engineer did not understand enough about running an engine to know that steam should not come in a steady stream from the drip pipe from the cylinder.

Trouble Could Have Been Prevented

Another instance where a little observation and thought would have prevented trouble is shown in the following incident. The engine in a factory plant was giving trouble and the engineer, acknowledging himself to be at a loss to account for the cause of the difficulty, allowed the proprietor to send for outside aid. When the expert arrived, he was told that the engine not only would not govern, but used so much steam that the boiler could not keep up the required pressure to run longer than half an hour at a time. The engine had been shut down for two weeks' repairs and after being started behaved in this way. The cylinder and valves on this engine are illustrated in Fig. 2, which shows the steam and exhaust valve on the crank end, the head-end valves being cut away to show the steam passages.

The engine was started to observe its action and the first thing noticed was that steam was steadily blowing through somewhere. The trouble was located at once on the crank end of the cylinder. After shutting down, the steam-chest cover on the crank end was taken off, and while turning the engine one complete revolution, it was observed that the steam valve did not seat by 1/8 inch at any time. The steam was blowing through on that end all the time, but why this valve should not seat was puzzling, for the stems appeared, as shown in Fig. 3, with the lower end turned to a small shoulder. This small end enters the yoke up to this shoulder and is secured in place by a set screw, as can be seen in Fig. 2.

The valve stem in this instance was apparently down on this shoulder and the valve should have seated.

When the valve and stem were taken out, the cause of the trouble was apparent. The valve stem had worn small in the packing box; to remedy it, it had been turned off up to the [illegible] the size of the small end of the stem, and a bushing had been put over the stem, making it the original size, with the lower end of the bushing forming the shoulder in fitting up on the valve yoke. It was assumed that at some time the valve stem

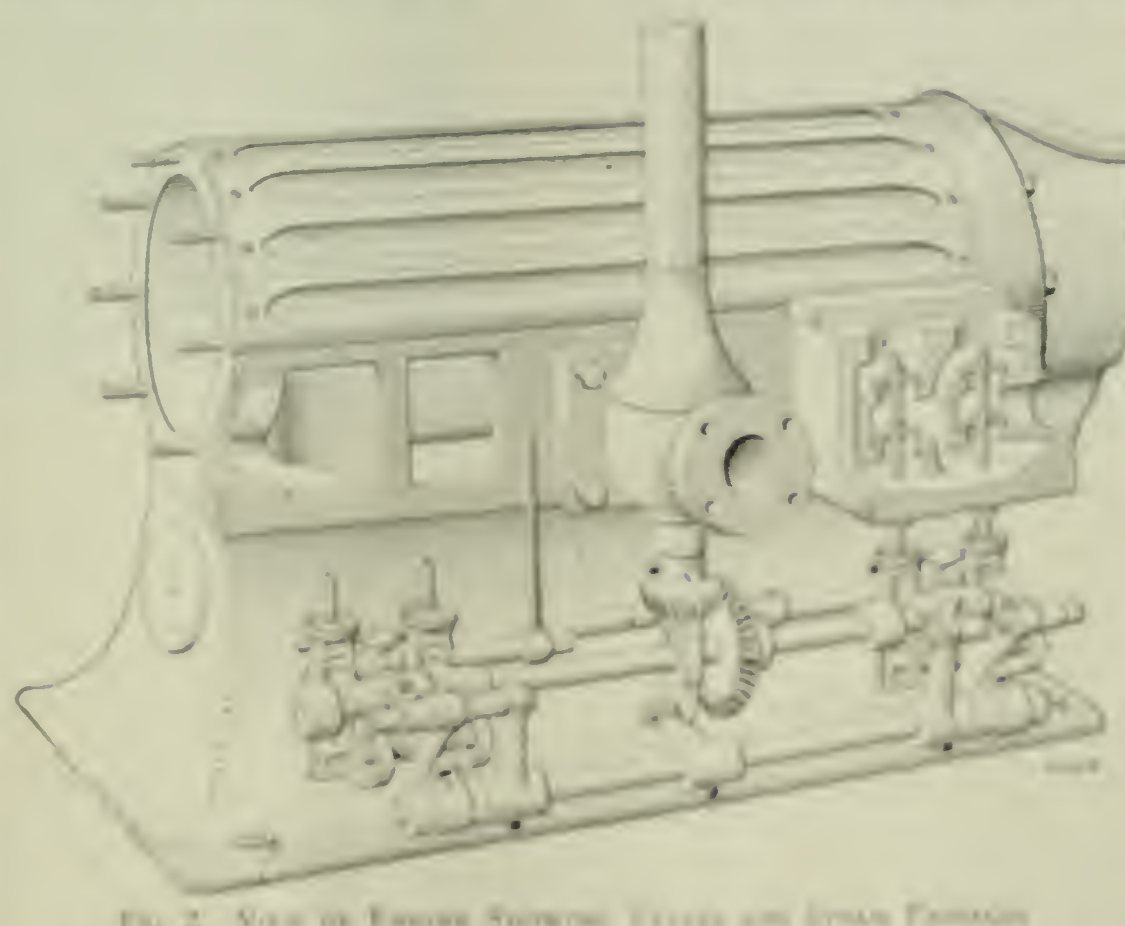

Fig. 2. View of Engine Showing Valves and Steam Passages

had become loose in the yoke and slipped up through the bushing until it was flush with the end of the valve stem, so that whoever took it out thought the small end was broken off, not noting the gap on the stem between the bushing and disk.

At any rate, the bushing on the stem had slipped down to the end of the old stem and a hole had been drilled and tapped into this, with a stud screwed into it, making the whole stem length longer by as much as the bushing had slipped down, in this instance ⅝ inch. This is shown by Fig. 4, where *A* is the gap between the bushing and disk on the stem. The amount added to the length is apparent. The stem had been put back with this added length which did not allow the valve to seat.

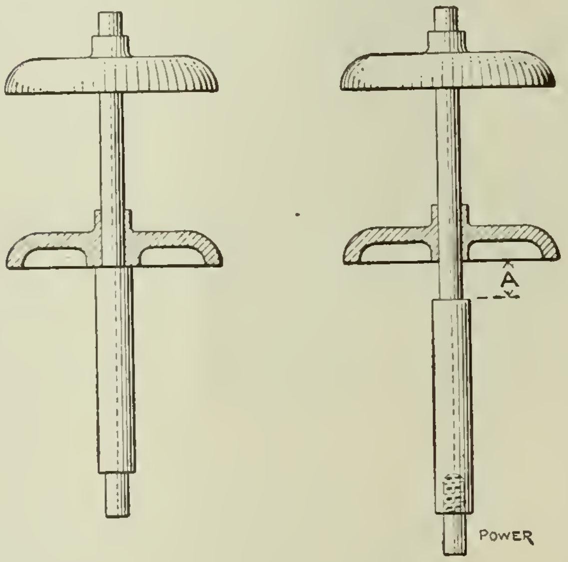
A striking feature of it all was that the valve stem was of steel and the bushing of brass; so that it attracted the expert's attention to the trouble at once. Neither the machinist nor the engineer had noted this, but had deliberately gone ahead and added to the length of stem and thus caused the trouble.

Pump Cylinders Out of Line

In a department store there is a large three-cylinder compound steam pump, the valves of which had been reset after a complete overhauling by an outside firm. The pump would have been accepted if the diagrams had not shown that with 120 pounds initial pressure in the high-pressure cylinder there was from 36 to 41 pounds back pressure in the high- and only 29 pounds initial pressure in the two low-pressure cylinders. This showed too much back pressure in the high-pressure cylinder and too great a loss in the receiver. The cutoff in the high-pressure cylinder was about 60 per cent. of the stroke, and this was changed to about 45 per cent. of the stroke, with the result that the receiver pressure was brought down to 30 or 31 pounds and the initial pressure in the two low-pressure cylinders remained at 29 pounds. This economized in the use of steam and by reducing the back pressure in the high-pressure cylinder, the same amount of mean effective pressure was obtained with less steam and the two low-presusre cylinders received enough steam to do their work. It proved that before the change was made there was too great a volume of steam admitted to the receiver for the low-pressure cylinders to take care of. After this slight change in valve setting, the work was accepted.

This pump has three steam and water cylinders, side by side, and the center line of the steam cylinder and guides is also the center line of the pump cylinder.

When the pump was first stripped for repairs, the repairmen were told to run lines through the cylinders and report if they were out of line. They reported to the chief engineer that the water ends were from $\frac{3}{16}$ to ½ inch low and would need raising. This would have necessitated the breaking of eight large joints on the water end, the use of tackle and jacks to raise the water cylinders and the resetting of the frames on the foundations, which meant an indefinite shutdown and the expenditure of several hundred dollars. They were ready to proceed with the work when the chief called on the outside man to go over the lines and verify the supposed conditions. This is what was found: In the first place, the lines of twisted cord, about 3/16 inch in diameter, had been put through the cylinders. These lines were too heavy for such work and one end was fastened outside the open end of the steam cylinder and, passing through the stuffing box, guides and water cylinder, was fastened outside the latter in such a manner that the line could not be stretched very taut.



Figs. 3 and 4. Valve Spindle Before and After Being Altered

Even with the most rigid attachment, this line could not have been stretched enough to prevent a serious sag. This attracted the attention of the investigator at once and, after observing the conditions, he took the calipers and proceeded to find the truth of the setting. He found the line set true in the steam-cylinder counterbore and in the stuffing box of the same cylinder, but along the guides and in the water cylinder the line was high, or the guide and water cylinder were low, getting worse toward the end of the latter. Each of the three water cylinders were low, according to the setting of these lines, but the investigator contended that there was a sag in the lines so that in order to set the line true at the steam-cylinder end the opposite end would have to be raised, and the water cylinders were low in varying degrees, according to the tautness of the individual lines.

He had these lines taken down and new, fine lines of woven sea grass substituted. Then they were stretched taut and set true at the steam end, after which it was found that all three of the guides and two water cylinders were in line with the steam cylinders, and one water cylinder was 1/16 inch low. This cylinder was lined up by shimming. The job took only two days, as against the weeks of work that it would have taken to make the other cylinders so much out of line that the pump could not have run, in the first place, and the work would have had to be gone over again before it was right.

High Gas Velocity in Boilers

Of late much attention has been directed to the increased heat-transmitting power of boiler plates by making the hot gases travel at a high velocity. C. E. Stromeyer, chief engineer of the Manchester Steam Users' Association, has the following to say on the subject: High velocity means that the resistance in narrow and restricted passages is so much increased that it exceeds the resistance in the bed of fuel, and has to be seriously taken into account, and the question arises whether the extra cost for producing this necessarily powerful draft is balanced by the advantage of being able to use a small boiler. The question is perhaps deserving of attention by marine engineers, but with them the tendency is at present toward water-tube boilers, which, as is well known, offer very little resistance to the flow of gases. In any case trouble is almost certain to arise if the principle is carried to excess, for the effects associated with what may reasonably be called a blowpipe flame acting on a very small surface is that this surface tends to warp itself on account of very great differences of temperature on either side. If the water is sedimentary all the scale will be deposited locally and result in overheating, and in addition there will be difficulty in providing locally the necessary supply of water, without which, of course, no evaporation takes place, and overheating and bulging result. The locomotive boiler, the Lancashire multitubular and, in fact, most smoke-tube boilers, do cause the gases to move quickly, but further reductions of the tube section can only be made if artificial draft is resorted to, and artificial draft, although it is likely to be efficient in ordinary cases, where the natural draft is inefficient, does sometimes aggravate the evils which it is called in to remedy. The Admiralty had no end of trouble with leakages of the tube plates of its Scotch boilers because of the intense heat transmission at these parts.

Artificial draft has to be paid for in steam consumption, and when certain limits are reached no further gain is possible. In a recent case it was found that in spite of using 25 per cent. of the steam generated for jets, they added less than 20 per cent. to the steaming power of the boiler, which was therefore being more heavily worked than before, and yet supplying less steam.

Automatic Shaking Grates

By A. R. Maujer

Boiler grates originally designed to be shaken by hand were fitted with automatic shaking mechanism which resulted in improved operating conditions and economy.

With hand-fired furnaces and shaking grates a very common trouble is that the fires receive first a feast and then a famine of shaking, so to speak. Even though the fireman has had plenty of experience, he will neglect to shake the grates as long as he dares, in order to avoid as much work as possible and because it is slightly easier, probably, to operate the fires. As a consequence, the fires get dirty, the draft poor and the combustion becomes proportionately bad. When the grates finally are shaken, the fires are so broken up and the fuel bed so thinned that the temperature drops abnormally when green fuel is added.

FIG. 1. MECHANISM FOR AUTOMATICALLY SHAKING THE GRATES

To eliminate this variable element in the operation of the fires, George Schautz, consulting engineer for the Jacob Dold Packing Company, at Buffalo, N. Y., has designed and installed in the Buffalo plant of this company an automatic shaking mechanism, using the same grates that were installed with the boilers.

As happens in the power plant of practically every growing industrial concern, a time came when the boilers as well as the engines and other apparatus were so heavily overloaded that extension became imperatively necessary. The original boiler equipment consisted of ten return-tube boilers, each rated at 100 horsepower. The boiler room was so located between other buildings that no additional floor area was available unless some other location was selected and an entirely new boiler house erected.

The original amount of head room in the boiler house was only 21 feet. By increasing this to 34 feet it was possible to install water-tube boilers in the place of the old fire-tube boilers and, without increasing the floor space occupied, secure a great increase in boiler capacity.

The first change to be made was the removal of five of the 100-horsepower fire-tube boilers and the installation in their stead of four Fitzgibbons boilers, each of 275 horsepower capacity. Later, the five remaining fire-tube boilers were replaced by four Keeler water-tube boilers of a combined rated capacity of 2140 horsepower. Both the Fitzgibbons and the Keeler boilers were fitted with Ajax shaking grates for burning run-of-mine bituminous coal which comes from the Shawmut, Penn., district.

After the new installation had been in operation for a few months, Mr. Schautz decided that conditions in the boiler room could be improved if some means were found to obviate the irregularity which the shaking of the grates by hand produced. After some study and considerable experimenting, the arrangement shown in the accompanying figures for automatically shaking the grates was installed in connection with the Keeler boilers. Later, it was extended to operate the grates under the Fitzgibbons boilers also.

The chief difficulty was to secure a low enough rate of rotation for the eccentric shaft. This was finally overcome in the manner shown. A small high-speed engine was mounted in the alley between two batteries of boilers. A small sprocket on the engine shaft drives a lay shaft by means of a chain and large sprocket on the latter. A small sprocket on the

FIG. 2. MECHANICAL DETAILS OF SHAKING MECHANISM

lay shaft drives the chain which runs over the large wheel keyed to the eccentric shaft. In this manner the speed of the eccentric shaft is reduced to about two revolutions per minute.

The system has the greatest flexibility. Fig. 2 serves to illustrate the manner in which this flexibility is secured. The tappets *A* and *B* can be adjusted so as to give the grate either slight or considerable motion as may be desired; or, the eccentric rod may be completely disconnected when it is desired to shake the grates by hand or so allow them to remain entirely undisturbed for a period of time.

This automatic shaking arrangement has given complete satisfaction. It makes the firemen's work easier; the fires are maintained in a more even condition, and an appreciable gain in economy has been effected. The fires are carried at a uniform thickness of about 6 inches. The quantity of smoke emitted from the stack has been greatly reduced.

Recent Steam Engine Failures

By H. S. Knowlton

The description of a number of accidents taken from the reports of an insurance company, and the deductions arrived at by their investigators.

The following is an account of a number of recent accidents to steam engines, the facts being drawn from the investigations and reports of a large accident-insurance company:

The first case noted was that of a horizontal noncondensing engine fitted with a single slide valve driven by an eccentric keyed upon the crank shaft. The engine operated wood-working machinery, and was left without attention, as a rule, from the time the plant started in the morning until it was shut down at night. While the engine was in service it stopped suddenly, and it was found that the wooden wedge between the front end of the crank pedestal and the lug on the bedplate had come out of place and left the pedestal free except for the restraint of the holding-down bolts. The holes for the latter were long enough to allow considerable movement and the pedestal was forced forward sufficiently to bring one of the nuts which secured the slide valve upon its spindle into collision with the front end of the valve chest. The shock broke the eccentric strap, and at the same time the connection between the eccentric rod and the crank shaft thus leaving the slide valve stationary.

Another accident was caused by a stray bolt and nut. The trouble occurred in connection with a vertical, single-acting air pump, driven by links from the low-pressure piston-rod crosshead. The bucket was hollow, flat on top and conical on the under side, being divided internally by six radial ribs into compartments to which access was obtained by holes in the upper surface of the bucket; these had been filled by screwed plugs after the cores had been removed. The bottom of the pump was also conical, with a central hole 16 inches in diameter to facilitate boring. This hole was closed by a flanged and spigoted cover 7/8 inch thick, whose upper surface was turned to form the apex of the conical surface of the air-pump bottom. The cover was secured by fourteen 3/4-inch studs.

While in regular operation one morning, the cover was broken and driven off. Upon examination a crushed and battered T-head bolt was found below the pump, and on drawing the bucket the nut belonging to the same bolt was found jammed tightly into a hole in one of the compartments. It appeared that the bolt, possibly with the nut screwed upon it, had become lodged in the bucket after the cores had been removed, and had been left there when the core holes were plugged. Here it had rolled about till the nut had come off, and the bolt or nut, or both, had worn a hole in the bottom of the bucket. The bolt, having a head smaller than the nut, had dropped through the hole, rolled to the bottom of the pump, and been driven through the cover by the next downward stroke of the bucket.

The next case was that of a 42x60-inch vertical condensing engine, running compounded with a 19x60-inch horizontal noncondensing engine, the two being coupled to the same shaft. The speed was 42 revolutions per minute and a boiler pressure of 110 pounds per square inch was carried. Each cylinder had a short slide valve, the valve chest of the horizontal engine being on the top of the cylinder and that of the other engine being on the side facing the crank shaft. The valves of the latter were driven by an eccentric keyed to the crank shaft through a light eccentric rod, rocker shaft and links below the engine-room floor. The cylinder was a plain tube, with a port at each end, to which the valve chest was bolted. Its cover and bottom were spigoted, so that the vertical distance between them measured on the inside was less than the distance between the extreme edges of the ports; therefore, water could not lie on the bottom of the cylinder without running into the port. The valve chest was a large rectangular casting with flanged openings half way up the right and left sides, to which the steam pipe from the horizontal cylinder and the exhaust pipe to the condenser were bolted. These openings were about 16 feet above the water surface of the pond from which the condenser was supplied. The air pump, driven in the usual manner, was 25 inches in diameter by 30 inches stroke. The condensing water was supplied through about 40 feet of 5-inch pipe, and there were two injection cocks, one 3 inches in diameter and the other 4 inches.

During the temporary absence of the engineer the fireman noted a change in the speed of the engines. He found the engine room full of steam, but was able to reach and close the stop valve of the horizontal engine. He then found the piston rod of the vertical engine disconnected from the crosshead, and the cylinder fractured nearly all around, close to the bottom flange. Further examination showed that the piston-rod cotter, which was 3½x¾ inches, had been sheared through, the crank forced about 1½ inches around the shaft, the rocker shaft which worked the valves being twisted and the cylinder bottom and piston broken. As no mark could be found on the piston or cylinder cover it was evident that the damage to the piston-rod cotter and the cylinder and the shearing of the keyway on the crank shaft had been caused by water in the top end of the cylinder, and that it had happened just before the crank reached the bottom center and the piston the end of its up stroke. It was also clear that the cylinder bottom had been fractured by the impact of the piston, driven down upon it by the steam pressure, when liberated from the crosshead. At first it was not evident where the water had come from, why there was no dangerous accumulation in the bottom of the cylinder, or how the twisting of the rocker shaft was related to the other damage. The following conclusions were arrived at by the insurance company's engineer:

First, a comparison of the volume of water supplied to the condenser per stroke, calculated from the temperatures of the injection and discharge, with the displacement of the air-pump bucket, proved that the water could not have come from the condenser. At the normal speed the displacement of the bucket was five and three-tenths times the volume of the water and condensed steam entering the condenser; consequently, the air pump would clear the condenser as ng as the speed of the engines exceeded or 7.9 revolutions per minute. The eman who stopped the engines was cern that the speed was not as low as s. Therefore, the water came from her the pipe connecting the two cylders, or from the boilers. The pipe as bolted to a nozzle on the left side the valve chest of the high-pressure linder, and carried horizontally for a ngth of 10 feet toward the vertical enne, and then upward for 4 feet, enterg the right side of the valve chest of e latter. It appeared that the water me from the boiler. The fireman had n the water nearly up to a full column, eparatory to shutting down for the ght, and the boiler had begun to prime. ne water carried over had passed rough the high-pressure cylinder withit accumulating enough to cause damge, and had been carried on to the valve est of the other engine, where the me and scum carried over interfered ith the lubrication, causing the valves stick and the rocker shaft to twist. ne effect of this was to lower the valves bout [illegible] inch, and to put nearly this nount of lap on the exhaust edge of the p valve, while giving the exhaust edge f the bottom valve about the same nount of lead. The port at the bottom nd of the cylinder then remained open ir exhaust almost to the end of the own stroke, but that at the top was osed while the piston was yet some 9 iches from the top of the cylinder. hus, small quantities of water entering e bottom of the cylinder could run back ito the port and be blown into the conenser during the down stroke, but enring the top could not escape, owing the port being closed before the pisn reached its level. The water entering ie top port, therefore, remained upon e piston and accumulated until its olume became greater than the clearice; then the break occurred. When ie low-pressure valve chest was opened was found that the valves and faces ere covered with a white deposit which roved that there had been priming, and ie rocker shaft had also been twisted nce before and at about the same time f day, apparently from the same cause. here was no relief valve on the top end f the cylinder of the vertical engine.

Another breakdown was caused by ater entering the upper end of the lowressure cylinder of a 10 and 1[illegible] by -inch vertical engine. The exhaust pipe ed from the valve chest of the low-presure cylinder in a horizontal direction, hen turned vertically upward for 2 feet, hen ran horizontally for 7 feet and fielly downward to the top of the conlenser, a conical receptacle of small caacity. The higher of the two horizontal engths of the exhaust pipe was about 0 feet above the surface of the pond rom which the injection supply was drawn. The air pump was of the horizontal type, with a 12x10-inch cylinder, and was steam driven. The frame which inclosed the cylinder and the moving parts fractured circumferentially close to the flange by which it was bolted to the bedplate. It appeared probable that the accident had been caused by the air pump failing to discharge the water forced into the condenser by the atmospheric pressure on the surface of the pond. This might have occurred in two ways: first, owing to the steam pressure being reduced previous to stopping, the air pump might have been running at a speed just sufficient to keep the condenser clear while the normal supply of water was passing through the injection cock, but not sufficient to discharge the larger supply which would enter the condenser when the vacuum improved owing to the governor's cutting down the steam supply when the machinery was being shut down; second, the engineer may have slowed down or stopped the air pump before destroying the vacuum in the cylinder. The condenser was equipped with a float designed to operate a small atmospheric valve in the event of the water rising above the normal level, but as the engineer had never seen the inside of this mechanism it was probably out of order; or, if it did lift the valve, the air entering was unable to destroy the vacuum before the water reached the cylinder. The insurance company's engineer called attention to the fact that water entering a condenser under a vacuum of 12 pounds had a theoretical velocity of about 42.5 feet per second, and an actual velocity of about 25 feet per second, which is sufficient to carry a considerable quantity of water into the condenser, even after the vacuum has been destroyed if the injection pipe is long. The best practice is to stop the engine before shutting down the air pump, in independent condensing plants.

A case of piston-rod breakage occurred in a triple-expansion engine running at 62 revolutions per minute, where the high- and low-pressure pistons were carried tandem on one rod, and the intermediate piston on the other. The rod carrying the two pistons was 10 feet long by 3[illegible] inches in diameter where it entered the crosshead, to which it was secured by a [illegible]-inch cotter, with rounded edges and a taper of [illegible] inch per inch. The cotter hole in the rod was 1[illegible] inches broad and [illegible] inches long, and the inside diameter of the socket in the crosshead in which the rod was cottered was [illegible] inch larger than the diameter of the rod. Two steel disks or shims, each [illegible] inch thick, were inserted between the end of the rod and the bottom of the socket, probably to compensate for reductions in the effective length of the connecting rod by the wearing of the brasses.

The piston rod gave way inside the crosshead socket at the cotter hole. The two pistons which it carried were projected backward, driving out both cylinder covers, cracking the larger cylinder back of the flange and breaking some of the studs connecting the front end of the high-pressure cylinder to the engine bedplate. From the appearance of the rod it was evident that the failure had been gradual. It appeared probable that if the rod end had been carefully examined when it was taken out of the crosshead to put in a new packing piece, the crack would have been discovered and the failure averted. The cause of the initial fracture could not be determined, but there was little doubt that it was concentration of stress upon a small part of the cross-section of the rod by the pressure of an imperfectly fitting cotter. The load upon the pistons, divided by the cross-sectional area of the rod, was 6788 pounds per square inch.

Neglect of proper foundations in erecting new engines upon an old site led to the breaking of a bedplate in connection with a 1700-horsepower horizontal tandem-compound engine. The foundations for the original engines had been built of good ashlar blocks, but during many years of service the stones became saturated with oil, the cement softened and squeezed out of the joints, and settling took place, especially under the crank-shaft bearings, until finally the bedplate broke. When the replacement of the engines was under consideration the casualty company's engineers advised the rebuilding and strengthening of the foundations, but on account of a lack of time this advice was disregarded, and the new engines were erected upon the old dilapidated seats. As soon as they were put in operation, movements were observed, and, although the joints between the stones were wedged open, cleaned out and pointed, and the engine bedplates wedged up and screwed down, neither the engines nor their foundations could be made firm. A week was spent in cleaning oil from the joints of the stones and the bottom of the foundations, the joints were again run with cement, and the movement was much reduced, but the flywheel and shaft were not lifted to take their weight off the bearing, neither were the nuts of the holding-down bolts slackened, to allow the bedplate to come to its natural position so that it might be packed and properly supported. The result was that the bedplate cracked near the holding-down bolt next to the crank-shaft bearing. This accident illustrated the great importance of keeping oil off the foundations, particularly in cases where engines are erected on masonry foundation structures.

In this connection the insurance company's report pointed out that when using masonry foundations, bedplates cannot be placed on their under sides and bedded by running against the foundation. They are usually leveled up on small iron wedges and grouted with cement or fine concrete. The bearing surfaces on the under sides are often not more than 3½ or 4 inches wide, and even when kept dry are insufficient to hold a heavy engine absolutely steady for any length of time. As soon as motion begins, the cement is ground away and the wedges become loose. To stop the motion the foundation bolts are tightened, and so the process goes on till the bedplate breaks. When oil reaches the grouting, destruction is far more rapid. It is good practice, if wedges are to be used, to have them machined and of substantial thickness and large area, bedded to machined surfaces on the under side of the bedplate at each foundation bolt. The lower wedges should be set at the right level in cement, and the upper lightly driven between them and the bedplate, when the latter is in position, on temporary supports. At the crank end, projections may be cast on the under side of the bedplate to engage in recesses in the concrete, to prevent end motion. If wedges are not relied upon, the bearing surfaces on the under side of the bedplate must be broad, so that if the oil softens the edges of the grouting there may still be sufficient hard cement between. Footings at least 8 or 9 inches wide are desirable with large engines. The foundation bolts should also be increased in number to make the bedplate grip the grouting at as many points as possible. The most substantial plan, however, is to cover the concrete where the engine is to rest upon it with strong cast-iron plates with raised facings to receive the planed feet of the engine bed and raised edges to return oil and water.

Corrosion and the accumulation of scaly deposit in a 100-kilowatt steam turbine caused serious damage to the machine only five months after a complete overhauling. The turbine had fifty-four rows of blades, increasing in diameter from 6½ to 12½ inches, and its speed was 3000 revolutions per minute with a boiler pressure of 160 pounds per square inch. All the blades of the first thirteen rows at the high-pressure end and the corresponding blades in the casing were broken off at the roots and crushed into one mass, which stopped the turbine. In addition half the blades in the next eleven rows were found to have been in contact with the casing, but it was not possible to determine whether this had happened before or after the first thirteen rows had been stripped. The blades of the high-pressure end were of copper, brass being used at the low-pressure end.

Can and Plate Systems of Making Ice

By F. E. Matthews

What is meant by "can ice" and by "plate ice" and a description of the processes involved in their manufacture. The economic phase of ice making is also touched upon.

Next in importance to the direct utilization of refrigeration, such as for the cooling of perishable products, etc., is that of artifical ice making. While there are a number of systems which may in the future modify present methods, practically all the ice produced today is made by either the can or the plate system.

The Can System

In general, the process of manufacturing can ice consists of immersing cans of water in brine tanks not unlike those employed for cooling brine for brine-circulating systems. First, the specific heat, then the latent heat of the water is given up to the brine which, in turn, passes it on to the liquid refrigerant, most commonly ammonia.

Distilling Apparatus

Since any impurities in solution or suspension in the water fed to the cans are eventually frozen into the ice, it becomes necessary to use water as nearly pure as possible. The purity of ice, however, is somewhat erroneously judged by its transparency. Impure ice may be almost entirely transparent while, on the other hand, pure ice, except for the presence of air which produces whiteness, may be unsalable because of its opaque appearance. To remove air as well as both organic and inorganic impurities from the water, distilling systems are usually employed in can ice-making plants. As large quantities of water must be evaporated to make the steam necessary for driving the ammonia compressors and other machinery of an ice-making plant, it follows that the boilers and engine should constitute a part of the water-distilling system.

Fig. 1 illustrates diagrammatically the simple or high-pressure system commonly employed in making can ice. As a steam boiler is virtually a thermal filter which separates out, in the form of incrustation and sludge, most of the impurities brought to it in the feed water, the water supply for an ice plant should be selected with particular care, especially as it often becomes necessary to supply raw "make-up" water to the storage tank when the supply of distilled water runs short.

As shown in the illustration, the exhaust steam from the engine driving the compressor passes first to the grease separator in which it is freed of a large part of the entrained lubricating oil by impinging upon baffle plates. From the grease separator it passes to the steam condenser from whence, after being condensed, it flows to the reboiler, skimmer and hot-water storage tank. From the latter the hot distilled water is allowed to flow as required into the water cooler; entering at the bottom and passing up through a series of pipes it is here cooled by water flowing down over the outside of the pipes. From the water cooler it passes to a charcoal filter or deodorizer and on through a hose to the can filler. When frozen the ice is removed from the cans by spraying with hot water and then gravitates down an incline into the ice-storage room.

In traversing that part of the system between the steam condenser and the ice cans the distilled water, after having been freed from air and other gases in the reboiler, is not again allowed to come in contact with the air; the reason for this is twofold: First, any air entering into solution in the distilled water will separate out in the form of minute bubbles during the freezing process and give the ice an opaque appearance; second, distilled water in the presence of air is very corrosive to iron and should they be allowed to come in contact with any part of the system not thoroughly protected by galvanizing, a sufficient amount of iron would be dissolved to discolor the ice.

Freezing Time Required for Can Ice

With brine at 14 degrees the average time of freezing different-sized blocks of can ice is as shown in the following table:

TIME REQUIRED FOR FREEZING CAN ICE.

Size of Can, Inches.	Weight of Ice, Pounds.	Freezing Time, Hours.
6x12x26	50	15—25
8x16x32	100	30—50
8x16x42	150	30—50
11x22x32	200	50—72
11x22x44	300	50—72
11x22x57	400	50—72

While no exact rule can be formulated for expressing the freezing time in terms of difference in temperature between the brine and the freezing water in the can, because of the fact that the heat-transmitting surface of the freezing water is decreasing and the insulating effect of the ice forming is increasing; it, nevertheless, has been claimed by some that the time required for freezing can ice with brine at the usual temperature varies directly as the square of the thickness of the cake of ice. On this basis the relative time of freezing 6-inch and 11-inch blocks would be as 36 is to 121, or allowing 50 hours for the latter, the former should freeze in 14.9 hours.

The Plate Ice System

Where pure water is available the can system with its distilling apparatus is often replaced by the plate-ice system. The important requisite of any ice-making system from a commercial standpoint is its ability to produce marketable ice, which, unfortunately, often depends more upon the appearance than upon the purity of the product. In the can system practically all solid impurities are left behind in the process of distillation, air and foreign gases being expelled by violent boiling in the reboiler. In the plate system the keeping of the product free from both solid and gaseous impurities is almost wholly dependent upon the agitation of the freezing water. Snow may be pure but it is white because of the presence of a large number of minute air spaces between the crystals of ice. Gases, in general, are soluble in liquids, the degree of solubility varying widely with the temperature and pressure; the higher the pressure and the lower the temperature, the greater the amount of gas a liquid will absorb. In the case of freezing water, however, the air is driven out of solution and collects in the form of little bubbles on the freezing surface. These bubbles will finally be frozen into the ice if not forcibly dislodged.

In the manufacture of plate ice the principal inorganic impurities to be guarded against are the salts of iron which give a reddish discoloration, and the carbonates and sulphates of lime and magnesia which produce a slight cloudiness. Unless large quantities of magnesium carbonate or carbonate of iron are present the effects of these impurities, as well as that of air, can be overcome by increased agitation. In the case of carbonates of either magnesia or iron, increased air agitation may tend to increase the discoloration through the hydrating of the former and the oxidizing of the latter. This difficulty may be overcome, however, by the substitution of mechanical for air agitation.

Mechanically, a plate plant is so constructed that the raw undistilled water to be frozen is brought in contact with plates of sheet metal bolted to either brine or direct expansion coils in which a sufficiently low temperature is maintained to bring about the necessary heat transfer from the water at 32 degrees. These plates, which are not usually less than 14 feet long by 10 feet deep, are submerged in the plate tanks. The refrigerating agent, whether brine or ammonia, is allowed to flow through the coils until ice has accumulated to a thickness of 12 to 14 inches on the plate. The cold brine or ammonia is then shut off and hot brine or ammonia is circulated through the coils until the ice is loosened from the plate and floats free in the water. Chains are then fished around the cake and it is hoisted from the tank by a traveling crane and carried to a tilting table where it is carefully deposited to avoid breaking. Here it is sawed into cakes of the required size, by two gages of traveling circular saws, one traveling lengthwise and the other crosswise of the table. Because of being frozen from water at 32 degrees Fahrenheit with which it is always in contact, the actual temperature of plate ice is not as low as that of can ice, the temperature of which is limited only by the temperature of the brine. On account of this fact, plate ice is less likely to be brittle, has less tendency to freeze together and, therefore, can be stored more readily than can ice.

The factor which limits the application of the plate system is the time required for freezing, the absorption of heat having to take place in this case wholly from one side while that in a can is from five sides. This disadvantage has been overcome to some extent in the "Center-freeze" system in which the plate of ice is frozen on a comb-formed series of vertical brine pipes attached at the top to suitable feed and return headers. In this system heat is absorbed radially from all directions to each pipe and, being located in the center of the plate of ice, the total thickness of ice frozen through need never be over half that of the usual plate system producing a plate of the same thickness. The center pipes are loosened from the ice as in the preceding case.

Evaporators and Vacuum Distilling Apparatus

In can ice-making plants of over 100 tons daily capacity and employing engines of the Corliss type, there is seldom sufficient excess of distilled water from the exhaust-steam condensers to supply the freezing tanks. This defeats maximum steam economy where the usual high-pressure distilling apparatus is employed. For instance, assuming a 100-ton ice plant requiring 2.75 horsepower per ton and operated by a four-valve engine using 30 pounds of steam per horsepower per hour, the steam required for the engine would be about 100 tons per 24 hours. The auxiliaries and reboiler, together with the usual condensation and leakage past the valves of the engine and auxiliaries would probably amount to 25 tons, making in all about 125 tons of steam. This amount of steam would supply sweet water for the 100-ton can plant and allow for a loss of 20 per cent. between the exhaust pipe and the cans. If, however, the loss were as much as 25 per cent., which might readily happen, the make-up water required would amount to about 8000 pounds per 24 hours. This amount of steam at a cost of 20 cents per thousand pounds would be worth $1.60 per day.

If the engine employed were of the Corliss type, simple noncondensing, and having a steam consumption of 28 pounds per horsepower-hour, the steam required to drive the compressor would be about 92.4 tons. Hence, the amount of make-up water, even on the basis of 20 per cent. waste, would be 52,100 pounds, which at 20 cents per thousand pounds would cost $10.42 per day.

From the foregoing it is evident that

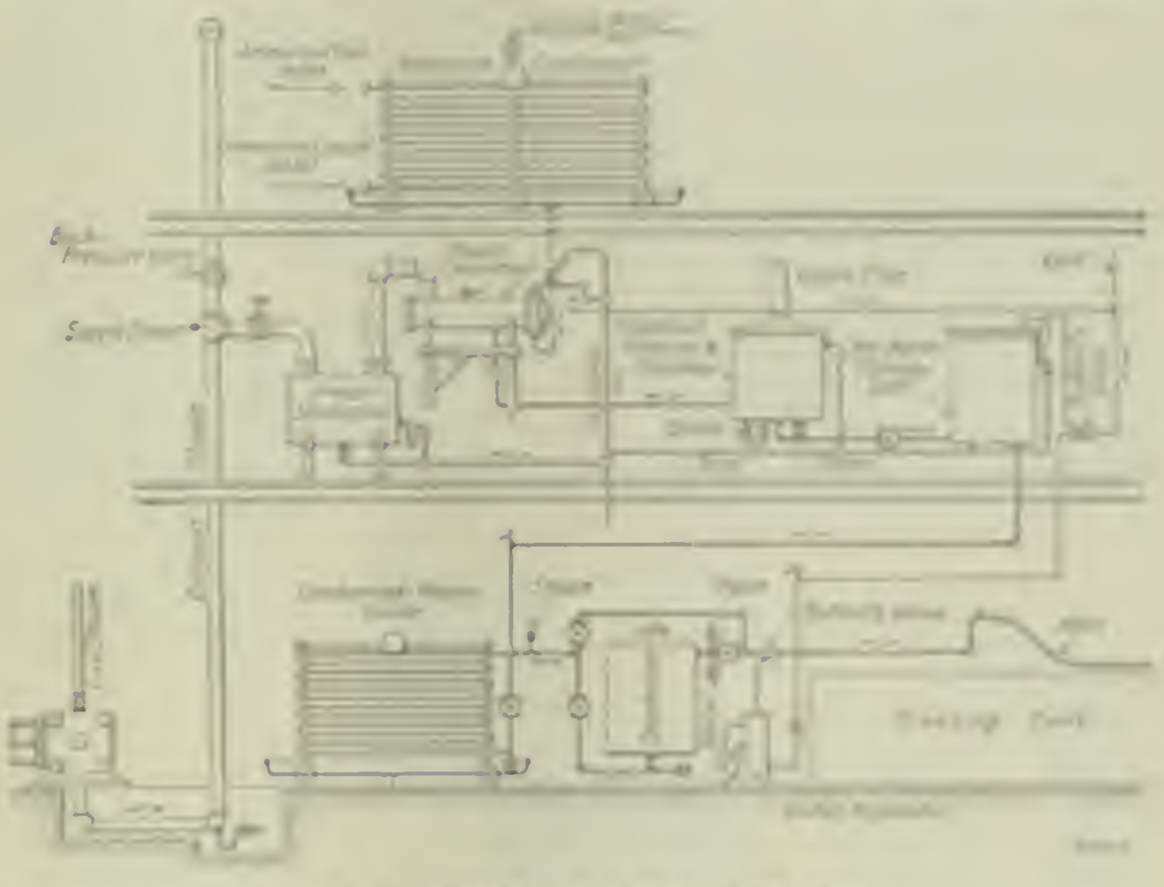


Fig. 1. System for Making Can Ice

to employ engines of lower steam consumption results in developing an ice-making capacity in excess of the amount of sweet water available. This excess capacity over that required to freeze the available distilled water, may be employed to freeze ice in a plate tank, or the deficit in sweet water necessary to supply the can plant may be made up by means of evaporators.

A combination can and plate plant, designed to satisfy the first of these conditions is illustrated diagrammatically in Fig. 2. Leaving the ammonia compressor the gas is first discharged into the two pressure tanks where any entrained oil is deposited. From there it passes through pipe B to the condensers and after liquefying it flows through pipe D to the liquid receiver. The line from the bottom of the liquid receiver branches off, line F supplying the can plant and ice-storage room and E supplying the plate plant. The water forecooler is fed in series with the plate plant, after passing through which, the ammonia gas returns to the compressor.

The circuit traversed by the sweet water is as follows: The exhaust from the engine, encountering the back-pressure valve on the main exhaust pipe from the engine, is diverted through a grease separator into a steam condenser. The condensed water then passes through the vacuum reboiler and enters the suction of pump P which discharges it into the hot-water storage tank; from here it flows through a regulating valve through the water cooler and into the cold-water storage tank from whence it is drawn to fill the ice cans as required. The water for the plate plant passes first through the water filter in the engine room, through the water forecooler and into the plate tank. Similarly the air used for agitation in the plate-ice tank is discharged by the air compressor through an air-storage tank in the engine room, through the water forecooler and into the plate-ice tank.

Fig. 3 represents a vacuum-distilling system, having an evaporator which provides the second means of maintaining the full capacity of the ice plant when the available sweet water is insufficient. For simplicity only the distilling part of the ice-making plant is shown in this illustration.

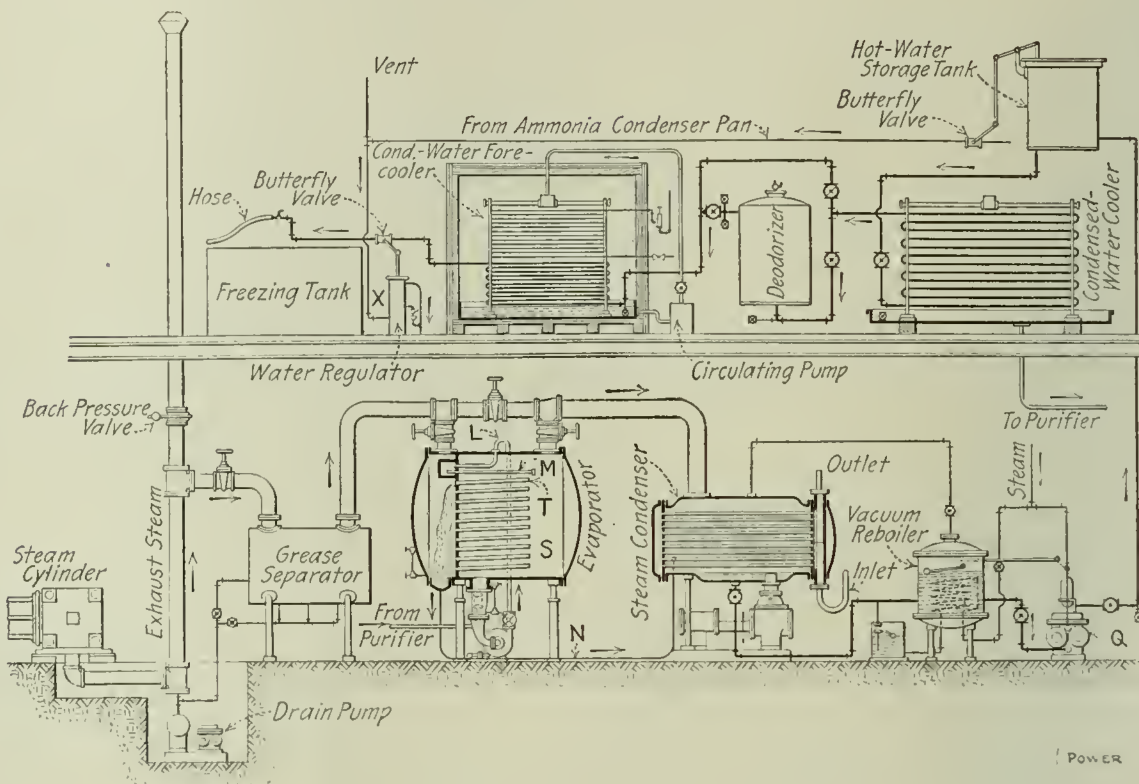

FIG. 3. VACUUM DISTILLING SYSTEM

The exhaust steam, as before, passes first through a grease separator, but in this case it also passes into an evaporator where the steam must stop, the heat being carried over by the vapor to the steam condenser. Assuming that the engine is running under 18 inches of vacuum, the exhaust from the low-pressure cylinder will enter the evaporator at about 168 degrees Fahrenheit. The steam enters the dead-ended copper tubes T which extend upward at a slight angle through the tube sheet into compartment S. Here it is condensed by cooling water circulated from the bottom of the evaporator, through the centrifugal pump, distributing pipe L and discharge line M. On the condenser side of the tube sheet a vacuum of from 24 to 26 inches is maintained by the condenser and this higher vacuum enables the heat liberated by the condensation

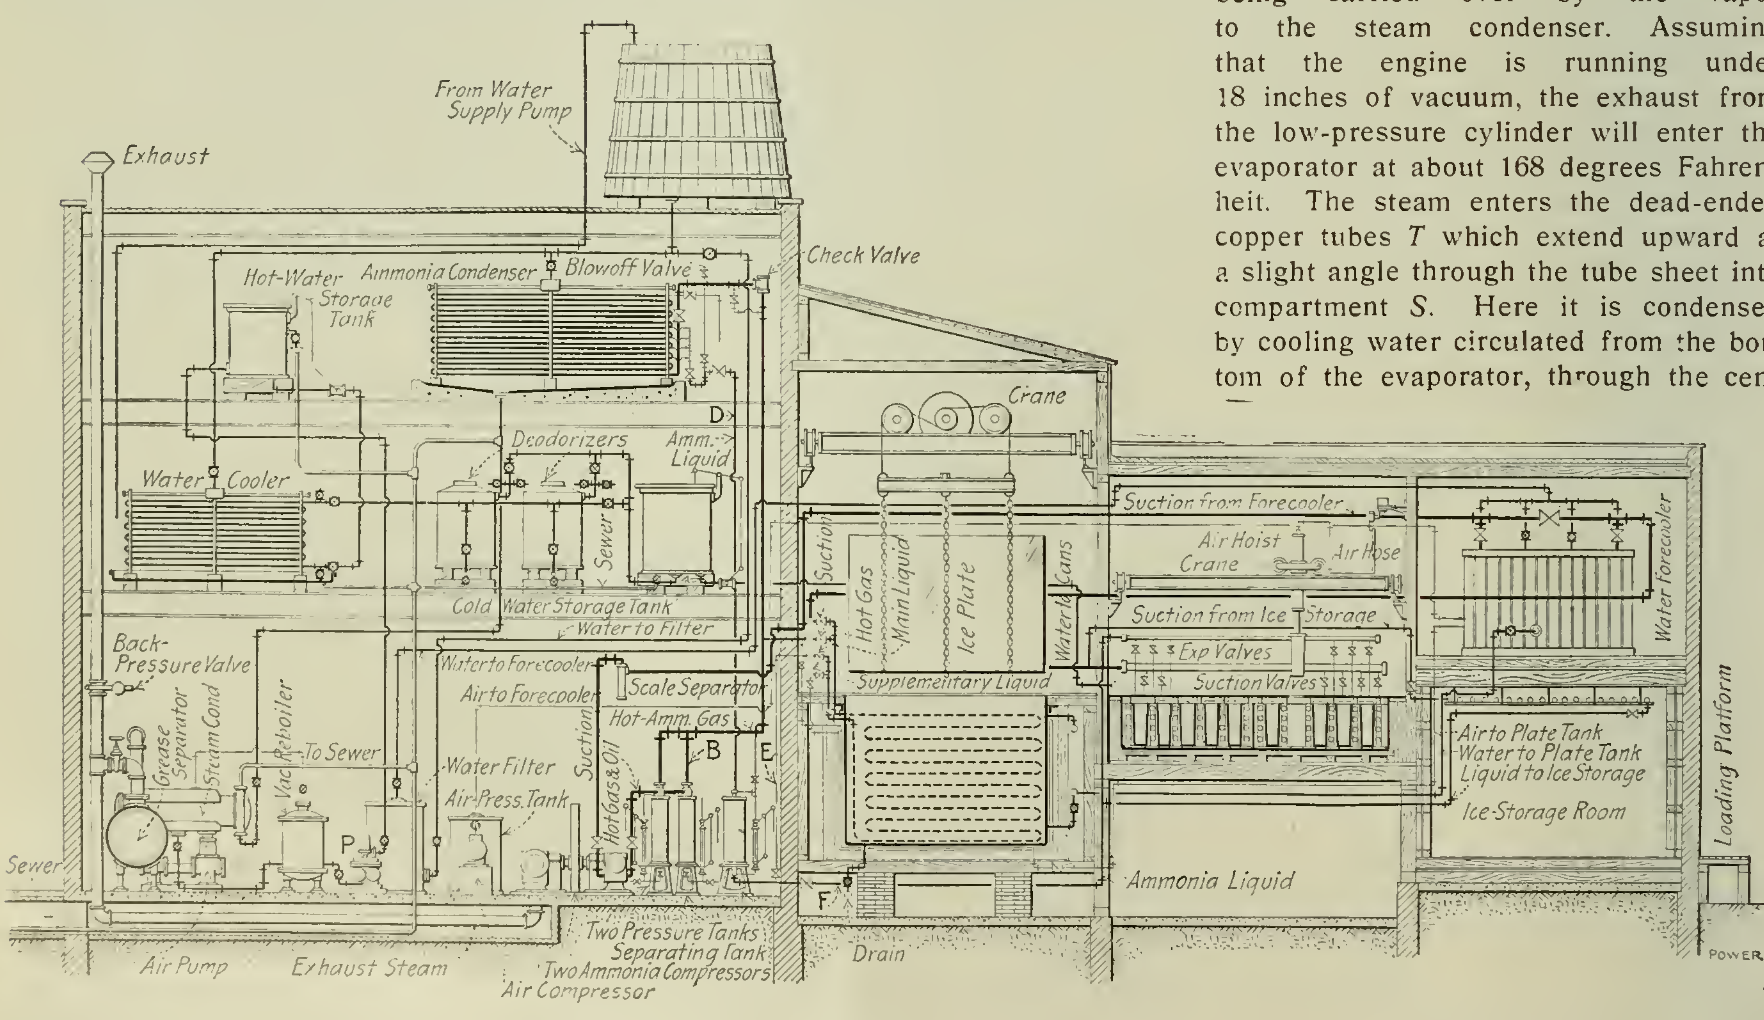

FIG. 2. COMBINED CAN AND PLATE-ICE PLANT

of every 1.15 pounds of exhaust steam to evaporate about one pound of cooling water. The cooling-water vapors are liquified in the steam condenser. Here they are joined by the condensed exhaust steam from the evaporator which is drawn through pipe N by the higher vacuum in the condenser, and also by a small amount of vapor drawn through the vent pipe from the top of the vacuum reboiler; condensed water from both the evaporator and steam condenser being drawn into the reboiler by the vacuum maintained in the steam condenser. The water from the steam condensed in the coils of the reboiler drains into a trap provided with a float, which as soon as the water has collected to a certain level, admits it into the suction line leading to the sweet-water pump Q. This pump discharges the sweet water into a hot-water storage tank, from whence it flows through the condensed-water cooler, deodorizer and condensed-water forecooler to the ice cans. In the reboiler a float valve controls the operation of the condensed-water pump, allowing it to draw water from the reboiler only when it has accumulated to a predetermined hight. In the trap from which the water condensed in the coils of the reboiler is drawn, there is a similar float valve opening only when there is a certain amount of water present. A float valve in the hot-water storage tank controls the position of another valve through which water from the ammonia condenser pan flows into a regulating device X which operates a butterfly valve in the sweet-water supply line leading to the ice cans and prevents the drawing of water from the storage tank below a certain level. These precautionary measures are all taken to prevent the possibility of air entering the pipes of the distilling system.

The deodorizer into which the sweet water is introduced through a strainer to insure uniform distribution through the filter bed, consists of a vertical cylindrical shell filled with charcoal covered with a second strainer which prevents any of the material from floating and entering the discharge pipe at the top. By means of a simple bypass the deodorizer can be cut out of the system for cleaning, and the sweet water fed direct from the cooler to the cans. In some instances the presence of iron salts in the water makes it advisable to supplement the deodorizer with a sponge filter.

The forecooler shown in the illustration consists of an insulated compartment in which a direct-expansion coil is installed over the distilled-water coil. Water is circulated from the pan beneath these coils and passes over the expansion coil where it is cooled to practically 32 degrees; it then gravitates down over the water coil and absorbs heat from the sweet water. As the circulating liquid is water, it is impossible to freeze up the sweet-water coils and since this circulating liquid can be chilled to the freezing point the condensed water can also be cooled to within a very few degrees of the freezing point, resulting in a great saving in freezing time, which is equivalent to increasing the capacity of the ice-freezing tanks. The reboiling of the sweet water under a vacuum at a temperature of from 200 to 204 degrees not only reduces the amount of steam required to effect the reboiling but also the amount of cooling necessary to reduce its temperature to that of the freezing tank.

The Ratchetless Wrench

By John E. Sweet

The history of this wrench is this—I was engaged as draftsman at the Patent Nut and Bolt Company in Birmingham, Eng., and we had commenced the manufacture of finished nuts before the case-hardened ones were in vogue. On these the spanners (the English word for the American wrench) would mar them unless a mechanical fit—and this led to the design given in the illustration. As at that time I had commenced writing for *Engineering* this appeared in that paper on page 112, July 31, 1868, as follows:

"In the use of the ordinary spanner on finished nuts either one or the other of two objections has to be endured. If the spanner is a perfect fit it must be brought to the exact angle at which the nut stands before it can be entered on, and then the least dirt or bruise will make it stick or prevent it from going on altogether. If the spanner is a loose fit all the strain is thrown on the corners of the nut and perfection in workmanship in this case only aggravates the evil.

"The spanner shown above may be a perfect fit, takes a bearing on three sides of either a square or hexagon nut and will enter on freely when brought to any angle within ten degrees of the angle at which the nut may stand. Although the jaws are thick and strong, a nut

"Ratchetless Ratchet Wrench"

standing against a flange can be turned even when there is only room for the corners of the nut to pass. This principle may be carried out in different ways, and even introduced into shifting spanners; but the form here shown has the merit of extreme simplicity and yet should be used for the work for which it is designed—finished nuts—and only by men who, it is hoped, will appreciate its advantages, 'finished workmen.'"

Crosshead Buckled

An item comes to us from a New England daily newspaper. It contains a mine of information which is not procurable from any other source of which we know.

Anxious to have the good work go on, we reproduce it herewith verbatim, omitting only the identifying name:

"A defective cylinder in the engine which operates the machinery of —— mills 6 and 7 caused the mills to close yesterday afternoon and men were compelled to work late into the night in adjusting the machinery.

"The accident occurred at 2:30 p.m. yesterday. The crosshead is a short bar which acts as a sort of a hinge between the piston of the engine and the shaft of the wheel. When the crosshead 'buckles' it moves so far toward the cylinder on its backward journey that it becomes caught and cannot make its next forward movement.

"The buckling was caused yesterday by some water getting into the cylinder. A vacuum was created which allowed the crosshead to move so far back that it became wedged too tightly for it to return.

"It is fortunate that no accident of a very serious nature occurred, for if the steam had not been turned off very quickly an explosion of the cylinder might have occurred.

"As it was, mills 6 and 7 had to suspend operations for the rest of the day, and the machinists had to work on the engine late into the night. The necessary repairs have been made and the mills are running today."

Investigations to discover the causes of rusting in galvanized wire have been undertaken by the agricultural-engineering department of the University of Iowa, Ames, Ia. It has been well known that the lower wires of the fence, down among the moist grasses and weeds, where rusting action would be expected to be most active, invariably last longer than the upper wires in the dry air. M. L. King, experimentalist for the department, says he has found that these lower wires in fences of any length ordinarily carry small currents of electricity, reaching in some cases a value as high as 0.001 ampere, and sometimes showing a difference of potential of as much as one volt above ground. Such currents are absent in the upper wires, and it has been suggested, but not proved, that the greater preservative action of the lower strands is due to the suppression of local electric couples by the through currents flowing in the lower wires.—*Ex.*

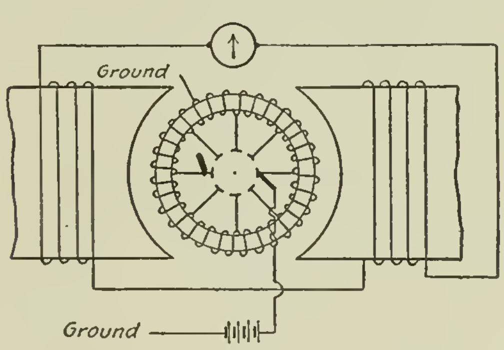
Locating a Grounded Armature Coil

By Francis H. Davies

The location of a grounded coil in the armature of a direct-current dynamo or motor may be very simply done by the following method: The connections should be made as per the diagram, from which it will be evident that the field circuit is entirely disconnected from the armature and its terminals are connected to a galvanometer; this should be of a fairly sensitive type—the ordinary lineman's instrument will do very well. After making this connection the brushes should be shifted to the position shown. One of them should be raised clear of the commutator and the other connected through a switch to three or four storage-battery cells; the other terminal of the battery is grounded on the frame of the



Connections for Testing

machine. When the switch is closed, current will flow through the armature winding to the core at the grounded point and the magnetic field generated in the armature core will give rise to a momentary induced current in the field winding, which will produce a kick by the galvanometer. The armature should be rotated step by step and the operation repeated as each commutator segment comes under the brush; when the segment connected to the grounded coil is reached, the galvanometer will show no indication upon closing the switch, or, at the most, a very slight one. The reason is, of course, that the current from the cells then flows through little or none of the winding, and therefore produces little or no inductive effect upon the field winding.

It is important that the brushes should be rocked into such a position that the coil connected to the commutator bar under the brush will be situated right in the center of the field-magnet pole face, in order to enhance the inductive effect. It must, however, be borne in mind that the brush position is not necessarily that shown in the diagram, which only applies to the type of armature represented. Generally speaking, it will be so, but some machines are built with the commutator displaced at an angle of about 90 degrees ahead of the winding in order to make the brushes easier of access, and in such cases the correct position will be *between* the poles and not opposite the pole-face center.

A ground will sometimes make itself apparent upon the surface of the armature by signs of burning; but if this is not the case it may be possible to locate it by applying a current of the full voltage of the machine between the commutator and the frame. If the fault is a bad one, arcing will be either seen or heard.

The Excitation of Alternators Working in Parallel

By G. E. Miles

While much has been written on the subject of the parallel operation of alternators the feature of the adjustment of excitation does not seem to have received much attention. This may be because the subject is considered so simple that it deserves little comment. However that may be, both practical and theoretical men have fallen down on this point.

I do not wish to be understood as posing as an authority on the subject but think perhaps some of my experiences and observations along this line may be of help to others.

A certain company operated two hydraulic plants situated about two miles apart, either of which was capable, during the season of high water, of carrying the load alone during the morning "shift." At station No. 1 the voltage was regulated by hand, but at No. 2, where I was located, the voltage was controlled by an automatic regulator. By visiting back and forth I soon observed that when the plants were operating in parallel, with the voltage controlled by the regulator at No. 2, the voltage at No. 1 was higher than I had been instructed to carry it by the man on the opposite shift at that plant. I also observed that the power factor was better at station No. 1.

After a few more weeks the water fell off so that both plants had to be run in order to carry the load, so another man was put on at No. 1. No. 2 was run with a waterwheel governor and automatic voltage regulator and took care of all changes in load and voltage, while No. 1 was run with a constant load and with constant excitation. The new man at No. 1 adjusted the excitation as instructed by the man on the opposite shift but I found the power factor very low at No. 2. By comparing notes over the telephone, the power factor at No. 1 was found to be high, so I asked that the excitation there be adjusted until the power factors were the same at both stations.

After a few weeks more I was transferred to station No. 1, when a discussion at once arose between the man on the opposite shift and myself, the other man insisting that I was using more excitation than was necessary when the plant had the entire load.

To make sure of my position, I submitted the question to an authority in whom I had the greatest confidence, and was advised that when two machines are operated in parallel and one of them takes care of the changes in load and voltage, the excitation of the other machine should be such as to make its current the minimum, which would be true when the machine took no wattless current from the system and delivered none to it. A trial was unnecessary to convince me that these instructions were wrong; nevertheless, I resolved on a trial. As I expected, the power factor on my machine rose to about 100 while that at the other plant went below 50.

A short time after making this trial an occasion arose for carrying the entire load on station No. 1 for a few hours. This gave an opportunity for observing the exciting current required when the load was all on one machine (the load was low enough part of the time for one machine to carry it all) and also the effect of varying the excitation when it was necessary to run two machines. I promptly found that in order to carry the same load at the same voltage and power factor it made no difference, as to the exciting current required, whether a machine was running alone or in parallel with another.

From this experience I would lay it down as a safe rule that when alternators are running in parallel the ratio of amperes to kilowatts should be the same on both machines, which, of course, gives both machines the same power factor.

LETTERS

Mr. Greer's Rotary Converters

I note that Mr. Greer in the January 31 issue takes exception to my analysis of his converter trouble, claiming that it is largely in error; also that he takes the same view as Mr. Farwell, who claims that No. 1 converter actually "hogged" the load from Nos. 2 and 3 converters.

Mr. Greer further states in his letter that "it was not simply an exchange of current between No. 1 and the others, but No. 1 actually was carrying the load of both feeders." He undoubtedly comes to this conclusion on account of the ammeters of Nos. 2 and 3 having reversed or dropped back against the zero stops. The fact that these ammeters reversed is not proof that No. 1 took all the load.

The diagram by Mr. Harvey in the January 31 issue (Fig. 1 herein) shows quite clearly the path taken by the negative current; as stated by Mr. Harvey, the negative current of the east and west feeders passed through the negative lead and armature of No. 1 converter, and in addition to this there was the excess of cross current from the negative leads of Nos. 2 and 3. As stated in my previous article and by Mr. Harvey, if ammeters had been connected in the positive leads of Nos. 2 and 3 converters they would have shown the load current of the west feeder passing through the positive leads of Nos. 2 and 3 and of necessity through the armatures of Nos. 2 and 3.

To those familiar with the principle of rotary-converter operation it will be evident that the current which passes into the armature at the negative brushes passes out on the alternating-current leads nearest to the point of negative commutation or at nearly ground potential, where the negative is the grounded side of the direct-current system. The negative current of the west feeder would therefore pass through the armature of converter No. 1, along the alternating-current leads nearest to ground potential to the alternating-current busbars, through the armatures of the generators or the windings of the transformers supplying the busbars, thence back through the alternating-current leads nearest to the point of positive commutation in the armatures of converters Nos. 2 and 3; this current would then pass through the armatures of Nos. 2 and 3 and appear at the positive brushes at the working potential of the machines above ground.

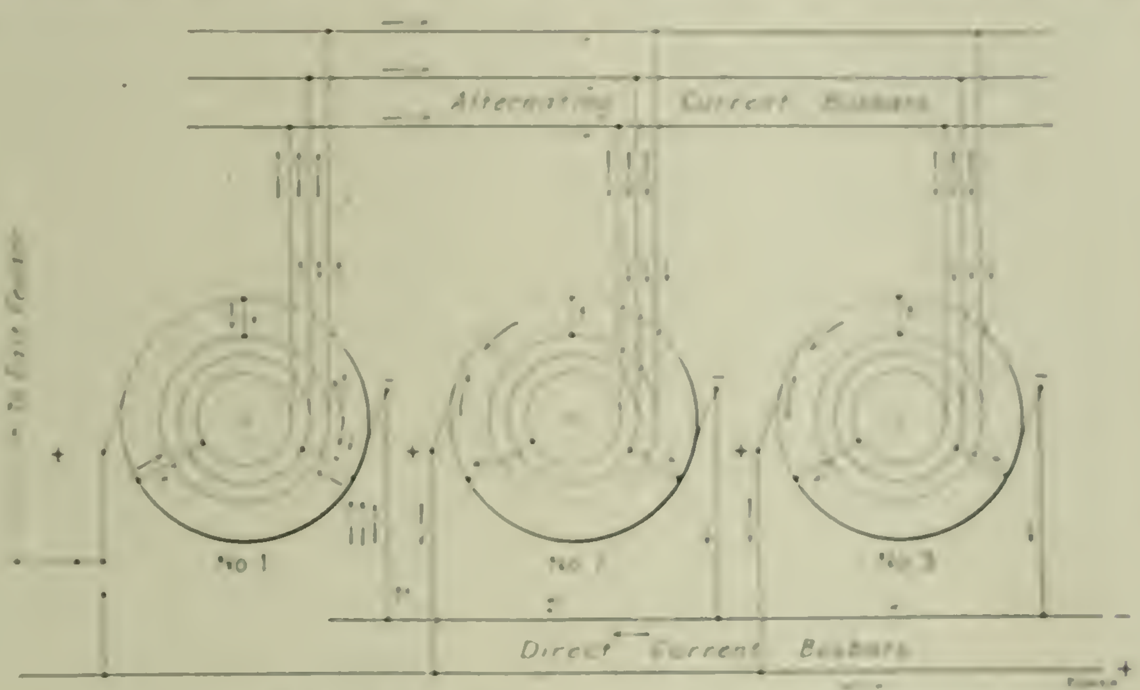


FIG. 1. MR. HARVEY'S DIAGRAM OF CIRCUITS

Bearing in mind that the alternating-current generators supply all the power it will be evident from the foregoing that No. 1 converter rectifies the positive current of the east feeder and the negative current of both the east and west feeders, and that Nos. 2 and 3 rectify the positive current of the west feeder. Nos. 1, 2 and 3 all rectify the current in the local circuit. It, therefore, cannot be properly said that No. 1 took all the load of the west feeder.

The current flowing in the local circuit between No. 1 and Nos. 2 and 3 was due to a very small difference of potential between the negative brushes of No. 1 and those of Nos. 2 and 3, and, therefore, represented only a small amount of power, although the current flowing was probably of a very high value.

I agree with Mr. Harvey that the wave form of the current in the alternating-current leads between No. 1 and Nos. 2 and 3 was very much distorted and I should very much like to see an oscillogram taken under these conditions.

Referring to Mr. Farwell's December 20 article, I would say that I can hardly agree with his statement that "all necessary conditions for parallel operation existed." Suppose, for instance, that Nos. 1 and 2 were of the same size and we should attempt to operate them in parallel with the connections as shown in Mr. Greer's original diagram, reproduced here as Fig. 2. Assume that No. 1 has been properly adjusted so that trouble with local currents will not be experienced; if a load be put on the west feeder equal to the combined normal capacity of the two machines and carried for any great length of time, the armature of No. 1 will be burnt out, as it is evident that the

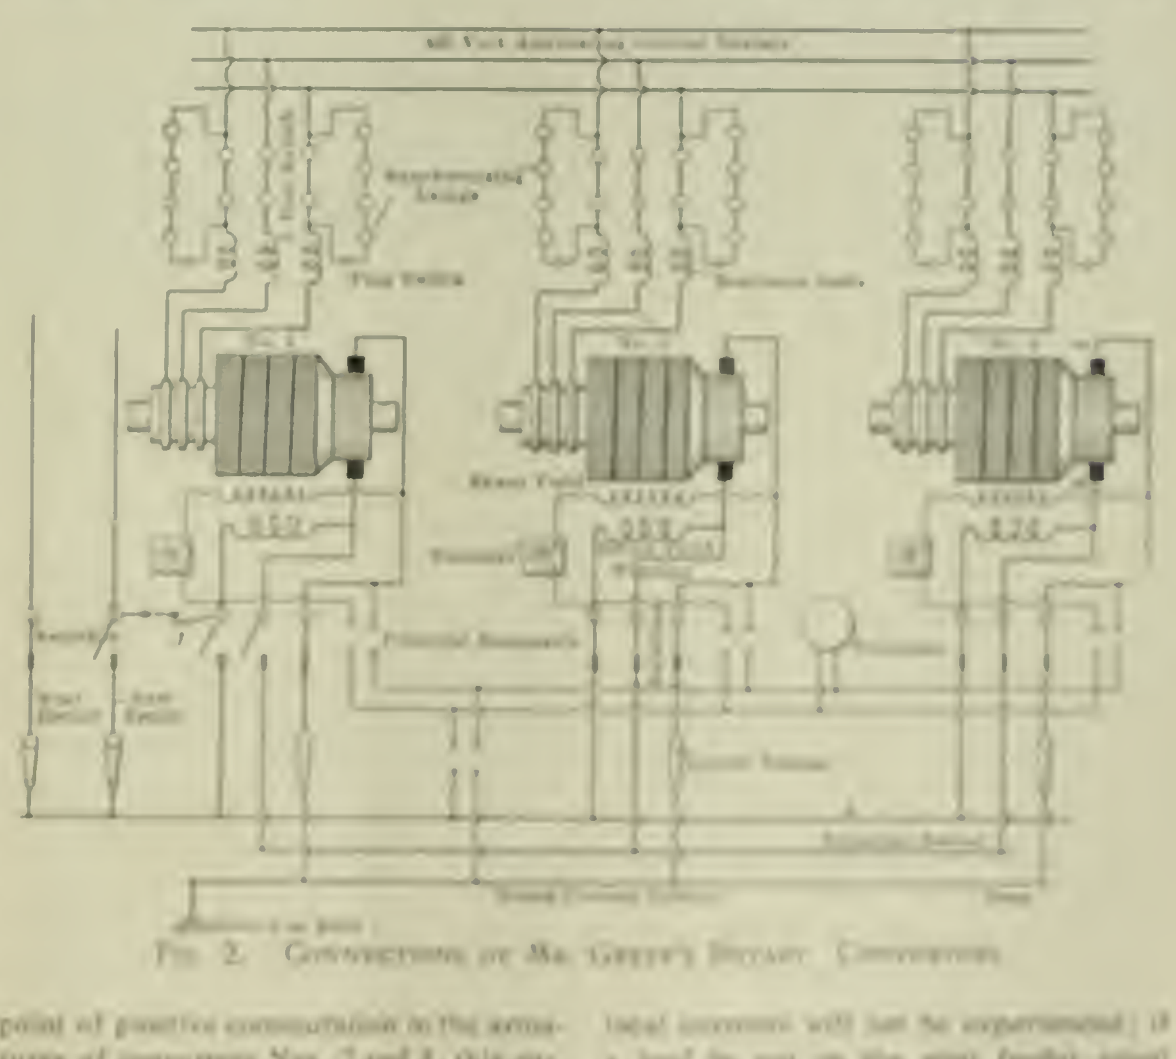

FIG. 2. CONNECTIONS OF MR. GREER'S ROTARY CONVERTERS

connections that all the positive current must pass through the armature of No. 2. This is certainly not an ideal condition for parallel operation.

If Mr. Greer still believes that No. 1 took all the load perhaps he will kindly explain how the positive current gets from No. 1 to the west feeder.

If it were possible to operate these machines in parallel with only the negative terminal of No. 1 connected on the direct-current side, using the alternating-current leads to carry the positive current, why would it not be well to go a step further and leave off the negative lead, using the alternating-current leads for both positive and negative current?

LESTER MCKENNEY.

Wappingers Falls, N. Y.

[Mr. McKenney's analysis of the occurrence is the only plausible one unless there were other conditions which escaped Mr. Greer's notice and were therefore not stated. Rotary converters cannot be paralleled in the accepted sense through their armature windings, because of the opposing electromotive forces generated therein.—EDITOR.]

Dynamo Burned Out Due to Misplaced Steam Drains

Several years ago I took charge of a small central station which ran only during the night and furnished light for an enterprising little borough. The equipment of the plant consisted of a compound-wound single-phase generator, belt driven by a waterwheel. The flume, a 40-inch steel tube, passed through part of the plant to the turbine, which had a draft tube extending down to the tail race. An auxiliary steam engine and boiler were housed in a building alongside of the main power plant; this equipment was used only in cases of emergency, and these would usually happen in the dead of winter.

I had been warned that I could expect trouble from this auxiliary equipment but never had occasion to use it until one day, a few days before Christmas, when something went amiss with the turbine. The engineer, a man on the job about three years previous, started the fire and got everything in good shape. The boiler was connected to the engine by an overhead 5-inch pipe passing through the partition between the boiler house and the dynamo room; this pipe had never been protected by a covering and naturally there was much condensation. The cylinder, valve-chamber, exhaust-pipe and water-separator drains were arranged to discharge into a terra-cotta pipe laid underground and emptying into the draft-tube pit of the waterwheel.

Toward evening the engineer got ready for the night's run, and, as it was a bitter cold day, he started to "warm up" the engine. During this process the steam escaping through the drains into the draft-tube pit was forced back into the engine room by an up draft from the tail race, and this cold air condensed the steam, which settled on the dynamo and turbine; drops of moisture settled even upon the commutator, field winding and armature. The generator was wiped as dry as possible and the engine was started slowly. As we were obliged to leave the exhaust-pipe drain open on account of the condensation caused by its passing under ground into the boiler house to the feed-water heater, steam was drawn from the draft-tube pit up to the generator and kept it pretty damp. The engine was very gradually brought up to speed, but we had to cut down the exciting voltage on account of excessive sparking at the rectifying commutator, due to the condensation on it. We finally had everything working in good order, apparently, and brought the generator up to its full voltage slowly; while looking after the brushes, however, the armature suddenly became ablaze. We shut down as quickly as possible, but found that the whole armature was damaged; where it was not burned it was punctured.

All this was caused by placing the drain pipe wrong, principally to save in the cost of installation.

The trouble was subsequently abolished by changing the position of the drain outlet.

A. J. ALTHOUSE.

Birdsboro, Penn.

Exciting an Alternator from an Arc Dynamo

An electric-lighting and pumping station where I was employed a few years ago was equipped with a 250-horsepower Corliss engine, a 2000-volt direct-current arc-light machine and a 100-kilowatt 1100-volt alternator, both dynamos belt driven from a line shaft. A shutdown would cause the city to be thrown completely in darkness and stop several small motor-driven factories, which were entirely dependent on the plant for power.

Early one morning the lights in the plant went out, and the trouble was finally located in the exciter which supplied current to the field winding of the alternator. There was a broken wire in the armature winding and it was so far in the coil that I could not splice it; bridging across the commutator bars was not feasible because the winding was grounded on the core.

As a last resort, I tried the following expedient, which worked very well temporarily: After rocking the brushes on the arc machine as far forward as possible and blocking them in that position, I ran two wires from the direct-current switchboard panel to the exciter terminals on the alternating-current panel, after disconnecting the exciter leads, and excited the alternator from the arc-light machine. The object in blocking the arc dynamo brushes forward was to prevent excessive voltage at the terminals of the alternator field winding.

M. V. MILLER.

Fort Snelling, Minn.

Mounting Trolley Wire Hangers in Mines

I have had a good deal of trouble with trolley-wire hangers in mines. Expansion bolts set in the ordinary way will not "stay put" because the rock soon becomes soft and the hanger is then easily pulled down. Finally I set the bolts in a mixture of cement and sand, half and half, enlarging the bolt hole and nearly filling it with the mixture, then pushing the bolt up in the hole, tightening the wedge and cementing it around the bottom. The result is a neat, inexpensive and permanent job; the hanger bolts do not pull out any more.

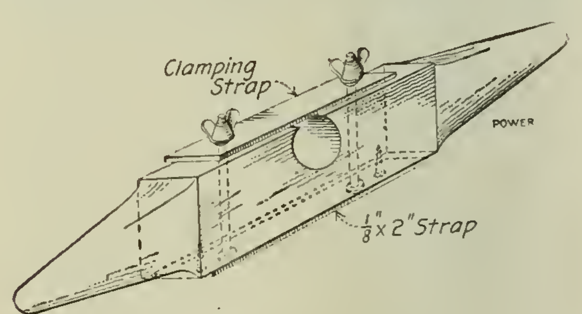
JOHN CULLOM.

Collinsville, Ill.

Another Armature "Stretcher"

Some time ago I saw a description in POWER of a frame made up of pipe fittings and used for carrying armatures. I had tried such an arrangement but had to give it up because I could not use it to advantage on account of narrow doorways and short turns and short flights of steps in the office building where our plant is.

I then made a pair of stretcher beams like the accompanying sketch, which I find to be more convenient. They are easily and cheaply made, do not take up much room and can be juggled around



A "STRETCHER" BAR

short turns. I made my pair out of the pine cross arm of a telegraph pole, which I sawed into two lengths, making each beam 28x5x2⅞ inches.

I shaved each end down to make a good hand hold, cut a circular "notch" across the center of the top edge and reinforced the bottom edge with a piece of ⅛x2-inch strap iron. The two ⅜-inch bolts which pass through the beam serve to hold the armature shaft in the circular opening, a clamping strap being forced down on the shaft by the thumb nuts on the through bolts.

I have six armatures, all of the same size, weighing nearly 400 pounds each, and with two men and one of the beams ahead and the same behind we can carry an armature very comfortably.

T. F. MCFADDEN.

Columbus, O.

Gas Power Department

Everything worth while in the gas engine and producer industry will be treated here in a way that can be of use to practical men

Elementary Lectures on the Gas Producer

By Cecil P. Poole

Usefulness of the Economizer

In one of the early lectures it was explained in a general way that the air which is admitted to the fuel bed is first passed through an "economizer," which heats it. The study of specific heat has

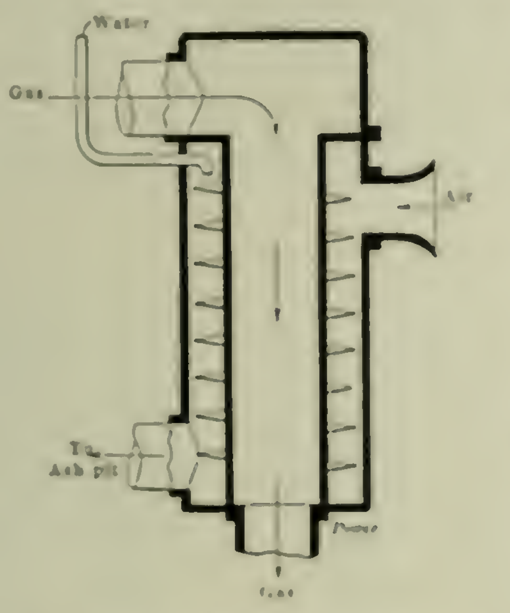


Fig. 2. Combined Economizer and Vaporizer

since put the student in position to understand more definitely the advantages gained by this process.

When the gas leaves the top of the fuel bed it is at a rather high temperature—somewhere around 700 to 800 degrees ordinarily. This is too high for use in a gas engine for reasons that will be discussed at some future time; for the present it is enough to say that the gas supplied to an engine should be as cool as possible.

If the gas should be cooled entirely by the water spray of the scrubber, a large part of the sensible heat in the gas would be simply carried off in the scrubber water and thrown away. Instead of doing this, some of the sensible heat is transferred from the gas to the air passing to the ashpit and carried back into the generator, thereby avoiding the taking of just that much heat from the fire zone to heat the air.

The saving effected by preheating the air with the outgoing gases will be made clear by considering the details of a practical case. Suppose a generator 3 feet 3 inches in diameter (across the fuel bed) gasifies 100 pounds of anthracite coal an hour; also, suppose that the coal contains 78 per cent. of fixed carbon, 1½ per cent. of hydrogen and 5 per cent. of moisture, the remainder being noncombustibles.

Further suppose that carbon monoxide is made with 66 of the 78 per cent. of carbon and carbon dioxide with the remaining 12 per cent., that one-fourth of the oxygen required for operation is obtained from steam and the remaining three-fourths from air. The operations will figure out as follows:*

Air supplied per hour, lb.	374
Steam supplied per hour, lb.	[illegible]
Steam units per hour, total	[illegible]
Gas made per hour, lb.	402
Refuse rejected per hour, lb.	15½
Heat energy in the gas, B.t.u.	980,100
Sensible heat per degree of temperature of the gas, B.t.u.	138½

The air contains

$$374 \times 0.77 = 288$$

pounds of nitrogen and argon, air being 23 per cent. oxygen, 76 per cent. nitrogen and 1 per cent. argon. For simplicity the argon is considered as nitrogen.

From the foregoing, the gas characteristics are as follows:

	Pounds		Cubic Feet at 700°		Per Cent. by Vol.	Sensible Heat per Degree	Heat Energy, B.t.u.
CO	[illegible]	=	[illegible]	=	[illegible]	[illegible] × 0.246 = [illegible]	[illegible]
H	[illegible]	=	[illegible]	=	[illegible]	[illegible] × 3.409 = [illegible]	[illegible]
CO_2	44	=	[illegible]	=	[illegible]	44 × 0.217 = [illegible]	0
N	288	=	[illegible]	=	[illegible]	288 × 0.243 = [illegible]	0
Totals	402	=	17,[illegible]	=	100	[illegible]	980,100

Specific heat = [illegible] ÷ 402 = 0.2815

The gas will leave the fuel bed at a temperature of about 785 degrees, Fahrenheit. Suppose that the air takes out of it only enough sensible heat to reduce its temperature 300 degrees. That will amount to

$$300 \times 138\tfrac{1}{2} = 41{,}550$$

B.t.u. per hour, because there are 402 pounds of gas delivered per hour and the specific heat is 0.2815, making the sensible heat per degree, for the entire quantity,

$$402 \times 0.2815 = 138\tfrac{1}{2}$$

B.t.u. (See details in the footnote.)

As the heat energy in the gas delivered to the engine is 980,100 B.t.u. per hour, it is evident that the heat saved by the economizer (41,550 B.t.u.) amounts to about 4 per cent. of that used in the engine. That it is a clean saving is undeniable; if the air were not partly heated by the outgoing gases it would have to be entirely heated by the fire in the generator and the heat in the gas would be thrown away in the scrubber water.

The 41,550 heat units taken out of the gas by the air will raise the temperature of the latter 468 degrees, because the specific heat of air is 0.2375 and there are 374 pounds affected by the 41,550 heat units;

$$0.2375 \times 374 = 88.825$$

B.t.u. required to raise the temperature of the 374 pounds one degree and

$$\frac{41{,}550 \text{ B.t.u.}}{88.825 \text{ B.t.u. per degree}} = 467.77$$

degrees, or practically 468.

Effect of the Vaporizer

The vaporizer also effects an important saving when it is arranged to use the heat of the outgoing gases to make the steam, as in the types illustrated by Figs. 2, 3 and 4. In all three of these the steam is made by the heat from the generated gas. Figs. 2 and 3 show combined vaporizers and economizers; in the type represented by Fig. 4 the air is preheated in an economizer before entering the vaporizer and picking up the steam.

Consider the case previously assumed. The generator was supplied with [illegible] pounds of steam per hour, and in order to make steam at this rate from water

*The figures given are derived in this way:

Oxygen required to burn 66 pounds of carbon to carbon monoxide, 66 × 1⅓ = [illegible] lb.

Oxygen required to burn 12 pounds of carbon to carbon dioxide, 12 × 2⅔ = 32 lb.

Total oxygen required, [illegible] + 32 = [illegible] lb.

Oxygen supplied by steam = [illegible] lb.

Remainder supplied by air = [illegible] lb.

Air required to supply [illegible] lb. of oxygen, [illegible] ÷ 0.23 = 374 lb.

Steam required to supply [illegible] lb. of oxygen, [illegible]	[illegible] lb.
Water in the coal	5 lb.
Steam brought in with air	[illegible] lb.
Hydrogen in 100 lb. of coal	1½ lb.
Hydrogen in the total of steam [illegible]	[illegible] lb.
Hydrogen in delivered gas	[illegible] lb.

of, say, 62 degrees temperature, 37.240 B.t.u. must be supplied per hour, because it takes 1120 B.t.u. to heat one pound of water from 62 to 212 degrees and evaporate it into steam at atmospheric pressure.

If these 37,240 heat units were not supplied from the sensible heat of the gas, they would have to be supplied from some other source; if they were so supplied, it would cost something to supply them, whereas they are there in the gas, ready for use, and would be thrown away if carried into the scrubber.

Adding this saving of 37,240 heat units

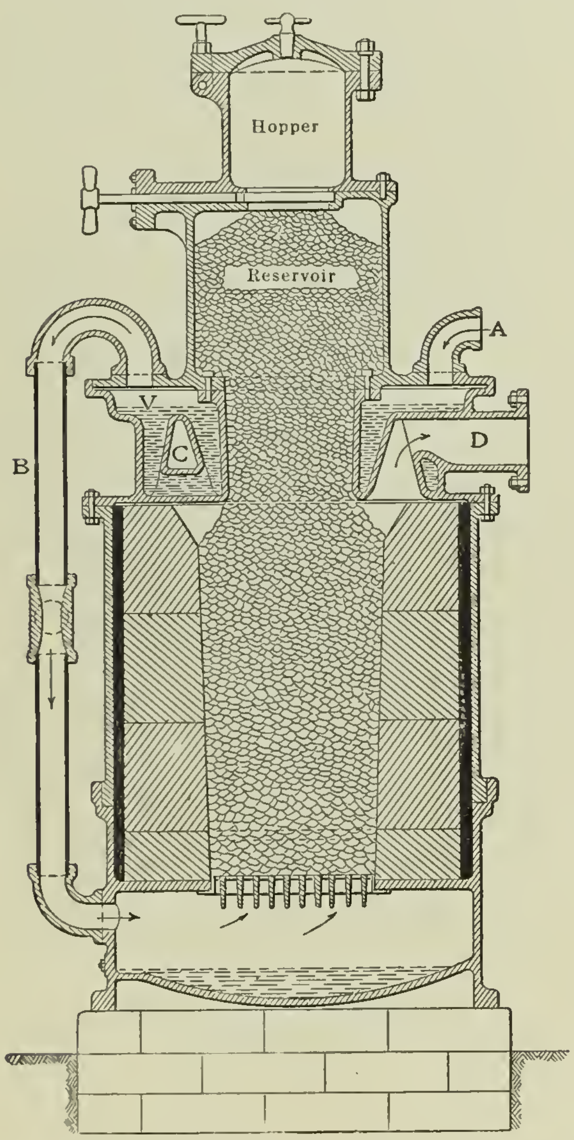

Fig. 3. Vaporizer Built in Top of Generator

by making steam to the 41,550 units of sensible heat utilized in heating the air makes 78,790 heat units per hour "rescued" from the gas on its way to the scrubber. This is the equivalent of

$$\frac{78,790}{2545} = 31$$

horsepower, theoretically, or nearly 8 actual brake horsepower at the engine.

The Scrubber's Share

When the gas finally reaches the scrubber its temperature will be much below 485 degrees, because of the use of sensible heat in making steam. As just shown, the total sensible heat used in heating the air and making the steam amounts (in the assumed example) to 78,790 B.t.u. an hour. The temperature of the gas will be reduced, therefore, by

$$\frac{78,790}{138\frac{1}{2}} = 568.9$$

degrees, instead of 300 degrees, and if we consider the effect of radiation it will be safe to assume a reduction of 570 degrees by the time the gas enters the scrubber. Its temperature then will be 215 degrees.

Suppose it is desired to cool the gas to 85 degrees in the scrubber. That is a temperature reduction of

$$215 - 85 = 130$$

degrees and it means that the scrubber water must take 18,005 heat units out of the gas per hour, because the sensible heat of the gas per degree* is 138½ B.t.u. and the temperature change is 130 degrees;

$$138\frac{1}{2} \times 130 = 18,005.$$

As the gas is to be cooled to 85 degrees, the temperature of the water cannot rise above that point; say it rises to 82 degrees and is at 62 when it enters. With this rise each pound of water will absorb 20 heat units and as there are 18,000 heat units to be absorbed per hour, there must be

$$18,000 \div 20 = 900$$

pounds of water passed through the scrubber per hour. In practice, a good deal more than this would be needed because it is impossible to make each drop of the water come into contact with its share of the gas.

Now, 900 pounds of water is not such a tremendous lot; at 62 degrees temperature it is 108 gallons. But suppose for a moment that the gas had not been cooled in the economizer and the vaporizer before reaching the scrubber. Instead of taking out 18,000 heat units an hour the scrubber would have to take out that much plus 78,790, or 96,790 heat units an hour. This would require about 580 gallons of scrubber water per hour instead of 108 gallons.

It would also be necessary to use a large scrubber, because efficient contact could not be obtained between the gas and five times the normal quantity of water in the same sized scrubber.

However, this final consideration is of minor importance, not only because it is indefinite but because the saving of heat makes it advisable to preheat the air and make the required steam with the waste heat that is in the gas when it leaves the fuel bed.

Vaporizing in the Ashpit

The figures just given show very clearly that the practice of making steam in the ashpit, which is necessary with some forms of generator, is rather uneconomical. A gas-producer attendant once told me, with the air of having discovered an important labor-saving feature in producer operation, that he had found the vaporizer unnecessary; all he had to do was to throw a couple of pailfuls of water in the ashpit the first thing in the morning and another one just before the factory started up after the noon hour. The heat radiated downward from the fire zone vaporized the water as the generator needed steam and he did not have to bother with regulating a flow of water to the vaporizer.

*Sensible heat per degree is the number of heat units that must be added to a given quantity of gas to raise its temperature one degree, or taken from it to lower its temperature one degree.

This plan of working has only one merit—it is a little easier to dump bucketfuls of water in the ashpit than to adjust the small drip in the water supply to the vaporizer. It entails two serious disadvantages: waste of heat and irregularity of gas quality.

It might seem that there is no waste of heat because the "heat is already in the ashpit," as my operator friend expressed it. The answer to that is that it is largely untrue. There is some heat in the ashpit, of course; it is warmer there than in the outside atmosphere, but the heat normally there is not enough to make the steam required by the generator.

In order to allow enough heat to pass down from the fire zone to water on the

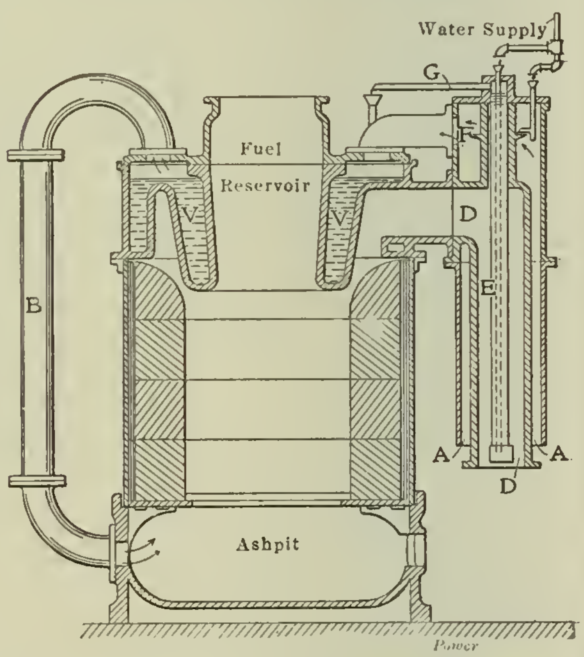

Fig. 4. Built-in Vaporizer and External Economizer

floor of the ashpit and vaporize as much as the generator needs, the bed of ashes beneath the incandescent coal must be kept thinner than it would otherwise be; this will permit more heat to escape from the fire than would get out under proper conditions. Moreover, with water in the ashpit the temperature there will be lower and, consequently, the flow of heat from the fire into the pit will be greater than if no water were there. Every heat unit taken from the fire *unnecessarily* is wasted, no matter what you do with it.

The quality of the gas is made irregular by this practice because more heat will flow from the fire to the ashpit immediately after ashes are shaken or poked out of the generator into the pit than immediately before; consequently, more hydrogen will be put into the delivered gas. As the ash bed beneath the fire zone increases in thickness, due to the combustion of coal, the heat passing from the fire to the water each minute or hour will gradually decrease, causing a decrease in the water evaporated and a resulting decrease in the proportion of hydrogen in the delivered gas.

In short, when the fuel bed is poked down or the grate shaken, the proportion of hydrogen in the delivered gas suddenly increases; then it gradually decreases until the next poking or shaking is done. And an increase in the proportion of hydrogen usually means an increase in the proportion of carbon dioxide and a corresponding *decrease* in carbon monoxide.

The reason for this is that increasing the proportion of hydrogen can be done only by increasing the proportion of steam passed through the fire; this reduces the temperatures of both the fire and the decomposition zones, and the reduction of temperature almost always reduces the percentage of carbon monoxide and increases that of carbon dioxide, as explained in the last lecture (January 10, 1911).

An Engine that Generates Its Own Gas from Coal

Another stride toward ultimate simplicity has been made. A. M. Low, an English engineer, has devised an engine which generates from coal the gas by which it is driven. The accompanying sketches illustrate the more important constructional features of a small experimental engine that has been in operation some time.

Fig. 1. Rear End of Engine with Generating Attachment

Fig. 1 is a view of the "breech" end of the engine, which is of the single-cylinder single-acting type with a horizontal cylinder. Several tubes pass horizontally through the combustion space of the cylinder, from the coal box at the right to the water-sealed gas box at the left; these tubes, where they lead from the cylinder to the gas box are indicated by the letter *A* and at other points by dotted lines. The tubes pass also through a distillation box *B*, where they are subjected to the heat of the exhaust gases as the latter leave the cylinder.

The coal box is filled with crushed coal and this is forced into the tubes just mentioned; when it reaches those parts of the tubes inclosed in the distillation box, the heat of the exhaust gases distils out the lighter volatiles in the coal and these are immediately taken out by the small branch pipes *C* and carried to the gas box. When the heavier constituents in the coal enter the tube sections which are located in the combustion chamber, they are heated to a very high temperature, of course. At this point, steam and air blown in by fans supplied with steam from the water jacket of the cylinder (this connection is shown semi-diagrammatically in the horizontal section, Fig. 2) act upon the carbon exactly as in a gas generator, forming hydrogen, carbon monoxide and carbon dioxide.

These final gases pass on to the gas box, which is really a small holder, where they mix with the volatiles previously distilled out of the coal. From the holder the gases pass to the inlet-valve chamber of the engine, where they are mixed with air, in the usual way, before entering the cylinder.

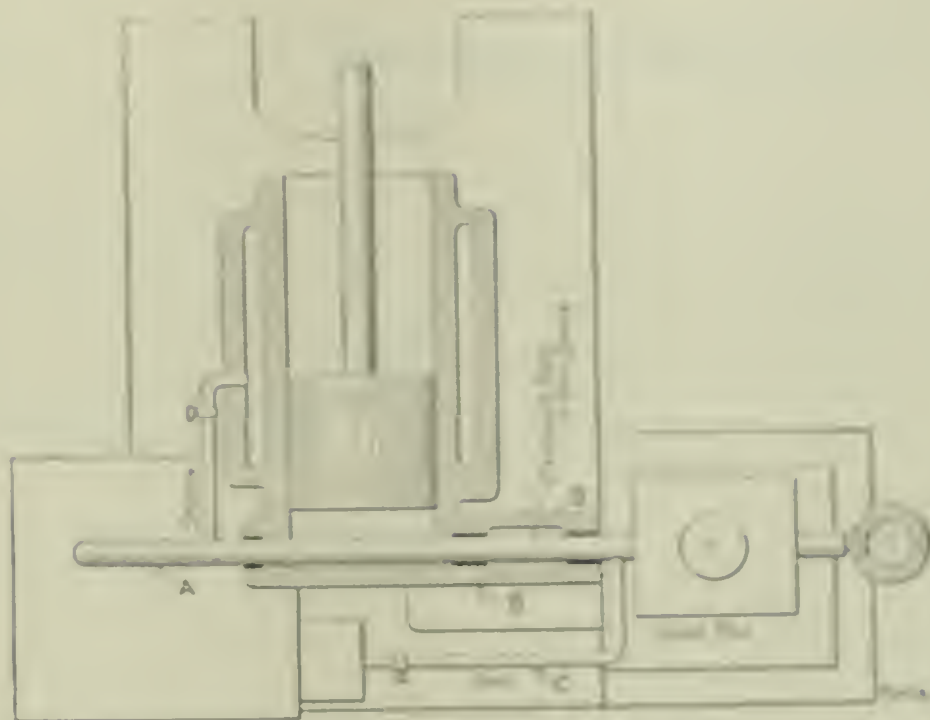

Fig. 2. Horizontal Section through Cylinder

The mechanism for feeding the crushed coal into the gas-making tubes consists of a number of archimedean screws, each arranged as represented in Fig. 3. In the engine illustrated by Fig. 1 there are four gas-making tubes; coal is forced into each of these by an individual screw and the four screws are gear-driven from a single vertical shaft. This shaft is driven through an adjustable clutch by a belt from some part of the engine mechanism and the governor controls the clutch so as to vary the supply of coal according to the load conditions.

Fig. 3. Coal Feed

The inventor claims that his experimental engine has shown a fuel consumption of ¾ of a pound of coal per brake horsepower-hour; also that the coal is "cracked" so quickly by the high temperature that all hydrocarbons can be passed through the engine and discharged without any difficulty. Several weeks of running, he states, have failed to show any tar or lampblack. The producer part of the outfit works on practically the "Dowson" system, the coal being fed in minute quantities as needed and immediately gasified.

We are indebted to Gas and Oil Power for the general information and the illustrative material utilized in the preparation of this article.

Readers with Something to Say

Practical information from the man on the job. A letter good enough to print here will be paid for. Ideas, not mere words wanted

Pumping Water by Air

A State institution has a well that is 135 feet to the water, and it is 57 feet to the top of a tank into which the water is to be delivered. They wished to do the work by means of air, and had a 15-horsepower gasolene engine and an 8 and 4 by 8-inch two-stage air compressor set up, the latter to run 265 feet piston travel per minute. The engine had a 34-inch pulley and the air compressor had a 42-inch pulley.

The air line extended down 285 feet below the water level.

As the engine would not do the work, I decided, after a night's sleep, to make it do it. The intake was bushed from 3 to 2 inches and a close nipple and a globe valve were screwed in the 2-inch opening. The valve was partly closed and the trick was done. By opening the valve, all the air that the engine could pull could be admitted and all the water that the 15-horsepower engine could supply air for was obtained. I think that if the pulley on the engine were reduced to 24 inches in diameter, so the intake could be opened to its full size, better results might be obtained. Would this be the means of producing any more water, the engine running at the same speed? I would like to hear from those who have had a similar experience.

H. T. Fryant.

Mobile, Ala.

Distant Control Valves and Oil Indicating Scheme

During a recent visit to a large pumping station I was much interested in the arrangement made use of for operating the service gates and heavy valves in the neighborhood of the station. Many of them were of several tons weight and all were operated by hydraulic pressure from the engine room.

The water used in the operation of the gates was pumped to an ordinary pressure tank where a pressure of 160 pounds per square inch was maintained. It was admitted to the cylinder at the top or bottom as desired, by a four-way valve, which also serves the double purpose of admitting pressure upon the side of the piston necessary to operate the gate, and that of opening a means of escape for the water already contained in the cylinder to the return tank.

The operator can control the gates with perfect ease by means of a small hand lever upon the control board. The opposite end of this lever is extended beyond the valve stem a few inches and serves as a pointer indicating upon a quadrant which way the four-way valve is open.

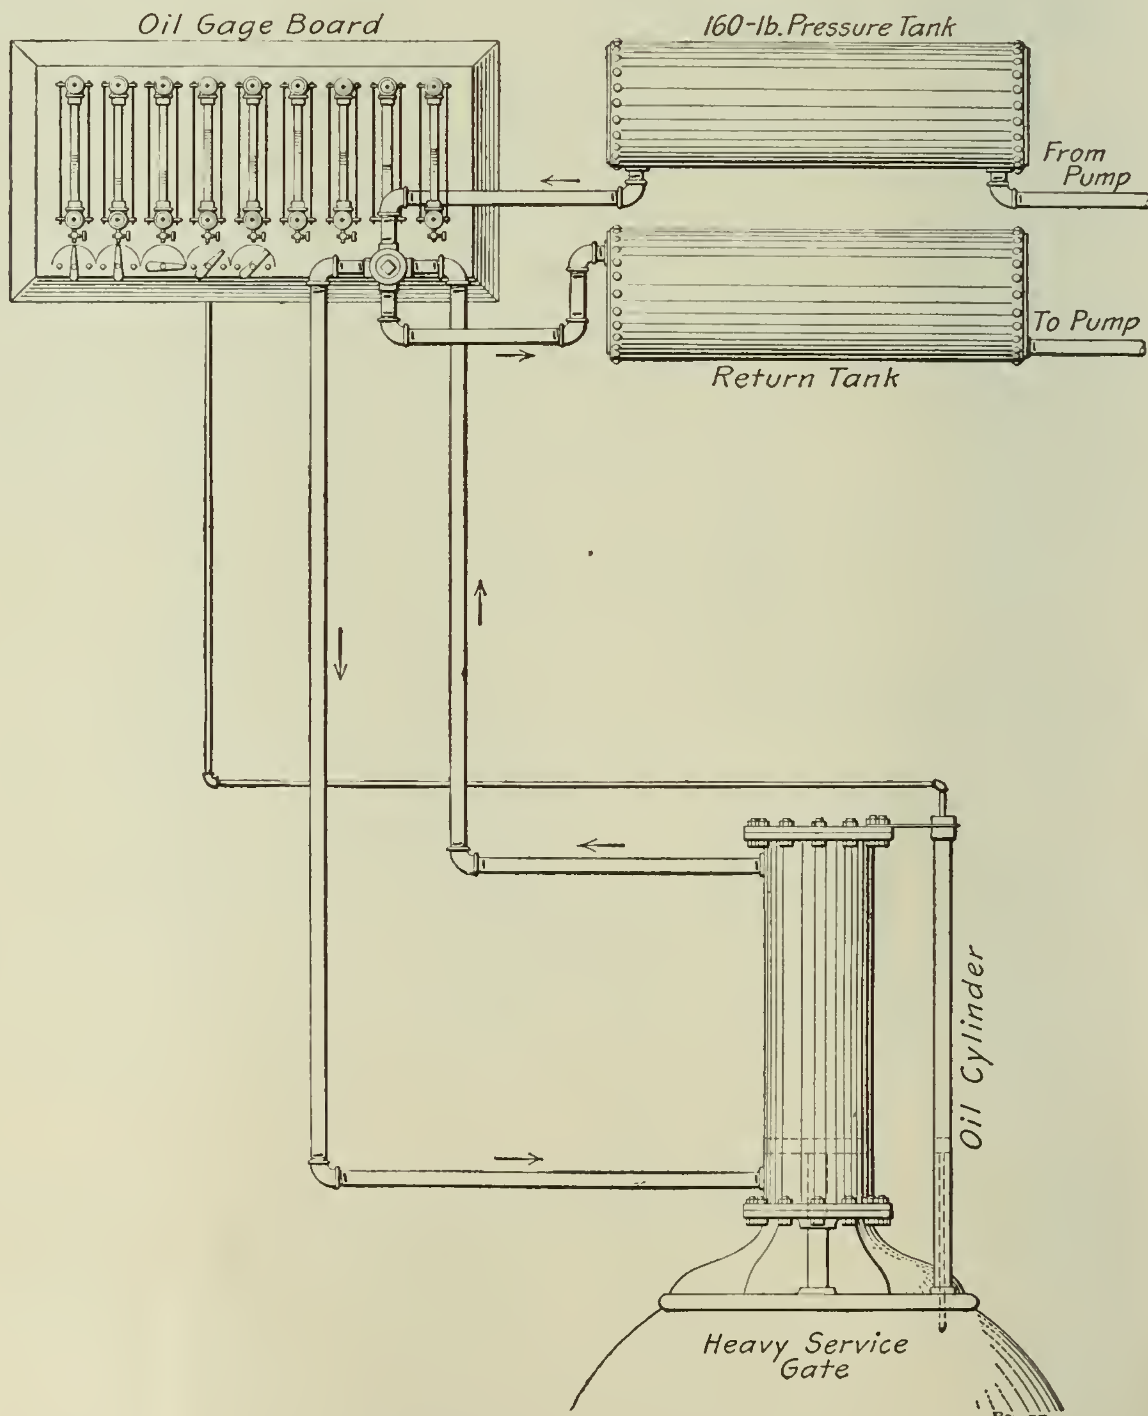
An interesting oil-indicator scheme has also been worked out. A tail rod is attached to the valve disks in the conduits, which plays up and down with them.

This rod operates a piston in a small cylinder of the same length as the large ones.

This cylinder is filled with oil, also the pipes which run to the control and gageboard. There is a gage glass for each valve where its position is plainly indicated by the hight of the oil.

When a gate is open, the corresponding oil gage glass will be nearly full. The tail rod forces the oil up out of the small piston and when it is closed the conditions are reversed.

A little difficulty was encountered when



Showing Piping of Indicating Device

the system was first installed, due to air bubbles in the oil, which would give an incorrect reading, and some experimenting also had to be done before the proper oil displacement could be gotten at to keep the range of altitude right for the glasses. The first difficulty gradually adjusted itself after the system of piping was opened at the highest point. The second trouble was overcome by the establishment of a common reservoir for all the lines at the top of the gageboard. It serves as a sort of an overflow tank and replenisher. The accompanying sketch gives an idea of the scheme. One pump, pressure tank, return tank, etc., are used in common for handling all heavy gates about the station. Only the four-way valve and piping for one are shown.

EDWARD T. BINNS.

Philadelphia, Penn.

Reduced Discharge Pipe Increased Motor Load

In the plant where I am employed, there is an 8 and 7 by 10-inch steam pump and a 5½x8 triple-plunger power pump, driven by a 10-horsepower motor. This outfit furnishes the town with water, but the former pump is used only in case of emergency.

Upon taking charge of this plant I looked over the pump-piping layout and found the suction and discharge pipes to be 4 inches in diameter. The discharge pipe from the power pump had been reduced to 3 inches by putting a bushing in the pump flange and one in the main discharge pipe with a nipple between.

The old pipe was removed and a new 4-inch pipe was put in its place, and it was found that the motor load was reduced from 6.2 to 5.2 kilowatts per hour. This was partly accounted for by the fact that the old pipe was badly scaled.

T. K. LEE.

Benson, Minn.

Temporary Pipe Repair

A 2-inch supply pipe to an overhead tank was allowed to freeze and when thawed out was found split open for about 30 inches. The tank was situated at the top of a steel tower some 70 feet in hight.

This 2-inch supply pipe, a 3-inch discharge pipe and two 1½-inch steam-heating pipes ran up the center of the tower inside a wooden casing. The leak was about 50 feet from the ground.

Owing to the close proximity of the other pipes it was not possible to use the pipe cutters, and it seemed that the only alternative was to remove the casing and pull down a long run of pipes.

However, it was decided to put a patch on the pipe until the weather should become milder. A piece of 2½-inch pipe, 36 inches long, was procured and cut lengthwise into two equal parts.

One-half was retained and lined with sheet rubber. This was placed over the leak and drawn firmly up to the pipe by means of four clamps placed about 10 inches apart.

This effectually stopped the leak.

WILLIAM WATT.

Lambton Mills, Canada.

A Condenser Accident

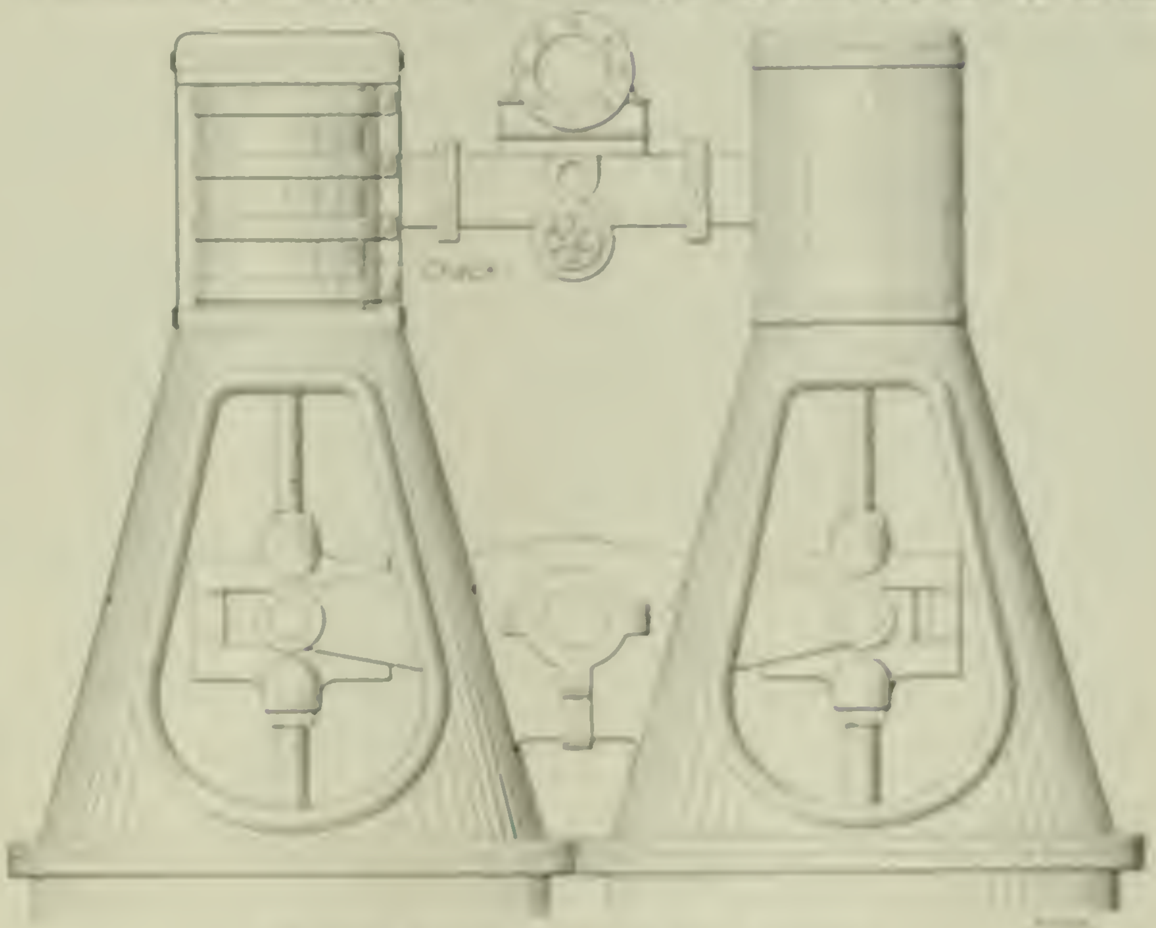
A large compound jet condenser had been used in a power station for about five years. The high- and low-pressure piston rods were connected by means of crossheads and wristpins on the end of a rocker beam that was pivoted in the center.

The valve gear was automatic and often caused the pump to hang up whenever the valve stuck, which reduced the vacuum. Requests had been made to have a valve rod connected to the beam, but without success.

A cylinder head had been blown out of the high-pressure cylinder soon after it had been installed. Some time later a new cylinder was put on because a thin wall had been discovered when drilling a hole to allow a quicker flow of steam to aid in operating the main valve. Everything went as usual after the new cylinder had been put on and the men predicted the pump would always be a hoodoo in the plant, owing to its design.

Last winter it refused to work and an examination revealed that the low-pressure cylinder had cracked on one side the length of the cylinder.

Temporary repairs had to be made and as the low-pressure cylinder worked under a low steam pressure, it was decided to put a strip of gasket rubber over the crack and a flat strip of iron over the gasket to hold it tight. Bands fitted with draw bolts were made of such a length as to go around the cylinder over the strap. They were then bolted tight, as shown in the illustration, and made the crack tight enough for service, although there was some leakage at the flanges.



HOW THE CRACKED CYLINDER WAS REPAIRED

The condenser was run this way for nearly six months when two new high-pressure cylinders were put on, also, a new valve and steam chest, the valve having a rod connected to the beam, which made the action of the valve more regular and positive with each stroke.

Just what caused the cylinder to crack is not known, but when the piston, which was of the solid type, was taken out, the lower packing ring was found broken and a piece had worked over into the other slot where the ends of the ring were found to have worn thin. The thin end of the broken ring extending over the edge of the slot had become wedged between the piston and the wall of the cylinder. When the piston was on the downward stroke the force from the high-pressure cylinder transmitted through the beam, together with the weight of the descending bucket, probably caused the fracture. But how the piece of ring got over from the bottom slot into the top one, is most mysterious, as it could not have overridden the intervening 8 inches, the thickness of the piston, or swing enough to allow the top ring to spring out, or it would also have been broken.

R. A. COLLINS.

Cambridge, Mass.

Manhole Gaskets

Perhaps my method of putting manhole gaskets on manhole plates will be of interest. I take any good make of ⅝-inch round gaskets for the manhole, but, before using, the plate is cleaned with a sharp tool, and a mixture of either red or white lead and boiled linseed oil with a consistency of a thick paint is applied to cleaned surface. The gasket is cut to the proper length and the lead tube inserted in both ends and the joint taped.

Then a coating of graphite and cylinder oil is applied on the exposed side of the gasket and the plate is then placed in position in the manhole.

Before removing the plate again, I take a sharp tool and mark it so as to always replace it in the same position.

When removing the plate the gasket will stick to it, and it is only necessary to trim off the overhanging parts of the gaskets and apply a coating of graphite and cylinder oil before replacing it.

I have used this method for many years with success and have used the same gasket twenty times or more, without leakage, before replacing with a new gasket.

E. L. Morris.

Salem, Va.

Boiler Setting

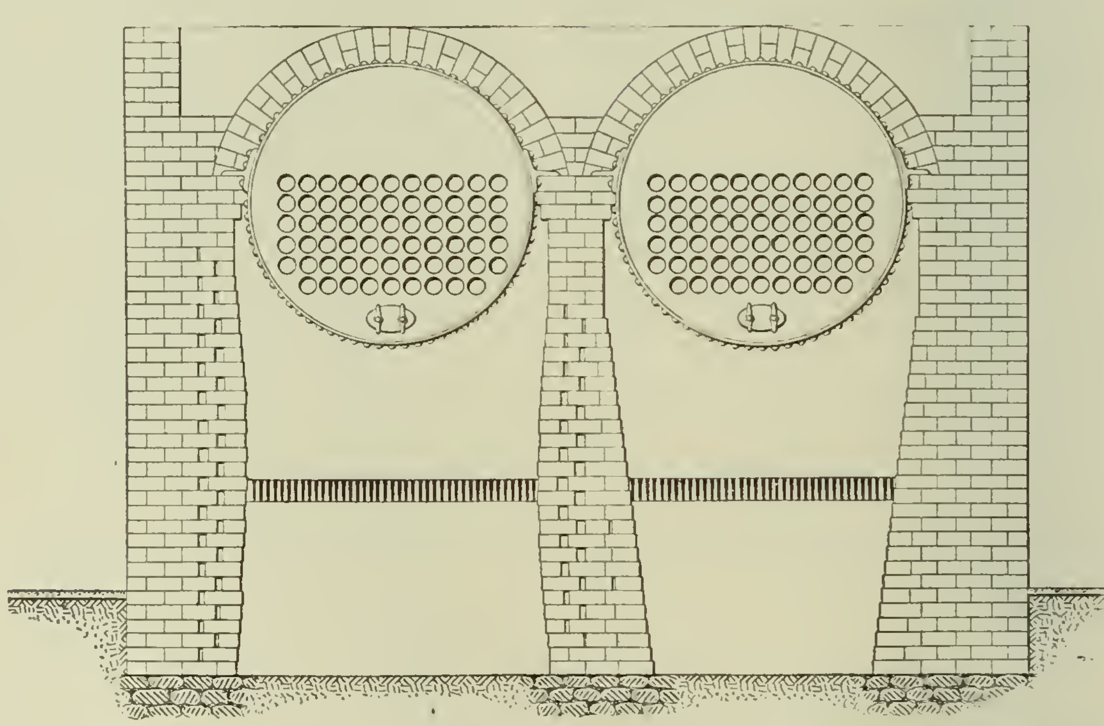
Perhaps a job of repair work which was recently done on the brick settings of some horizontal tubular boilers may be of interest. There were four 5x18-foot horizontal return-tubular boilers, set in batteries of two, each boiler supported by lugs resting on wall plates in the usual way.

For some reason the walls were never properly built, the furnaces having been made with thirteen courses of firebricks on the side walls before any headers were reached, and the bridgewalls had been faced with bricks laid flatwise to the grate surface. The side walls of the combustion chambers were laid up with common red brick, the joints being from ⅜ to ¾ inch thick, and considerable lime had been used in the mortar. Further, from twelve to fourteen courses of bricks had been laid up before any headers were tied into the wall. As a result the mortar worked out of the walls and the heat caused the walls to bulge in about 6 or 7 inches, and one side wall fell into the combustion chamber before the boiler could be laid off for repairs.

The furnaces were first repaired by taking down the wall and rebuilding the lining, cutting in a course of headers at the sixth course above the grates and using a good grade of firebrick, and fire clay so thin that it could be put on very thin, which allowed the bricks to come practically brick to brick, only clay enough being used to fill in the unevenness of the bricks.

The rear wall was quite another proposition, as it was not advisable to tear down the whole of the wall if it could be avoided, although that was what I recommended be done and an entire firebrick wall be built in its place.

The combustion chamber of these boilers had been carried down to within about eight inches of the ashpit level as there were many reasons for not entirely rebuilding the wall. As much of the face of the wall as was deemed safe was removed, after the boiler had been blocked up to prevent accident, and at the bottom of the combustion chamber the wall was brought out 14 inches and then built up to a hight nearly to the lugs and under a course of headers, above which the wall was sound. This wall was stepped in about one-quarter inch for each course and was all of firebrick, laid close together and headers every fifth course. The old red bricks were used as backing to the firebricks. These walls were carried from the bridgewall back to the rear wall on all four boilers.



Condition of the Old Furnace How the New Furnace was Bricked

The bridgewalls were taken down far enough to allow firebricks to be set in edgewise and was lowered 4 inches, so that it is now 13 inches from the boiler shell, whereas, before it was but 9 inches. The changes can perhaps be better understood by referring to the right-hand view, which shows the side walls as they are at present.

These boilers steam much easier than before and lowering the bridgewall has increased the draft considerably. As the center wall has a batter on both sides, built entirely of firebrick, it is expected that these repairs to the combustion-chamber walls are good for the life of the boilers, and so far the results have been better than was expected.

Return-tubular boilers are set too low in most cases for soft coal. From my observation a 72-inch boiler should be set at least 40 inches if not 48 inches above the grate bars, and plenty of room left for the combustion of the gases.

One experience I had some few years ago, on some large boilers which were set high, has convinced me that any engineer having the matter of setting new boilers in hand can do no better than by setting them high above the grates for soft coal, with good, thick walls and headers every fifth or sixth course, thin joints on the outside walls, all firebrick surfaces practically rubbed together, a low bridgewall and plenty of room between the rear wall and the rear head of the boiler. The first cost may be a little more, but it will be found a first-class investment.

William S. Trofatter.

Boston, Mass.

Starting a Plunger

An old, rusty steamboat doctor had been idle for over a year, and the plungers were stuck tight.

Every available suggestion was tried but it would not "break loose" even with a heavy leverage upon the flywheel, and even coal oil had not touched every part of the surfaces in contact, though a large quantity had disappeared.

Someone tucked some oily waste around the top of the plunger and then set fire to it, which was followed by an explosion. No damage was done and the plunger was loosened.

The same scheme was carried out on the other plunger, but less oil was used and the waste was put in and set on fire before much oil had time to soak down.

This method of loosening a pump plunger is not to be recommended, and is more or less dangerous.

Questions Before the House

Comment, criticism, suggestions and debate upon various articles, letters and editorials which have appeared in previous issues

Expansion Valve

Of late several letters have appeared in POWER under the above head. Some of the writers seem to be under the impression that engineers apply the term "expansion valve" to the feed valve through ignorance of the principles of refrigeration, but that is not the case. We get the term from the builders of ammonia valves and fittings, and the use of it is no more incorrect than the use of such terms as "expansion coil" or "flooded system."

R. E. HENSLEY.

Hico, Tex.

Blowoff Piping

In the December 20 issue, Edward Hamilton described the blowoff arrangement for his boiler. O. B. Critchlow in the January 24 issue criticizes it, claiming that it is in no way satisfactory to him. He thinks that all of the circulation would be due to the condensation in the small riser, which would be of no practical value. I think that he is in error, for in my experience the device works satisfactorily. Further, it is recommended by boiler inspectors.

W. STEINDORFF.

Brooklyn, N. Y.

The Benefit of Organization

I have been following the items in POWER on engineers' wages. Strive as we may our wages will never go up, unless we all join and form an organization of some kind, and "stick together." Nowadays if an engineer demands more pay, no matter how good a man he is, the employer will say "Well, if you can't work for the wages you are getting, we can get someone that will work for even a little less." He will not stop to think, "Is my next engineer going to be capable of handling my expensive machinery?"

I have been in the employ of one company for the last eleven years and have been engineer for six years in charge of one 150-horsepower Corliss engine, one 75-kilowatt generator, seven motors, ranging in capacity from ½ to 12 horsepower, and one 200-horsepower water-tube boiler. I have all of the repair work to look after, and still can not convince my employer that I am worth more than some of the men working in the factory, running one machine for ten hours a day.

But, then, whose fault is it? Surely we cannot blame the employer. In a way, it is the engineers' fault. As I said before, why not stick together and form an organization. Then we can demand higher wages, and not until then.

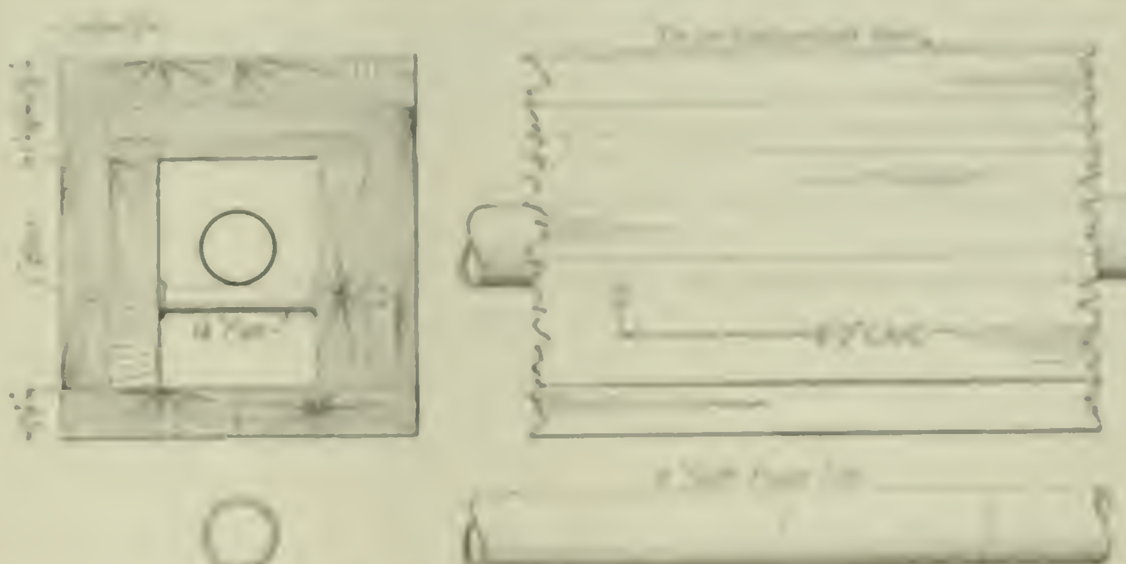
CHARLES GOTSTEIN.

Algoma, Wis.

Underground Pipe Protection

Having seen several articles in POWER on underground steam-pipe protection, I submit the accompanying sketch showing the construction we have used with good results.

Opinion may differ as to the proper size of the space for the pipe. For a 4-inch pipe the inside width should be about 8 inches, the inside depth about 12 inches and the rollers about 4 inches above the bottom. The 1½-inch insulation space at the sides may be filled with shavings to good advantage. If desired, the top of the box can be covered with old tin or galvanized iron so that the water cannot soak through the top of the box. The rollers are made of old 1½-inch pipe and 1-inch bolts or rods so that when expansion occurs the pipes will be free to roll.



BOXING FOR UNDERGROUND STEAM PIPES

In case the soil is very wet, a 3- or 4-inch field tile should be laid about 3 inches under the box to drain the water away. If several hundred feet of pipe are laid in a direct line in the box and a leak occurs the pipe can be disconnected at both ends and then easily drawn out and repaired; a rope should be secured to the one end so when the pipe is repaired it can easily be drawn back in place again. In this case the cost of digging and searching for the leak, and the time lost in replacing the dirt can be saved, which is quite an item.

W. H. WOLFGANG.

Toledo, O.

Reliability of Test Figures

The editorial in the February 7 number under the above title is quite true. I firmly believe that one of the greatest hindrances to engineering progress today is the overconfidence which the average man has in his own work and the readings and results obtained by himself.

Erroneous results of gas analyses made with the Orsat apparatus have undoubtedly occurred hundreds of times. In the majority of cases the operator is not as inquisitive as the one referred to was, and fails to learn the cause of the inaccurate results; in fact, many are unable to tell when the results are right and when not.

The trouble described can easily be avoided by having the tubes in the front leg of the pipette supported on a spiral wire so that none of them will drop in to the small U-tube connection through which the liquid passes back and forth between the two legs of the pipette.

F. G. BAILEY.

Boston, Mass.

I was interested in the editorial headed "Reliability of Test Figures" in the issue of February 7, especially that part relating to the Orsat apparatus, as we had the same trouble recently in analyzing producer gas. In all previous tests we had obtained only a trace of oxygen, generally none. All at once we began to get anywhere from 4 to 11 per cent. The action described in the editorial was all there. We thought that the new reagent was at fault and emptied it out of the oxygen pipette at which time we found that one of the little glass tubes had slipped down into the neck of the pipette. We got all of the tubes up into the body of the pipette, put the reagent back, made an analysis and the percentages ran about as they should.

J. O. Benefiel.

Anderson, Ind.

Capacity of Refrigerating Plant

The article under the above in the February 21 issue contains errors.

The total heat transmission,

$3.43 \times 484 \times 55 = 91{,}307$ *B.t.u., not* 91,770.

After having ascertained the number of B.t.u. to be abstracted it is useless, and not customary, to convert this quantity into "pounds" (ice-melting effect), because in dividing B.t.u. by 288,000 the capacity of the compressor in tons refrigeration per 24 hours is obtained directly. For 12 hours' run simply use 144,000 as the divisor.

The temperature of ammonia evaporating under a back pressure of 27 pounds gage is 14 degrees Fahrenheit. As the room temperature is to be 35 degrees, the difference will average 21 degrees. A lineal foot of 1¼-inch direct-expansion pipe will abstract between 9.6 and 13.7, say on the average 12, B.t.u. per 12 hours for each degree difference; hence, in our case 252 B.t.u. For 12 hours' run we, therefore, require only

$91{,}770 \div 252 = 364$ *lineal feet of pipe,*

not 3500 or 4000 feet as was given. With 3500 feet of piping properly distributed there would be absolutely no storage space left in the size of refrigerator under consideration.

To operate for only 6 hours continuously is bad practice, because of the incidental fluctuating temperatures which are injurious to the goods stored, their temperature having to be reduced to below 35 degrees in order to counteract excessive temperature rise during the 18-hour period of shutdown. The proper way then is to use brine-storage tanks which continue to refrigerate after the machine is stopped. When, however, expansion pipes only are employed, the machine should be run mornings and evenings. With but 6 hours' continuous operation, provided the goods can be cooled down in so short a time, we require not only twice the amount of piping needed with 12 hours' run but rather more, say 800 feet (as against 6400 feet) because toward the end the temperature difference will be small. Rather than crowd in the 800 feet of pipe, the machine should be proportioned to do its work with ammonia gas at some temperature lower than 14 degrees.

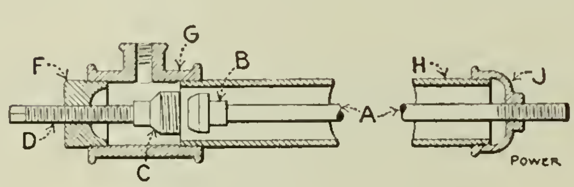
One receives the impression from the article that for 6 hours' run *less* than double the amount of piping needed for 12 hours is sufficient, while, as shown above, *more* than the double amount is required, at the same back pressure.

Charles H. Herter.

New York City.

Homemade Trap

I saw in the January 31 issue of Power a description of a homemade steam trap, by George J. Little. I have had a good deal of experience with traps of the same general type, and find that they give excellent service. They can be so constructed that there is practically no loss of steam. The outlets from all of our traps of this kind are exposed; in operation there is a flow of water, then a barely perceptible puff of steam which instantly stops. Good satisfaction may be secured by making the brass pipe from 18 to 24 inches long. This allows a sufficient movement for satisfactory operation.



A Homemade Trap

The construction of the traps which we make is shown in the accompanying figure. The pipe *A* is of brass, the size depending on the amount of water to be handled. This pipe is threaded on both ends. One end screws into the half *B* of a ground brass union, the other into the reducing coupling *J*. Enough thread is cut on this end to allow for a connection to the system to be drained. The coupling, in turn, goes onto the piece of iron pipe *H* which is large enough to contain the two parts of the union. On the other end of the iron pipe is a tee *G*, with its side outlet connected to the discharge for the water. Screwed into this tee is a reducing bushing *F*, through which passes the solid rod *D*, with a squared outer end, connected to the other half *C* of the union. This rod affords a very easy method of adjusting the relative positions of the two parts of the union.

The advantages of this trap are its uniform reliability, ease of adjustment to prevent loss of steam, and the simplicity of its construction.

Vacuum for Reciprocating Engines

I cannot but feel a little sorry for the young engineer who learned some facts about steam distribution in engines and then lost confidence in his knowledge when confronted with the arguments of John H. Ryan, as presented in Power for January 31. It seems hardly possible that the young man was considering the change of the low-pressure cylinder to permit of expansion clear down to 28 inches vacuum—producing a sharp point on the indicator diagram. The 36-inch low-pressure cylinder of the engine (an 18 and 36 by 48) would probably be operated with a terminal pressure of from seven to ten pounds absolute, according to load. An improvement in the vacuum would not imply an increase in cylinder dimensions, but only a little greater drop at the end of the diagram.

I am ready to credit the young man's next statement, that a well designed new engine in the same town was being operated with 28 inches of vacuum. His instructor's bet—that indicator diagrams from that engine would show the exhaust valves opening early in the stroke, with the cylinder pressure falling to the exhaust back pressure (28 inches of vacuum) by the end of the stroke—was safe. What well designed engine would be operated otherwise than with the exhaust valves opening early enough so that the forward-pressure line would fall to the back-pressure line at the end of the stroke, or very shortly after? A later opening of the exhaust valves would cause what every engineer knows as a "toe" on the end of the diagram.

The fact is, the young student was right in principle, but perhaps failed to make sufficient drawback allowances when estimating the saving to be realized by the proposed condenser improvements. He was right in believing that a pound pressure removed from the front of the piston is equal to a pound applied to the back. He was also right in suggesting a larger air pump for a higher vacuum as a means of increasing the economy of the plant. The larger pump would have to handle twice the quantity of entrained air and noncondensable gases, not twice the volume of vapor or steam, when the vacuum increases from 26 to 28 inches, and the volume of the air would, of course, be much less than the total volume of the vapor exhausted from the engine into the condenser, therefore, much less than 60 additional cubic feet volume per pound of steam, upon increasing the vacuum from 26 to 28 inches. Air-pump operation costs the same, whether the steam comes from cylinders or turbines; why use 28 inches vacuum on a turbine, if the cost to produce the higher vacuum is as much as the gain?

In regard to cylinder cooling and the consequent initial condensation, the terminal pressure due to the expansion of the steam in the cylinder has more effect than has any subsequent terminal "drop" or free expansion of the exhaust into the condenser. If the compound engine of this argument were operating with a mean effective pressure, referred to the low-pressure cylinder, of 40 pounds, the removal of 2 pounds back pressure, by increasing the vacuum from 24 to 28 inches, would make it necessary to cut off enough earlier to reduce the average forward pressure by 2 pounds in order to keep the same area in the indicator diagram. This indicates, roughly, a saving of 2/40 or 1/20 of the steam, against which there would be some increased losses, so that the full 5 per cent. saving would not be realized; but as large compound engines often operate on lower mean effective pressure than 40 pounds, I am not convinced that the ambitious young engineer was all wrong in expecting to save enough coal to justify a better vacuum than 24 inches.

S. H. BUNNELL.

New York City.

It looks to me, after reading J. H. Ryan's article in the January 31 issue, that he tried hard to throw dust in the young refrigerating engineer's eyes concerning this low-vacuum theory for reciprocating engines. I believe that the young fellow knew better but had not the argumentative tact necessary to pin Mr. Ryan.

Of course, I do not believe that 28 inches of vacuum makes for economy in this size of engine, but neither do I believe it would prove economical were the cylinder twice as large. What has the size of the low-pressure cylinder to do with the degree of vacuum attainable or maintainable by the condenser? I always thought that consideration of the power required to drive the air pump and the amount of heat to be supplied to the feed water by the primary heater determined the economical degree of vacuum, provided there was sufficient cooling water to be had. During my experience with a number of compound engines of different cylinder ratios, I never yet was able to take a diagram where the low-pressure steam expanded to the temperature of the vacuum, before the exhaust valve opened. Therefore, did Mr. Ryan expect to overawe the engineer by all that talk about the expansion laws of gases, and did he think the young fellow swallowed such statements that he would require a 60-inch low pressure cylinder and 500 degrees of superheat to obtain 28 inches of vacuum? What did all these engineers who operate a compound engine, having a low-pressure cylinder of 30x48 inches think on reading the statement that 21 inches of vacuum is all they should carry if they would run their engine to the best advantage?

In one paragraph Mr. Ryan allows something sensible when he states, "I admit that anyone could get 28 or more inches of vacuum if he had water enough." That is just what the young engineer was after, the very thing that Mr. Ryan was called to settle—the question of obtaining more and cooler water. It seems to me that he should proceed to show (if it were true) how the interest on the initial expense would offset in dollars and cents whatever gain resulted from an increase of the vacuum. Instead of that, however, he wants to wager that the exhaust valves of the cotton-mill engine open for release before the piston reaches the end of the stroke. Of course, the young engineer did not take him up. Would you?

Further on he states, "There would probably be more than six pounds absolute pressure in the low-pressure cylinder when the exhaust valve opened and all this heat would be rejected into the condenser," when 28 inches of vacuum was carried on the cotton-mill engine. Now, would there be any less heat rejected if 21 inches was the rate of vacuum carried? Is it common sense to assume that the higher the vacuum the higher the terminal pressure? Toward the end of the article he states, "Reciprocating engines running with complete expansion to a high vacuum do not show as good results (as turbines) because the loss from the cylinder condensation is high," meaning thereby, from what can be gleaned from preceding paragraphs, that most of the condensation takes place in the low-pressure cylinder if a fair vacuum is maintained. Now, taking Mr. Ryan's example of 15 pounds receiver pressure, I would like to ask in which cylinder is the greater condensation in the following case: The high, assuming the common absolute pressure of 165 pounds and a back pressure of 30 pounds; or the low, which expands this 30 pounds absolute pressure to an absolute back pressure of 2 pounds? It is commonly asserted, and generally believed that cylinder condensation is due to the difference in temperatures between the initial and the exhaust steam in each cylinder. Presuming this to be correct, Mr. Ryan, when considering the question, may neglect the fact that usually, due to a "drop" in the receiver, the initial steam of the low-pressure cylinder is dryer than that of the high-pressure cylinder.

C. HOONAN.

Saxonville, Mass.

Engineer or Laborer

The editorial under the above caption in the January 31 issue is one of the best I have ever read. The employment of such men as the quoted advertisement would undoubtedly bring out, probably is responsible for more waste and accidents than any other single cause. I remember one plant in which low-grade men were employed on the night shifts, there always was enough repair work to keep one or two men busy all the time.

Besides the man who does not know, the man who "boozes" is one of the most dangerous that can be employed in a plant. I remember a case where three high-speed engines were put out of commission on account of a night engineer who would "booze." The next day was a busy one for all hands, getting those engines into shape again. This man had been in the habit of "hitting it up" and then depending upon an assistant to carry him through. Because he ill treated his assistant the man stayed in the boiler room at his post and away went the engines. After that the management hired a higher-priced and more reliable man.

C. R. McGAHEY.

Baltimore, Md.

Plant or Unit Efficiency

One is frequently startled by the news that someone is producing a kilowatt-hour on something like 2.25 pounds of coal. Hence, it was with much pleasure that I read the editorial under the above caption in the February 7 issue.

My idea of the way in which to get the coal consumption per kilowatt-hour is to divide the pounds of coal consumed each month by the electrical output minus the quantity of current used by the electrical auxiliaries.

For instance, if there are 5000 tons (2000 pounds per ton) of coal in the bunkers at the first of the month and 15,000 tons are received during the month and if 4000 tons are left over at the end of the month, it is evident that 16,000 tons, or 32,000,000 pounds, of coal have been consumed.

Now, if the output of all of the generators is 9,000,000 kilowatt-hours and the consumption for station lighting and for driving the electrical auxiliaries, such as motor-driven wet pumps, motor-driven circulating pumps and motor-driven exciters, is 1,000,000 kilowatt-hours, the net output to the line is, evidently, 8,000,000 kilowatt-hours, and the coal consumption, four pounds per kilowatt-hour.

Now, to figure in another way, suppose that two 5000-kilowatt machines make a kilowatt-hour on 15 pounds of steam, that another uses 16 pounds and that four engine-driven 3000-kilowatt units use 17 pounds. With an evaporation of seven pounds of water per pound of coal, in the case of the machines consuming 15 pounds of steam it is the idea of some that a kilowatt-hour is being generated on 2.14 pounds of coal, and so on down the line.

Although it may seem paradoxical, sometimes the machine making a kilowatt-hour on 16 pounds of steam is using more coal than the one requiring 17 pounds. If the machine with the lower rate is a turbine, it probably would use nearly twice as much circulating water as the reciprocating engine and, hence, considerably more power for condensing purposes. Also, as it is essential that a high vacuum be maintained for the turbine, the condenser temperature is usually as close as possible to 70 degrees. On the other hand, with the reciprocating unit no undue alarm is caused if the condenser temperature is as high as 95 degrees. Roughly, this means 25 B.t.u. per pound to the good when it comes to making a pound of steam from the condensate.

Although I have transposed a few of the sizes in the foregoing, the averages and rates are the same as those obtained in a plant with which I was connected. It may be interesting to learn how closely the monthly overall plant results compare with individual test results.

Suppose that two 5000-kilowatt machines put out 4,500,000 kilowatt-hours per month at the rate of 15 pounds of steam per kilowatt-hour. This, based on seven pounds evaporation per pound of coal, would seem to require 4815 tons of coal.

Let the 5000-kilowatt machine with a 16-pound rate put out 2,700,000 kilowatt-hours. This would indicate the consumption of 3037 tons of coal. Then, consider that the four units with a 17-pound rate have a total monthly output of 4,000,000 kilowatt-hours. These would apparently require, then, 4840 tons of coal and the total for all of the machines would appear to be 12,692 tons. As a matter of fact, in a plant containing machines of these sizes the coal consumed per month would amount to very nearly 20,000 tons.

If the current used by the auxiliaries equaled 200,000 kilowatt-hours, the actual coal consumed would amount to 3.63 pounds per kilowatt-hour delivered to the line.

One naturally asks what causes such a large discrepancy. Besides the steam-driven auxiliaries there are the peak loads, and peak loads are not money makers by a long shot.

In a plant of the size under discussion there would be needed about 40 boilers of 600 horsepower capacity each. The maximum load would have to be carried on about 38 boilers, two necessarily being down for cleaning. The peak would probably amount to about 33,000 kilowatts. The smallest load would probably be 4000 kilowatts and the morning load would run about 8000 kilowatts less than the evening load. The load during the middle of the day would probably average about 17,000 kilowatts. At the usual rating of 700 kilowatts per boiler, there would be required 33 or 34 boilers in the morning and about 24 during the day. Thus, some of the boilers are banked twice each 24 hours and this necessarily entails quite a loss.

To sum up, the editorial states that unit tests are more common than plant tests. This is true to a certain extent, but if every engineer keeps a monthly report, as he should do, he has virtually a plant test each month and it is the only true test, for the fact remains that the only true way to figure plant economy is to find out what it will do month after month and not during few hours of frenzied effort to lower the world's record for steam consumption. A plant is not run under those conditions day after day. If the right sort of a record is kept, one can tell at the end of each month wherein the efficiency has dropped, whether it be waste, oil, machine supplies, low feed temperature or any other item used day after day.

L. H. Edwards.

Kittanning, Penn.

Compound Engine Proportions

Referring to Mr. Cassidy's criticism in the January 31 issue of my article on "Compound Engine Proportions," which appeared in the issue of November 29 last, the first point of misunderstanding is due to a typographical error. Where an engine operates against back pressure, the mean effective pressure, of course, will be reduced and not increased.

Relative to the next point, which pertains to terminal pressure, this may be made somewhat clearer as follows:

Assuming that an engine is cutting off at one-quarter stroke in the high-pressure cylinder with a 4-to-1 ratio, the number of expansions will then be 16, neglecting cylinder clearance. Now, the terminal pressure obtained in the low-pressure cylinder is dependent upon this ratio of expansion and the initial pressure in the high-pressure cylinder; that is, with 16 expansions and a known steam pressure a certain terminal pressure will result; thus it is a comparatively easy matter to calculate, at least approximately. If, now, with this same engine the size of the high-pressure cylinder is reduced, the cylinder ratio is increased. If the number of expansions or the steam pressure is not changed, there will be no change in the terminal pressure. By changing the high-pressure cylinder only the cylinder ratio and the point of cutoff in the high-pressure cylinder are changed.

In connection with the example worked out in the article of an engine having a 5-to-1 ratio and a cutoff of 0.275, it is true that in the case of an engine proportioned with a high cylinder ratio there is some drop in pressure at the end of expansion in the high-pressure cylinder, or, in other words, there is expansion through the receiver as Mr. Cassidy points out. But, tests show without question that up to a certain point, high-cylinder ratio is conducive to economy; that is, the benefit obtained by additional expansion secured by increased cylinder ratio more than offsets any loss due to expansion through the receiver. Some may say that the drop at the end of expansion in the high-pressure cylinder can be reduced by shortening the low-pressure cutoff, but when this is done the condensation in the low-pressure cylinder is increased and matters are not helped. It is, therefore, found in the case of an engine designed with a high cylinder ratio that it is best to divide the load about equally between the two cylinders; when this is done some drop will be obtained at the end of expansion in the high-pressure cylinder.

Relative to the next point: With an engine with cylinders 20 and 40 inches in diameter, cutting off at 0.2 of the stroke in the high-pressure cylinder, I would say that in the case of the average engine working, say, with 150 pounds steam pressure, condensing, it would improve the economy slightly to reduce the high-pressure cylinder to 18 inches in diameter. Theoretically, of course, there should be no change in economy since no change has been made in the steam pressure or the number of expansions, but when the engine is cutting off at only 0.2 of the stroke there is excessive cylinder condensation because this cutoff is somewhat earlier than is best for producing the most economical results. Therefore, the condensation losses would be reduced by reducing the diameter of the high-pressure cylinder.

I would like to add that in the article under discussion it was not my intention to give the student of engineering a complete treatise on compound engines and the rules for proportioning them, but to bring out certain points which it has been found are not always understood by engineers. The article and the diagrams were rather intended for those who have had some experience in designing engines—the diagrams having been found useful in making determinations of cutoffs, cylinder ratios and mean effective pressures rapidly without any calculations whatsoever. The results given in the diagrams have been checked up with a large number of indicator diagrams taken from a variety of engines and found to be very close to the results actually secured.

Alwin Hofmann.

New York City.

Consul Albert Halstead, of Birmingham, learns that there are now 80 plants in the United Kingdom for the conversion of garbage of cities into electric power, and that they are increasing at the rate of 20 a year. An English mechanical engineer calculates that there is a long ton of refuse for every 1000 inhabitants, equal to about 300 pounds of steam per hour for nine hours per day, if destroyed in the properly designed destructor.

Mayor Gaynor's Attitude—?

Last May, the New York Engineers' Protective Society, said to be the oldest engineers' organization in New York, addressed a set of resolutions to Mayor Gaynor calling for an investigation into the shutting down of several city plants and the substitution of central-station service. Although nine months have elapsed, there have been no visible signs of activity in the matter emanating from the city hall, nor has the communication been acknowledged. We do not believe the mayor has wilfully sidetracked the resolutions but rather are of the opinion that, in the rush of official business, their importance has been overlooked; or perhaps they have been relegated to the care of some subordinate who lacks both the interest and the authority to take action.

However, the Bureau of Municipal Research, a private organization devoted to investigating and remedying the abuses and mismanagement of city affairs, has gone into the subject very carefully and is about to make a report upon its findings. It would seem to be good form, at least, for the mayor to officially recognize the agitation now being carried on and to show that he has an interest in a subject so important to the city's welfare.

Scientific Management in Education

Just now, popular interest and the space in the ten-cent magazines is about evenly divided between aviation and scientific management. Both are useful and interesting, but perhaps slightly overdone at present.

Scientific management, as first developed by Mr. Taylor and Mr. Gantt and afterward by Messrs. Emerson, Day, Cooke and others, has undoubtedly come to stay and will find wider fields of usefulness as time goes on. It is not a universal panacea and will not cure all evils or suit all conditions.

One of the most interesting applications of the principles involved has recently appeared in a bulletin published by the Carnegie Foundation for the Advancement of Teaching, written by Morris L. Cooke, of Philadelphia.

As stated by President Pritchett in the preface to the report, Mr. Cooke was chosen to conduct this investigation as an outside expert, not an educator, who would view the conditions from the standpoint of a business man.

Both President Pritchett and Mr. Cooke appreciate the fact that there is much in college work which cannot come under the ordinary rules of business, much less under the strict rules of modern management.

It was certainly rather a bold experiment to apply business standards to the more or less psychological problems of the college and university. Some still bolder spirit may next apply the same standards to the work of an episcopal diocese or a presbyterian synod.

Considering the inherent difficulties of the experiment, it would seem that Mr. Cooke has done pretty well. For the most part, he has confined himself to the material side of college work, such as the purchase of supplies, the care of grounds and buildings and the use of rooms and apparatus, and here he is on safe ground.

When he steps over the line into the field of research, of instruction and of educational efficiency, he treads rather gingerly and occasionally breaks through. The use of the student hour is not original with him, since it has been used many years as a unit of comparison. It is not and never can be a gage of efficiency. Let us suppose, for example, that a teacher has a class of twenty students for five hours a week, making one hundred student-hours.

Let us further suppose that the exigencies of the time require an increase of the number of men in a section to thirty. According to business standards, the instructor is turning out fifty per cent. more product per week for the same cost in dollars, and is therefore that much more efficient. From an educational standpoint, he is probably less efficient than before.

The employment of functional superintendents for the material or concrete things of the college is desirable, but that a business manager should have anything to do with the administration of the teaching or the control of teaching ... is extremely undesirable. The efficiency of one man's teaching or the inefficiency of another man's teaching can no more be measured by hours or by dollars than the preaching of a clergyman or the work of a statesman.

On the whole, Mr. Cooke's report is instructive and interesting and is destined to have a decided influence in the administration of colleges and universities. He should be met and welcomed in the same spirit in which he writes. Such sarcastic and ill-tempered comment as comes from some educators is childish and out of place.

As long as educational institutions look to the taxpayers and to private benevolence for support, they are open to the inspection and criticism of the layman. The methods employed in educating the youth of the land are of interest to all, outside as well as in, and are no more exempt from investigation than other public utilities. Publicity is wholesome for colleges as for municipalities or corporations, and the surest way to meet and to disarm unfavorable criticism is to throw all debatable subjects open to frank and free discussion.

Our educational institutions, like our religious ones, cannot afford to take an attitude of superiority to the rest of mankind but must be prepared to defend themselves against any accusations of neglect or inefficiency.

Neglecting Opportunities

A certain class of engineers are seemingly imbued with the idea that if a piece of apparatus will operate something after the manner intended, there is no necessity of giving it further attention.

Getting after a repair job "as soon as there is time" is what some engineers say that they are going to do, but they directly proceed to waste more time than would have been necessary to put the defective apparatus into proper condition.

"I am going to fix it next Sunday when the plant is shut down" is what another says. "Then I can take all the time necessary and do a good job." But he does nothing of the kind.

"It is working, so what is the use of meddling with it and perhaps make matters worse," says another.

But the makers of such statements know that they are offered merely as excuses for failing to do duties that should be performed.

Any piece of apparatus that requires repairs should be attended to at once. Never mind whether it is convenient and agreeable or not. The main thing is to eliminate the defect so that the device will operate as it was intended to, when built.

How "penny wise and pound foolish" for an engineer to allow two or more tubes to leak in the rear head of a boiler, when they could be made tight in a short time with the boiler cold and the water run out.

How wasteful for an engineer to allow the valves of an engine to continue to operate when improperly adjusted, just because he thinks he does not have time to attend to them. Many times one is led to believe that failure to adjust valves properly is due to a lack of knowledge of how to do the work, rather than because of lack of time.

Putting sundry repair jobs off until Sunday is bad practice, not only because a man gets into the habit of putting off things, but because it makes him spend a day doing the same kind of work seven days a week when he should spend one of these days in an altogether different manner. A day of leisure, devoid of the nerve-racking occurrences of the daily grind prepares a man for better service on Monday morning, and more efficient work throughout the week.

Nothing can be good enough unless it is the best. Engineers make a great mistake when they neglect to improve the operating condition of their plants. Because so many have taken the ground that conditions are good enough, the central station has expanded. Its solicitors have been able to show the isolated-plant owner that his operating conditions are not as good as they should be. A contract is signed by the owner and the central station has supplanted a man and his job just because he did not cut down expenses and put the plant on a sound operating basis.

Conditions Have Changed

In this age of progress nothing stands still. Men are constantly gaining experience and the march of progress is astonishing because of the rapidity and masterful manner in which the problems to be solved have been met.

Steam-power plants have received their quota of attention from the inventor and mechanical engineer and the improvement in power-plant equipment has been so great that the engineer has been obliged to advance in both mental and mechanical training.

When stepping into a modern power plant it is hard to realize that only a few years ago the direct-coupled unit was the exception. It would be difficult to imagine a belt-driven generator of the capacity found direct connected and in general use today.

Power-plant centralization has been largely furthered by the improvement in power-plant machinery, and engineers operating the small plant have spent uncomfortable hours wondering what will be the ultimate end. Small steam plants are facing a serious proposition and the men operating them must fight every moment of the day for their very existence.

But this fight is beneficial to the engineer. He knows now that it is possible to succeed only by applying his energies to solving problems that formerly were not considered of importance or necessary for him to know in order to make a success of his work.

What is the result? Just this, the men who have improved their opportunities and fitted themselves for assuming more responsible positions than they formerly held are today operating the large power plants.

What has been done will be done again and the engineer running in the small plant today may be the man selected to operate the large plant of tomorrow. The demand for engineers in large power plants is steadily increasing and the opportunities for rising to better positions will be as frequent in the future as they have been in the past.

Wise engineers will make ready for stepping into the larger plants. There may not be much glory or financial gain at first, during the preparatory stage, but higher wages will come to the man who has improved his opportunity and is standing at the line ready to lead when the starting gun is fired.

Congress recently passed a bill appropriating thirty-six thousand dollars for the installation of a refrigerating system in the Capitol. It is to be used for furnishing cool air to the House of Representatives and the various committee rooms. Judging from the debates that have been going on recently between the members of that body, the installation of a refrigerating system is timely.

How much water are you evaporating per square foot of surface per hour? How much over their rated capacity are you running your boilers? What draft do you use? What are the conditions of impingement of flame on spots of the tube surface, and what are the conditions of cleanliness of the tubes? We should like to have the subject discussed in the light of actual experience.

Is not the recent increase in boiler-tube troubles due more to increased work than to increased pressure, or poorer material? A tube is more than twice as liable to suffer when it is evaporating six pounds of water per square foot as when evaporating three.

The verdict of the coroner's jury which inquired into the cause of the recent dynamite explosion in Jersey City, to the effect that it had been caused by a lighted match or cigarette dropped by some careless individual, is in the same class as some boiler-explosion verdicts.

We believe there was an international exposition once which was substantially ready at the date of opening, and it was a success—San Francisco papers please copy.

And now Rhode Island is after a law providing for the licensing of engineers and the inspection of boilers. There is, as usual, a bill before the New Jersey legislature, several in fact.

Lap-seam boilers are unsuitable for some classes of work; likewise lap-seam engineers. Neither should ever be employed where the real thing is needed.

Inquiries of General Interest

Questions are not answered unless accompanied by the name and address of the inquirer. This page is for you when stuck—use it

Replacing Mud Drum Nipples

If it were necessary to change nipples on a Babcock & Wilcox boiler, how should I go to work to replace them; the ones to be taken out are a foot away from the handholes in the mud drum, and what tools would be used?

C. N. T.

Use a bent diamond chisel to open the nipple, working through the handhole in the header. Then, with a blunt tool, drive in the side of the nipple between the header and mud drum, letting it drop into the drum. Hold the new nipple in place with wire and a wedge. Flare upper end slightly then expand it, being careful to see that each end projects ¼ inch beyond the tube hole. Change expander and expand lower end. After expanding the lower end, drop the expander to clear tube hole and expand slightly to flare the lower end. Use a Babcock & Wilcox special expander

Pressure on Projected Area

If the cylinder of an engine is 50 inches in diameter with 110 pounds pressure and 45 pounds receiver pressure, and if the crank pin is 12 inches in diameter and 14 inches long, what will the load be on the projected area of the pin?

P. O. P.

The total pressure on the piston is the product of the piston area multiplied by the difference in the pressure on its opposite sides. This divided by the projected area of the pin is the pressure per square inch. In this instance it is

$$\frac{1963.5 \times (110 - 45)}{12 \times 14} = 759.69 \text{ pounds}$$

Gravity and Vacuum Heating Systems

What are the essential points of difference between a gravity and a vacuum heating system?

G. H. S.

In a gravity system the condensation is returned to the boiler or led to a receiving tank by gravity. In a vacuum system the flow of steam is kept up by means of a pump or ejector connected to the radiators by which a partial vacuum is maintained in the system.

Change of Cutoff and Compression

How may cutoff and compression be changed in a simple slide-valve engine?

C. V. C.

Increase of outside lap shortens the cutoff. Increase of inside lap increases the compression and decrease of inside and outside lap lengthens the cutoff and decreases the compression.

Width of Belt

What should be the width of a double leather belt to transmit 500 horsepower, running on a 22-foot flywheel making 76 revolutions per minute?

J. A. L.

The rim speed of the wheel is 5250 feet per minute. Allowing 50 square feet of belt surface per minute for each horsepower, 25,000 square feet of belt will have to pass over the pulley each minute to transmit 500 horsepower, and the width will be

$$\frac{25,000}{5,250} = 4.76 \text{ feet}$$

Real and Apparent Clearance

What is the difference between the actual and apparent clearance in an air compressor?

A. R. C.

The apparent clearance is the space not swept through by the piston. The actual clearance is the space filled by the air compressed in the apparent clearance space after being expanded to the suction pressure. It shows on the indicator diagram at the point where the expansion line meets the intake-pressure line.

Power to Operate Elevator

Does it require the same power to operate a hydraulic elevator whether light or loaded?

O. L. P.

It is the same in both cases as it takes the same quantity of water to fill the cylinder and the water, whether from an accumulator or pressure tank, is under the same pressure.

Rewound Electric Motor

Suppose an electric motor rated at 15 horsepower running at 1200 revolutions per minute had its armature rewound to run at 800 revolutions per minute, would it then be able to withstand the throwing in of the switch without injury, and would its rating be 15 horsepower?

R. E. M.

If the work is properly done, yes.

Heat and Pressure Stresses

Which causes the greater stress to the sheets of a return-tubular boiler, heat or pressure?

H. P. S.

Heat, when it causes unequal expansion.

Equivalent Evaporation

If one pound of coal will evaporate ten pounds of water from and at 212 degrees, how many pounds will it evaporate from feed water at 80 degrees into steam at 100 pounds pressure?

F. O. E.

Water at 212 degrees contains 180 heat units above 32 degrees and steam at the same temperature 1150.4. It therefore requires 9704 heat units to change ten pounds of water at 212 degrees into steam at the same temperature. Water at 80 degrees contains 48.3 heat units per pound. Steam at 100 pounds gage pressure contains 1188.8, and it therefore takes

10 (1188.8 − 48.3) = 11,405 heat units

to change ten pounds of water at 80 degrees into steam at 338 degrees; and one pound of coal which will evaporate ten pounds of water from and at 212 degrees will evaporate

$$\frac{9704}{11,405} = 0.858$$

or 85.8 per cent. of ten pounds from water at 80 degrees into steam at 100 pounds gage pressure.

Patch on Boiler Sheet

In patching a boiler, should the patch be put on the inside or outside of the shell?

P. B. S.

It should be put on the inside, as otherwise it forms a pocket for the collection of sediment.

Hight and Capacity of Chimney

What is the relation of the hight of a chimney to its capacity?

H. C. C.

The capacity of a chimney varies as the square root of its hight. To double the capacity of a chimney its hight would have to be increased four times.

Boiler Explosion at Verona, Penn.

By Edward T. Binns

At about 4 p.m. on Monday, February 26, a vertical boiler, 36 inches in diameter by 6 feet high, exploded at the Ideal steam laundry in the town of Verona, Penn. A number of fatalities were narrowly averted. Two men were badly hurt; one of them, the engineer, in all probability will not recover. The boiler, which weighed about 1600 pounds, was shot vertically into the air about 300 feet, turning over several times and landing on top of a three-story building about two blocks away. It crashed through the roof, the third and second floors, and came to rest in the middle of a clothing store on the ground floor. As near as can be learned, the engineer, who was a new man and who came to the plant from the police force, had been doing some work in the main building and had just gone to the engine room to prepare for shutting down. On his way to the hospital he stated briefly that he had barely commenced these preparations when the explosion took place.

An examination of the ruptured plates plainly indicated that they had been red hot, the edges of the torn sections being curled and quite blue.

The firebox was 36 inches high and 30 inches in diameter, with a 9-inch flue leading to the smokestack. The feed water was delivered into the water leg. The city water pressure in Verona is about 150 pounds to the square inch, so that no pump or injector was needed to force water into the boiler, and in this case no heater was used.

Fig. 3. Interior of Firebox After Explosion

Fig. 1. The Boiler in the Clothing Store

Fig. 2. Damage to Engine Room

The boiler was only about three years old. About seven months ago it was inspected by the county boiler inspector who gave it a thorough hammer test. Also, at the owner's request, he gave it a hydrostatic test of 150 pounds. One hundred pounds steam pressure was allowed but the safety valve was set to blow at 80 pounds.

Some repairs to the steam gage, water column and safety valve had been ordered and made before the explosion.

The firebox, which was of 3/16-inch plate, was badly torn. The rupture commenced at one edge of the firing door and followed an irregular course for three-quarters of the way around. The tear was practically along the zone of the fire. The plate pulled loose from twenty-nine 3/4-inch, solid staybolts which were screwed into it, and doubled up against the crown sheet.

There is as yet no State engineers' license law in Pennsylvania, though a bill is now pending in the legislature.

The Industrial Safety Association

On Friday evening, March 1, D. T. Williams entertained at dinner at the Engineers Club, New York, a number of editors of technical and industrial papers for the purpose of acquainting them with the objects and activities of the Industrial Safety Association. After the host had effectually disproved his introductory declaration that he could not make a speech by setting forth most impressively the obligation of those in charge of industrial operations and others of the more fortunate class who are in a position so to do to minimize the hardships, dangers and chances for injury which surround the worker, he introduced Dr. F. R. Hutton, president of the new organization.

Doctor Hutton quickly demonstrated to his hearers that the association had a much wider field and loftier mission than the exploitation of mechanical devices for the guarding of life and limb, and impressed them with the economic importance of maintaining the efficiency of the working force of the community by establishing conditions conducive to health, comfort and security from bodily harm. His remarks were illustrated by a series of lantern slides, showing devices and methods employed toward that end.

The company then visited the American Museum of Safety, which is maintained in the Engineering Societies building, 29 West Thirty-ninth street, where many of the devices previously illustrated are upon exhibition, where statistics are available and methods exemplified. The museum is free to the public between the hours of 9 and 5 every day except Sundays and holidays.

Institute of Operating Engineers to Organize Branches

On Friday evening, March 17, at 8:30 there will be a meeting in the lecture room of the Modern Science Club, 125 South Elliot place, Brooklyn, for the purpose of organizing a branch of the Institute of Operating Engineers. Members and all interested are invited to be present.

On Saturday evening, March 18, at eight o'clock, there will be a meeting in the rooms of the Institute of all members and those interested, in New York City and the Bronx. This meeting is called for the purpose of organizing a branch of the Institute in New York City. At this meeting the officers of the branch will be elected, which will include the branch chairman, branch representative to the district council; lecturer on plant operation and chairman of the committee on apprenticeship training; lecturer on educational subjects and chairman of committee on educational subjects; a secretary-treasurer and three councilmen, each for one, two and three years' service. The naming of the branch will also be considered at this meeting and other matters of importance.

As this association will be looked upon as the leader and as all the meetings under the name of the Institute which are held in New York will have to be under its auspices, it is of the utmost importance for all interested to attend this meeting.

Organization of an N. E. L. A. Section at Pittsburg

A banquet to the employees of the Allegheny County Light Company was given by the officers at the Hotel Duquesne, Pittsburg, at 6:30 p.m., Tuesday, February 28. A section of the National Electric Light Association was formed, to be known as the County Light Section, and approximately 150 of the employees joined the section. Prior to this time about 35 of the employees were already Class B members and therefore the section started with 185. H. N. Muller, superintendent of distribution of the Allegheny County Light Company, acted as temporary chairman; W. H. Dunkin, general contracting agent of the same company, acted as temporary secretary, and James M. Graves as temporary treasurer.

H. H. Scott, chairman of the membership committee of the National Electric Light Association, gave a history of the organization, told of its growth and the objects for which the association was striving. A. R. Granger, of Chester, Penn., president of the Pennsylvania Electrical Association, followed Mr. Scott and told of the work the company sections were doing, particularly the Philadelphia section.

Erratum

The Heine Safety Boiler Company was organized by Col. E. D. Meier in 1884. Due to a typographical error on page 401 of the March 7 issue the year 1844 was given.

Prime Movers

The speaker for the regular weekly lecture on February 28 at the Modern Science Club, Brooklyn, was George A. Orrok, of the New York Edison Company. His topic was "Prime Movers." He briefly traced the development of the various types of engines from the time of the earliest waterwheels down to the present day.

It was shown that James Watt conceived practically all of the principles that underlie even the present-day reciprocating engine. Much of the increase in economy has been the result of the improvement in the machine tools upon which the manufacture of the engine parts depends.

To illustrate what progress had been made, Mr. Orrok stated that while some of the original pumping engines attained a duty of perhaps 60,000,000 foot-pounds, today a duty of very nearly 200,000,000 foot-pounds has been accomplished.

The lecture was attended by a representative gathering of members and friends.

"Game" to the Core

Frank V. Burlingame, age 30, was seriously injured at the Nickel Plate Railroad's Rocky River pumping plant, on February 24. He was caught by a key projecting from the end of the flywheel shaft and whirled around several times and thrown against the wall of the building. He was badly bruised and both legs were broken in several places. Notwithstanding these injuries he managed to crawl to the throttle when he recovered consciousness and shut down the engine.

Boiler Explosion Kills Four

On March 4, one man and three children were killed and six other persons injured when a boiler at the Blackburn-Gambill distillery on Howard's creek, Breathitt county, exploded. The children were playing about the distillery when the explosion occurred. The other victims were employees.

Flywheel Wrecks Building

On March 3 a portion of the Greensburgh Brush and Wire Factory was destroyed by a flywheel explosion. A defective governor allowed the engine to run away. Several employees were injured.

Moments with the Ad. Editor

A department for subscribers edited by the advertising service department of Power

Not long ago a great department store in New York City advertised a special sale of men's bath robes.

It was the intention to advertise them at a price of $5.00 each, but through some mistake in the copy the bath robes were advertised in all the morning papers for 50 cents apiece.

With the result that buyers were lined up before the counter three rows deep.

It was too late to do anything except to *stand by the advertising*. The clerks behind the bath-robe counter were instructed to politely explain the mistake, but to refuse no one a bath robe for 50 cents who insisted on having it at that price.

The result was interesting. The majority accepted the explanation and went away with no hard feelings. Some saw the value that lay in the bath robes at the intended price of $5.00, and purchased them at that figure. A few others, perhaps half a dozen, held their ground and refused to pay more than the advertised price—

And got them.

Back of this incident lies the great truth that nowadays *reliable concerns stand back of their advertising at all costs.*

And going into this a little deeper it is easy to see that when a reliable advertiser makes a statement in an ad. it is safe to assume that this concern has carefully sifted over what it has said in order that no misstatements may creep into the copy.

The concerns who advertise in POWER are *reliable* concerns.

They stand back of their advertising.

They claim certain things, secure in the knowledge that they can "make good."

What readers of advertised products need to cultivate more is a *belief* in the *truth* of what they read.

The power-plant man who thrusts aside the honest statement of a reliable concern with an "I don't believe it," isn't doing fair justice to the concern who makes the claim. Neither is he doing justice to himself.

The fact that an advertiser makes a statement which appears to you too big for him to fill does not affect the truth of that statement one way or the other.

Advertisers in POWER are not making claims that they cannot live up to.

They cannot afford it.

Thus, when the manufacturer of a lubricant, for example, tells you what his product will do, consider his word as his honest belief in the efficiency of what he is trying to sell. When the manufacturer of some new power-plant device claims certain advantages, consider his statement seriously and be willing to meet him half-way.

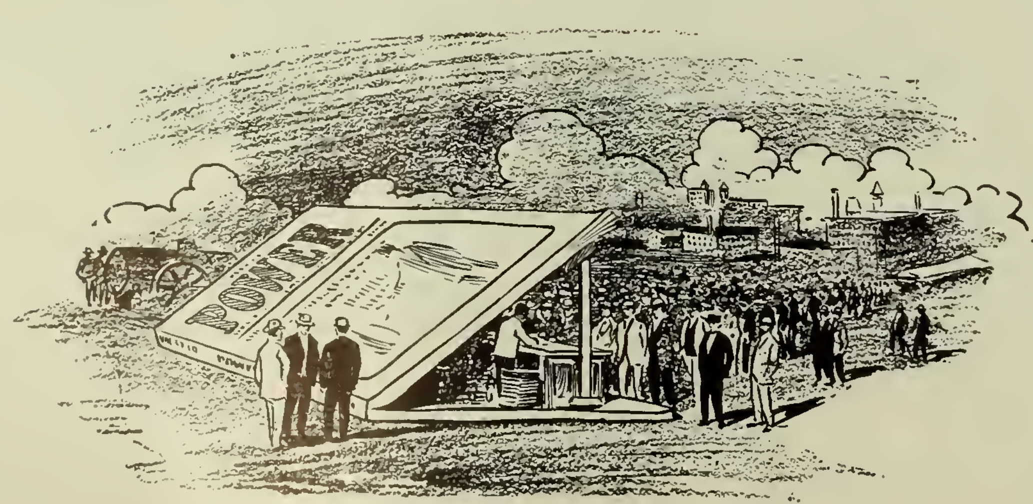
Naturally, the success of many advertised articles often depends upon conditions as they exist in your plant and advertised goods should be carefully studied with due regard to fitting them into existing conditions—

Which signifies that careful comparison and investigation are as necessary as a belief in the word of the advertiser.

The advertisers in POWER are in earnest. Every time they talk to you, through their ads., they put their reputation at stake.

Could they afford to say anything they knew they were unable to back?

Do more than merely *read* the ads.—



Read them with the knowledge that every statement made is an actual fact.

For, truly, the Selling Section is the very last place of all where an advertiser can afford to say anything except what is absolutely true.

POWER

NEW YORK, MARCH 21, 1911

HERE is an experiment that all may try: Select a straight joint in the sidewalk or floor and try to walk in a straight line, using the joint as a guide.

Observe the speed you make and the degree of success you have in following the line. Then, return to the starting point, pick out some distant object and with the eyes fixed on that object start the journey over again.

Your speed in the second case will be limited only by your ability as a "Marathoner" and, provided you are sober and in normal health, your course will be a true straight line between the starting and finishing points.

Consider the tight-rope artist; he does not concern himself particularly with the rope immediately under his feet—his eyes are focused on the end of the rope. And statistics tend to show that he is right, for casualties among professional tight-rope performers are less numerous than among even canal-boat cabin boys.

The lesson to be learned from the foregoing (there's always a lesson, you know) is that the safest and best progress is made when there is a definite objective point in view. The haphazard following of a line through life with the sight limited to but a few paces in advance never get anyone very far along—there are too many blank walls against which to run and too many blind trails upon which to get lost.

If your line is steam engineering, you are to be congratulated; you are "in right." There is plenty of room and glory ahead, perhaps more than in any other line today, for this is the mechanical age. Steam engineering and other branches of mechanical science are only just coming into their own. There never was such opportunity for intelligent, earnest endeavor. But don't take our bare word for this, look it up and prove to your own satisfaction that we are either right or wrong.

Pick out your goal, keep your eye on it and work to get there. If you are in earnest, not making believe, you will make good progress. Whether you ever actually arrive will depend on so many things that we cannot make an accurate prediction. But we repeat, you will make good progress.

Hustlers are needed badly. The busy man never complains of lack of opportunity; it is only the man who is too lazy to look for it who does the croaking.

There is some slight temporary gain to be secured by "pull" and "bluff," but the worth-while progress results only from "push" and merit.

Hydroelectric Plant in Italy

By J. B. Van Brussel

A low-head plant of 11,000-horsepower capacity supplying two transmission lines, one at 3750 volts and the other at 27,000 volts. The three-phase four-wire system of transmission is used on the line of lower voltage and the three-wire system on the one of higher voltage.

The Cervara hydroelectric plant, now in operation in the north of Italy, supplies electrical energy to the city of Terni, and to the electrochemical factories of the Societá Industriale Ellettrica della Valneria at Narni.

The water, which is supplied by the falls of the Marmore, passes into an open channel nearly 1300 feet long, 40 feet wide and 6 feet 5 inches deep with a fall of one foot in every hundred, and terminating in a clearing pond of about 25,000 square feet. Two parallel flumes, each 1640 feet in length and 13 feet in diameter, lead to an open reservoir from which intake pipes lead to 12 sluices. The original intention was to install 12 units of 1000 horsepower each, but this was later changed to six 2200-horsepower units. In order to utilize the existing sluices, each three intakes leading from the reservoir were combined jointly to feed two penstocks leading to the turbines. Nine intakes were thus combined with the six penstocks feeding the 2200-horsepower units; two more connections were used for two 1000-horsepower turbines which had been transferred from an old power house to the new generating plant, and the twelfth intake was arranged to feed two exciter turbines. In Fig. 1 only five of these penstocks are shown.

An expansion sleeve and a vertical air chamber, intended to compensate for fluctuations in pressure, are fitted to each penstock. The main locking gates of the turbines are hydraulically balanced and are controlled from the generator floor. The turbines are of the double-rim reaction type, and, according as the head varies between 65 and 79 feet, each utilizes from 2300 to 2700 gallons of water per second. Fig. 2 represents a cross-section through the turbine room and Fig. 3 is a view of the same room, showing the switch gallery at one end.

The general character of the electrical equipment was determined by the fact that two different kinds of service were required; current at 3750 volts for light and power at Terni, and at 27,000 volts for transmission to the electrochemical works at Narni. This necessitated two separate sets of busbars. At present there are installed five three-phase generators, each of 1900 kilovolt-amperes capacity coupled direct to a 2200-horsepower turbine, and space is provided for a sixth unit. Two generators of 865 kilovolt-amperes each, have been transferred from an old power house and are coupled to the 1000-horsepower turbines. Each of the larger generators can be connected to either of the busbar systems. When working on the 27,000-volt system, each of the generators is connected directly and only to a transformer of the same capacity, the high-tension side of the transformer being connected to the 27,000-volt busbars. When supplying the 3750-volt system, however, the generators are connected directly to the busbars. The two smaller generators serve the 3750-volt system exclusively. The Narni electrochemical works are fed by a duplicate three-wire transmission line and the Terni transmission line is of the three-phase four-wire type.

Fig 1. General View of Plant, Showing Penstocks and Reservoir

The basement of the switch house, which forms one end of the building, is occupied by the generator switches and the field rheostats. The transformers are on the first floor, the transformer switches and busbars on the second floor and the line switches and lightning arresters on the third floor.

The large machines generate three-phase currents at 42 cycles and a normal voltage of 3750, although this can be increased to 4150 volts. Two direct-current turbine-driven generators of 75 kilowatts each are used for excitation. Also, a motor-generator set, consisting of a 240-horsepower three-phase motor fed from the 3750-volt busbars and coupled to a direct-current shunt-wound generator of 120 to 150 volts, is provided for additional excitation.

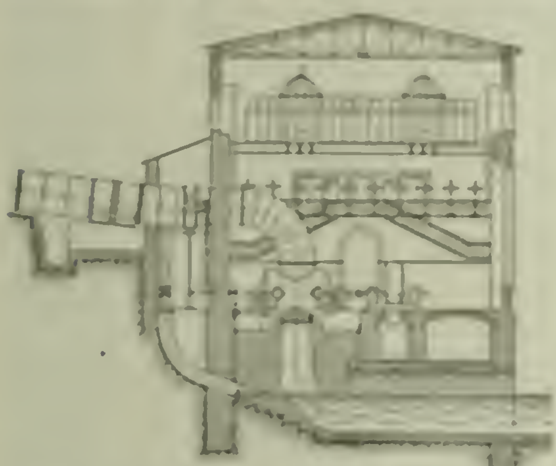


Fig. 2. Section through Turbine Room

The generator panels are separated by fireproof partitions and each contains a four-pole oil switch with a maximum and reverse-current relay, and the knife switches for connecting the generator to either the 3750-volt busbars or to its corresponding transformer. The oil switches are operated through hand ropes from the main switchboard.

In the compartment below the switch structure are located the series rheostats for the fields of the three-phase generators and the shunt regulators for the exciters. Provision has been made for six three-phase 3750- to 27,000-volt transformers, each of 1900 kilovolt-amperes capacity, although only five are installed at present. They are mounted on wheels, which permits them to be readily removed from their stalls. An air duct running under each of the stalls is supplied by two fans, either of which is capable of furnishing enough air to keep the transformer windings cool.

From the transformers the conductors lead to transformer switches provided with maximum-current relays, which are located on the second floor. These switches, which can be operated through hand ropes from the switchboard, are designed with the terminals at the bottom and all the operating mechanism at the top. From the switches the circuit passes through three current transformers, which actuate the maximum time relay, to a structure containing the busbars and section switches.

There are two sets of 27,000-volt busbars, one serving as a spare. Each transformer, as well as the outgoing line, can be connected to either set. The current and voltage transformers, used in connection with the ammeters and voltmeters, are inserted between the connections of the large transformers and those of the outgoing lines in the 27,000-volt and the 3750-volt busbars. Section switches permit any section of the busbars to be cut out in case of breakdown, thus cutting the disabled apparatus out of the circuit.

Fig. 3. Turbine Room with Switchboard Gallery at One End

Fig. 4. Transformer Mounted on Wheels

Fig. 5. Horn-gap Arrester

The outgoing 3750-volt line for the Terni plant, being of the four-wire system with neutral conductor, is controlled by a four-pole automatic oil switch having a time-element relay, and operated by a hand rope from the main switchboard platform. Horn gap arresters, each with a glass-tube water resistance and four-pole water jet, are used to handle excess voltage discharges. A 60-kilowatt transformer, reducing the voltage from 3750 to 500 volts, is connected to the 3750-volt busbars for station service.

The 27,000-volt line, which comprises two three-wire transmission lines, is controlled by an automatic remote-control oil switch operated from the main switchboard. Each outgoing wire is protected against atmospheric discharges and excess voltage by a horn gap arrester and a choke coil. Figs. 4 to 7 show the switching equipment, one of the transformers and the spark gaps.

The main switchboard is shown in Fig. 8. The instruments and operating levers for the generator sets are located on switch pedestals, while the switchboard is equipped for controlling the outgoing lines. Each of the pedestals for the 1900 kilovolt-ampere generators carries a hand lever for operating the generator oil switch, a hand lever for the transformer oil switch, and handwheels for the series rheostat in the exciter circuit and the carbon switchout of the exciter. The exciter switches are mechanically interlocked with the main switches of the generator, so that the latter can be closed only after excitation has taken place; on the other hand, the exciter switch can be opened only when the main switch is open.

The motor-generator set is also controlled from a pedestal, as are the two small turbine-driven exciters. One-half of the switchboard, shown in Fig. 8, is set apart for controlling the Narni line, and the other for controlling the Terni line.

Pierre and His CO_2 Recorder

Old Pierre, the French fireman, said that if he had that new CO_2 recorder he would fire it to the bottom of the lake where nobody would ever find it. He soon became thoroughly acquainted with the new recorder and was told that he could have it to take home when he raised the marks to 20 per cent. After receiving instructions on the theory of combustion and the principles of the CO_2 machine he was able at times to obtain about 15 per cent., which was much nearer 20 than the highest records he was able to get when the recorder was first installed. Still something strange would happen nearly every night which worried Pierre. The CO_2 would take an abrupt drop too great to be caused by any change in firing. This he could not account for. Every surmise was investigated, but the cause was not found, until finally one night Pierre rushed in—his face beamed with delight, and exclaimed, "Me finds zie troub', zie coal pass' go 'sleep in zie car, an' no coal in zie chute, zie cold air go down over zie fire an' zie machine mark a' no good."

Sure enough Pierre had located the trouble, which was soon overcome.

He decided not to throw the machine in the lake, even if he could get 20 per cent. CO_2.

Jet versus Surface Condensers

Some interesting data and cost figures which should aid materially in making a choice between jet or surface condensers for high- or low-pressure steam turbines.

There is a constantly increasing number of cases in connection with condensing plants for either high- or low-pressure steam turbines, where it is not obvious which is the best type of condenser to employ, and where, in fact, the wrong condenser is not infrequently selected. Little appears to have been written which is of use to power users in coming to a decision as to what type of condenser to adopt. In a recent issue of *The Engineer*, of London, an interesting article on "Jet versus Surface Condensers" was published. The following are excerpts from this article, with the exception that the English cost figures have been given their American equivalent, using $5 as the value of the pound.

In order to ascertain which plant it is best to employ in any nonobvious case, it is necessary to compare the capital outlay costs with the running costs. The former have a relatively greater importance compared with the latter if the plant has a low load factor, whereas with a high load factor the latter are of relatively

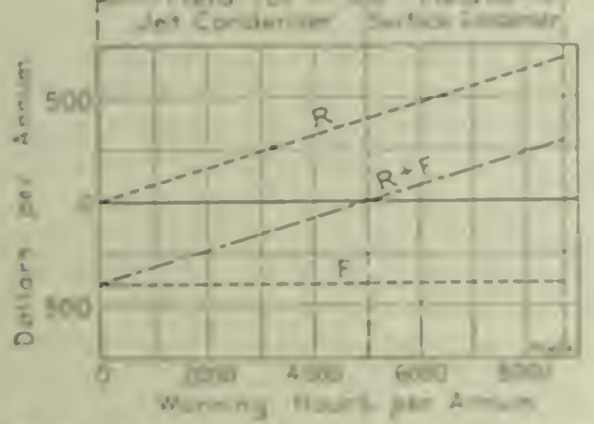

FIG. 1. TERMINAL PRESSURE AT TURBINE TWO POUNDS ABSOLUTE. CIRCULATING WATER 82 DEGREES FAHRENHEIT

great moment compared with the former. In the present investigation the condensing plant for a 3000-kilowatt turbine has been considered, and the fixed annual costs, which are proportional to the capital outlay, and are independent of the load factor, are taken at 15 per cent. of the capital outlay in the case of the surface condensing plant, including a cooling tower, and 13½ per cent. in the case of a barometric jet condensing plant, including a cooling tower. Where a cooling tower is not employed, 13 per cent. has been taken in the case of the surface plant, and 11 per cent. in the case of the jet plant.

The annual running costs, which are proportional to the load factor or to the number of hours that the plant is worked in a year, differ chiefly as regards the work absorbed in driving the air pump; and this work, with its incidental expenses, has been taken at 1.2 cents per effective horsepower-hour delivered to the air-pump piston rod or crank shaft.

Considering, in the first place, a case where a cooling tower is employed, and a turbine-terminal pressure of two pounds per square inch is desired, the cost of surface condensing plant is estimated at $19,300, which cost includes a natural-draft cooling tower capable of reducing the temperature of the condensing water to 82 degrees Fahrenheit. A barometric jet condensing plant, capable of maintaining the same terminal pressure, is estimated to cost $18,550. In arriving at the latter figure the pressure in the jet condenser has been assumed to be 0.13 pound per square inch less than at the exhaust end of the turbine to allow for drop in pressure in the long exhaust pipe and difference in level between the condenser and the turbine; 15 per cent. of $19,300 is $2895, which represents the fixed annual cost on the surface condensing plant; 13½ per cent. of $18,550 is $2500, which represents the fixed annual cost on the jet plant.

The ordinates in the figures represent annual cost, distances below the zero line being in favor of the jet condenser and distances above the line in favor of the surface condenser. The actual costs are not indicated on the diagrams, but only the differences between the costs of the rival plants. In Fig. 1 the line *F* represents the difference in the fixed annual costs between the surface and jet plants for the case just mentioned, that is, the difference between $2895 and $2500, which is $395. This is in favor of the jet plant, and is independent of the number of hours during which the plant is worked in the year.

As regards running costs the air pump of the jet condensing plant is estimated to require 14.12 horsepower, and, therefore, at 1.2 cents per horsepower-hour to cost 17 cents per hour at full load; and the corresponding figures for the surface condensing plant are reckoned to be 7.78 horsepower and 9.4 cents per hour; the difference in cost in favor of the surface plant is, therefore, 7.6 cents per hour at full load. The cost of driving the water pumps may be assumed to be the same in both cases. Line *R* in Fig. 1 represents the difference in running costs for any number of working hours per year from nothing up to 8760, which latter figure represents continuous working. The greater the number of working hours per year, the greater, of course, is the advantage which the surface plant possesses over the jet plant. The dotted line marked *R* + *F* is obtained by taking the algebraic sum of the ordinates of the lines *R* and *F*; and this line represents the net difference in annual cost of the two systems for any number of working hours per year. It will be seen that the jet condenser has the advantage up to 5000 hours per annum, and thereafter the surface condenser has the advantage. Where the working hours are less than about 5000 per year at full load, it is therefore advantageous to employ a jet condenser, but where the full power is carried for more than 5000 hours per year, it is better to employ a surface condenser.

As regards working at fractional load

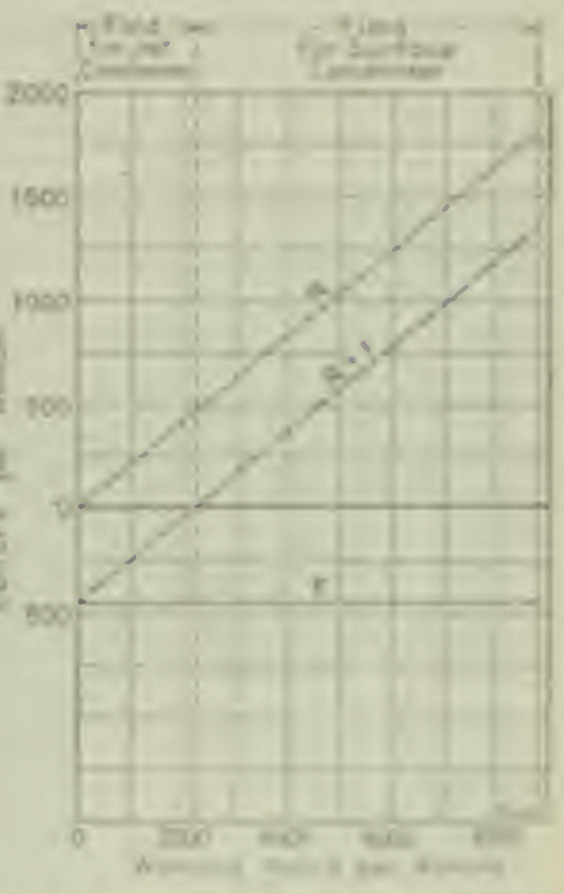

FIG. 2. TERMINAL PRESSURE AT TURBINE 1.5 POUNDS ABSOLUTE. CIRCULATING WATER 82 DEGREES FAHRENHEIT

the power consumed by the condenser auxiliaries then constitutes a greater percentage of the power of the main unit than in the case at full load. For the purposes of the present investigation, the motors driving the condensing plant are assumed to be designed so that they are able to handle a load considerably greater than the rated full load. A certain number of hours at a load which is a small percentage below full load may be taken as balancing an equal number of hours at which the load is about the same percentage above full load. Moreover, any hours at half load may be taken as equivalent to three-quarters of as many at full load; so that, for example, if the plant were ac-ways running at half load, the costs for jet and surface plants, instead of being the same at 4989 hours, would be the same at 6652 hours per annum.

Fig. 1 shows that, under the conditions assumed, namely, a terminal pressure at the turbine of two pounds per square inch, and the employment of a cooling tower, there are fields of considerable extent both for the barometric jet and for the surface condenser.

For terminal pressures greater than

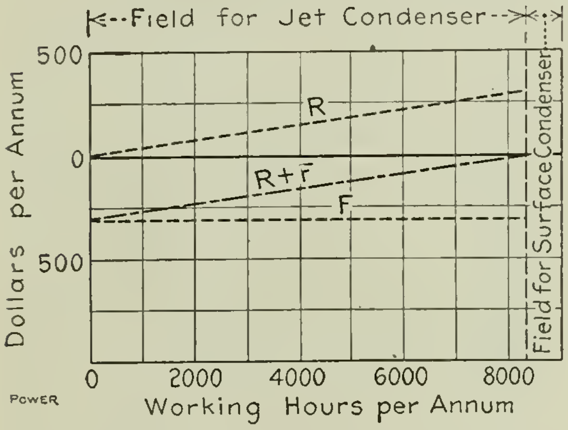

Fig. 3. Terminal Pressure at Turbine 1.5 Pounds. Circulating Water 60 Degrees Fahrenheit

two pounds per square inch, the field for the jet condenser is enlarged, and that for the surface condenser is reduced; but terminal pressures much above two pounds are seldom desirable for steam turbines.

For terminal pressures much lower than two pounds per square inch, the jet condenser has a very limited field. Fig. 2 corresponds to Fig. 1, but with plant designed for a terminal pressure of 1.50 pounds per square inch, a cooling tower being employed as before. The cost of the surface condensing plant is, in this case, estimated to amount to $21,600, and the jet plant is reckoned to cost $20,750. Fifteen per cent. on the former sum amounts to $3240, and 13½ per cent. on $20,750 amounts to $2800; the difference in the fixed annual costs is, therefore, in this case $440, and this is represented by the line *F* in Fig. 2. The working costs are higher in this case than in the last case, especially as regards the jet plant, which suffers not only from the greater specific volume of the air due to the lower pressure, but also from the greater weight of air admitted to the condenser due to the greater amount of condensing water required. The air pump of the jet plant is in this case estimated to require 26.8 horsepower, and, therefore, to cost 32.2 cents per hour at full load, while the surface condenser air pump is reckoned to require 10.09 horsepower, and therefore to cost 12.2 cents per hour at full load, the difference in running costs being therefore 20 cents per hour. The line *R* in Fig. 2 shows the difference in the running costs per annum for any number of working hours per annum; and the dotted line marked *R* + *F* represents the difference in total annual cost. It will be seen that the jet plant has the advantage only if the plant is worked per annum an amount equivalent to less than 2112 hours at full load.

Cases will now be considered where no cooling tower is employed, and where condensing water can be obtained at a temperature of 60 degrees Fahrenheit. The lesser amount of condensing water required in such cases enlarges the field for the jet condenser, so that for a terminal pressure of 1.5 pounds per square inch the jet condenser has the advantage over the surface condenser for practically any number of working hours per year. This is shown in the diagram, Fig. 3, which is of a similar nature to the previous two diagrams. The surface plant is in this case estimated to cost $8100 and the jet plant $6900. These two sums at 13 per cent. and 11 per cent. respectively represent fixed annual charges of $1055 and $760 respectively, the difference in fixed costs in favor of the jet plant being thus $295. The air pump of the jet plant is estimated to require 15.7 horsepower, and therefore to cost 19.8 cents per hour at full load, while the corresponding figures for the surface plant

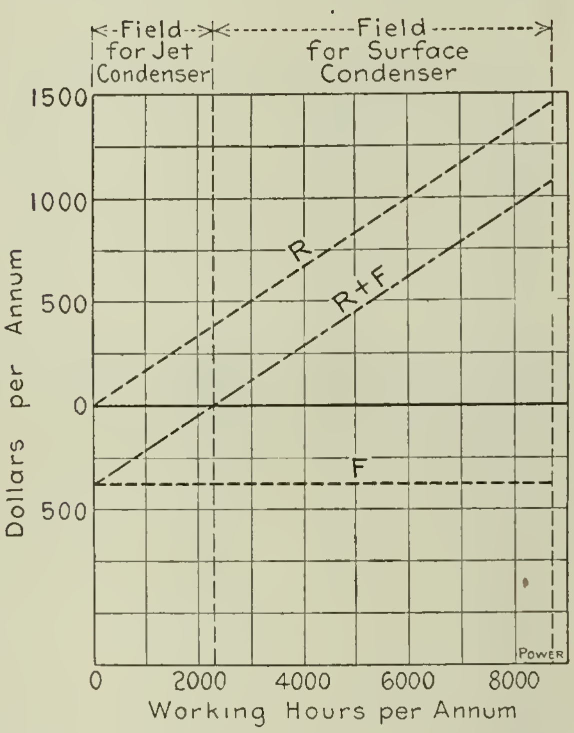

Fig. 4. Terminal Pressure at Turbine One Pound Absolute. Circulating Water 60 Degrees Fahrenheit

are 10 horsepower and 12 cents. The surface plant is, however, in this case estimated to cost 3.4 cents per hour more than the jet plant for water-pumping power, so that the difference between the running costs of the two plants amounts to

$$18.8 - (12 + 3.4) = 3.4 \text{ cents}$$

per hour at full load in favor of the surface plant.

Higher terminal pressures than 1.5 pounds with no cooling tower and with water at 60 degrees Fahrenheit need not be considered, as obviously the jet plant will have the whole field to itself. Terminal pressures lower than 1.5 pounds per square inch are, however, often desired, and Fig. 4 shows the fields for the two condensing systems when the terminal pressure is one pound per square inch. In this case the surface plant is estimated to cost $10,425, and the jet plant to cost $9000. Taking 13 per cent. of the former and 11 per cent. of the latter sum, the difference in the fixed annual cost is found to be $365. As regards running costs the air pump of the jet plant is estimated to require 28.4 horsepower, and therefore to cost 34 cents per hour at full load, while the corresponding figures for the surface plant are 11.4 horsepower and 13.6 cents. Allowing for a difference in cost of water-pumping power of 4.8 cents per hour in favor of the jet plant, the difference in running costs is 15.6 cents per hour in favor of the surface plant. The jet plant has in this case, compared with the previous case, a very limited field—only up to 2246 hours per annum—and for lower terminal pressures than one pound per square inch its field would be still further restricted.

An Inspector's Dream

By A. C. Terlene

It fell in my line of duty to go to a Central Western city to make the first inspection of six horizontal tubular boilers which had just been offered my company for insurance. This was a Sunday-morning inspection. The plant was a cereal factory which was in operation 24 hours per day, shutting down at midnight Saturday and starting up at midnight Sunday.

On arriving at the plant about 8 a.m., I was pleased to find that my coming had been prepared for, ashes and clinkers had all been nicely cleaned out from under the boilers, top and bottom manheads removed, boilers thoroughly washed, the furnace doors and flue caps closed and the damper opened so as to lower the temperature rapidly and remove all vapor from the interior. The tops of the boilers were all swept off nicely, smoke boxes cleared of soot and everybody was smiling and in good humor.

The chief engineer was on hand to greet me, took me into his engine room, which was nice and clean, and gave me a nice, clean locker in which to hang my clothes. The boilers were fairly hot, as might be expected, having been shut down so short a time, but by leaving the furnace doors and flue caps closed while inspecting above the flues it was quite bearable; then, when it came to going in under the flues I found that they kept a "buggy" for the purpose, this being a piece of 12-inch board 3 feet long with rollers under it. There was no scrambling along in an inch or so of dirty water in order to explore all the lower parts.

When the inspection was finished I could only report a few minor defects; the engineer, being a wide-awake man, had kept the plant in apple-pie order. I found that I had been provided with plenty of good hot water to wash up in and on leaving the plant I did so with a feeling that if all plants were like that an inspector's life would be much pleasanter than it really is.

But did I find the above? Emphatically no! That was only my dream, superinduced, no doubt, by the fact that when this inspection was finished I would go home for the first time in six long, dirty weeks. Here is what I found. On entering the plant at 8 a.m. I saw three or four firemen and helpers sitting around smoking and was pleased to hear one call out to the others, "Here's that feller; I was hoping he wouldn't show up."

One man went to the 'phone and called up the chief engineer and reported my arrival, asking for instructions. He reported that the chief said he would be down after a while and instructed them to "tear up" as little as possible.

On reconnoitering the plant I found that most of the ashes and clinkers were still under the boilers, no manheads had been removed and only two of the boilers were entirely empty. Of course, I could see breakers ahead but went to work to get the men to prepare the boilers for inspection. The head fireman said that they never removed the upper manheads as packing cost so much and the joints were so hard to make tight; besides it took so long to do it that he could not get his Sunday afternoon off. I insisted that all manheads would have to come out and he went back to the 'phone and held another séance with the chief, who apparently agreed that the upper manheads might be removed this time but that they could not make a practice of so costly a proceeding.

I hurriedly changed clothes in one corner of the boiler room, hanging my good clothes on nails against a dirty, smutty wall, wondering all the while if they would be in such condition that I would be allowed in the hotel when I got back to that place.

I found their statement as to not removing the back manheads borne out by the fact that it was necessary to use a short piece of railroad steel to butt them in and to make a run for it when we did, so as to avoid the gust of steam which poured forth. By twelve o'clock we had the boilers in such condition that I managed to get inside and found the passages between the tubes very generally stopped with scale, the back head being covered with nearly an inch of hard scale between the tubes. The internal extensions of the feed pipe were all disconnected at the point of entrance to the boiler; some of these pipes had evidently been forced off by the pressure of the feed pump as they were completely closed up with sediment and scale. Aside from a couple of broken braces, no defects were found in the boilers above the flues.

Below the flues I found that the front ends of the boilers were several inches lower than the back ends and as a consequence three or four inches of mud and water made inspection anything but pleasant as there was no "buggy" present. Externally, I found that several of the boilers were bagged on the front sheets above the grates, the girth seams were fire-cracked and leaking, the tube ends at the rear were nearly all burned off and a number of these were leaking badly. All but two of the soft plugs had been removed and replaced with solid plugs. I found only one safety valve that looked as if it had ever blown and the attendants stated that none of the others ever opened, one safety valve doing all the "popping" for six 72-inch by 18-foot boilers. Three of the water columns were 4 inches too low and gage cocks were conspicuous by their absence from the plant. The feed-water heater, of the closed type, was out of order, and the feed water was bypassed around it, so that the boilers were supplied with cold water. The chief did not show up at all during the day and we finished the inspection by about 4 p.m. Conditions were such that I deemed it advisable to stay over till next day and set the boilers in service and by so doing had an opportunity of meeting the chief engineer, also the officers of the company, which proved to be a new firm just taking over the plant. At the request of these men I staid over at this city three days, during which time their power plant was very thoroughly gone over, innumerable steam leaks were found and bad conditions generally were found. On visiting this plant three months later I found a great change.

The old chief had been given a permanent layoff, the boilers had been reset, a new feed-water heater installed, the pumps overhauled and such improvements made that four boilers now carried more load than six had formerly been able to do. Worst of all, a young man, one of the much berated "technical engineers," was in the saddle as chief. He had never shoveled a pound of coal and it is doubtful if he could have made up a decent pipe joint, but he knew how it all ought to be done and he was satisfied with nothing short of "right." Things done so that they would "do for a while" did not go with him. Many of us despised inspectors have seen parallel cases. My dream only showed the difference very distinctly between what some men are doing, as engineers, and what they should do or else prepare themselves to get out in favor of the technical man.

An Example of Incomplete Combustion

It requires but a glance at the accompanying illustration to see that a large amount of combustible was being but partly consumed. The photograph was taken at a fire that destroyed a storehouse of the Vacuum Oil Company at Weehawken, N. J., and several thousand barrels of lubricating oil.

Oil Fire at Weehawken, N. J.

Although the fire was marked by a pillar of smoke that rose two hundred feet or more, there was but very little flame to be seen. The heavy black smoke rolled up in great profusion.

Engineers are seldom given a better illustration of incomplete combustion, or an example of a fuel being burned so fast that the necessary air to produce complete combustion could not reach

Burning Small Anthracite Coal

By A. S. Atkinson

The lower cost of buckwheat coal has induced many plant owners to change over from the larger sizes, regardless of whether the equipment is suitable for burning the smaller coal; hence an apparent gain is often turned into a loss. A number of practical suggestions for burning buckwheat coal are given.

The inducements for plants to burn very small sizes of anthracite coal form a temptation to change from the larger sizes to No. 2 or No. 1 buckwheat, and this, in many instances, has resulted in loss rather than gain through lack of sufficient knowledge concerning the value of the various grades of anthracite. The lower prices of the small sizes are the chief factors in influencing owners of steam plants to adopt buckwheat coal, but frequently coal dealers in their eagerness to make sales will advise wrongly as to the results.

In order not to drift into an error that will cause trouble later, it should be understood that broken, egg, stove and even chestnut coal can be handled with great ease in furnaces without any great amount of chimney draft. They will generate steam in the most economical way, and as there is relatively little ash in these coals the operation of cleaning the furnaces is reduced to a minimum. Also, if the grates have wide openings between the bars the furnaces can be operated for long periods without cleaning. These factors make the larger sizes of anthracite popular among power-plant owners, and especially among firemen and engineers; but the smaller sizes can be purchased so much cheaper that there is a constant temptation to change to them. It is quite possible in many plants to make this change and save money, but the actual difficulties and drawbacks should be realized in advance; otherwise a money-saving proposition may be changed into a loss.

The first move should be to ascertain what changes must be made in the grates and chimney. If the latter is comparatively short, barely sufficient to furnish the draft required for burning the larger coal, it will not answer for the buckwheat sizes. This fact is so often disregarded in making a change of fuel that it should be particularly emphasized. However, with steam plants as ordinarily built, it is a simple matter to increase the draft without any material alteration.

If the chimney capacity is sufficient there still remains the problem of grates. The ordinary wide spaces between the grate bars, such as are suitable for large anthracite coal, would not be satisfactory for the small buckwheat sizes. A bar of the herringbone type with air spaces one-quarter of an inch wide probably gives the best results for all-round purposes where buckwheat coal is burned. This type of grate is superior to the pin-hole grates or bars of three-eighths of an inch in diameter for the reason that the latter have a very low percentage of air space. Frequently this is not more than 10 per cent., and they are suitable for buckwheat only when forced draft is used. The herringbone type, on the other hand, averages 25 to 35 per cent. of air space, which makes it suitable for either natural or forced draft. Some plants use grate bars with an air space aggregating 45 to 50 per cent., but this is entirely unnecessary; an average of 30 per cent. answers all purposes better and works for economy, as there will then be no leakage of coal to the ashpit. Everything depends upon getting the right grate bars, the right proportion of air space, and chimneys of sufficient capacity. With these as a start the rest of the work can be accomplished with good stokers and firemen who understand how to burn small coal economically.

In using buckwheat coal for steaming purposes there is no substitute for skilled operation. It is essential to ascertain how much buckwheat coal is required to produce the same amount of steam as is generated by a certain amount of the larger coal. There is a difference in the efficiency and heat values of the two coals, and this must be ascertained and kept in mind. To ascertain how much more small coal is required, it is necessary to find the difference between the amount of ash in the two coals. When this is found by actual test it is a simple matter to calculate how much more of the small size is needed for generating a given amount of steam.

Ordinarily, buckwheat coal contains about twice as much ash as egg, but this will differ considerably in various grades. Consequently each separate lot must be tested, and the ash determined before intelligent burning can be carried on. It is true that very few companies go into all of these details, but it is also true that many are burning the small sizes at a considerable loss in economy.

A number of tests have been made with small and large sizes of coals to ascertain the relative amounts of the two fuels required to produce a given amount of steam. Without going into the details of these experiments it may be stated roughly that for the ordinary furnace it will require nearly 10 per cent. more of buckwheat than egg coal to give the same steaming results. These calculations are based upon dry coal, and when the coal is bought in a wet condition allowances should be made for the moisture. This difference is quite important. In large-sized coal the moisture is not as great a factor, but in buckwheat it is very important, often representing a difference of as much as 10 per cent.; that is, 10 per cent. of the weight of the coal when saturated may be water, and the plant owner is paying for this moisture for every ton he buys. Dry pea or buckwheat coal alone should be purchased, and if delivered wet an allowance of 8 to 10 per cent. should be deducted from the gross tonnage. Dealers prefer to deliver coal in a moist condition, but keen buyers refuse to take it by the ton weight in this condition. Likewise, when stored the coal should be kept as free from moisture as possible.

When the necessary amount of buckwheat coal has been determined, the problem of obtaining the highest efficiency from it should next come up for solution. Here the fireman will determine the economy or loss resulting from the use of the new fuel. More skill is required for firing with buckwheat than many imagine. In the first place, it must be spread lightly and uniformly over the fire, and fired at frequent intervals. Any attempt to fill the furnace with sufficient coal to last as long as the egg size means a loss; yet this is the temptation to which many yield as it is the easiest way to fire the boiler. The grate will also need more frequent and thorough cleaning with the small sizes. This means more time and labor on the part of the fireman, and unless a good man is employed, it will be neglected. A competent and conscientious workman will, however, obtain as good efficiency from buckwheat coal as from egg if the conditions of the grate and chimney are satisfactory to start with.

The small particles of buckwheat coal form a much denser and more compact bed of fuel than egg coal, and in order to make this burn satisfactorily the draft must be stronger. There must be a greater suction or pressure to get the necessary air through the bed to insure perfect combustion, and here the problem of natural or forced draft is involved. If the chimney is of ample capacity, and the grate bars are wide enough to admit plenty of air, natural draft will suffice, but if there is not sufficient draft it will then be necessary to resort to artificial draft to secure the economical results aimed at. A little previous study and measurement of the chimney capacity and the draft at the boiler damper will obviate any trouble that may arise later.

A table based upon the results of a long series of experiments gives the following draft in inches of water at the boiler damper required for the combustion of pea coal under the best conditions:

10 pounds per square foot of grate per hour	0.[illegible] inch
15 pounds per square foot of grate per hour	0.[illegible] inch
20 pounds per square foot of grate per hour	0.7[illegible] inch
25 pounds per square foot of grate per hour	1.[illegible] inch

The engineer can increase the draft or increase the grate surface, or both, to obtain the desired results, but there must be careful study of the conditions before conclusions are drawn. Buckwheat coal can be used with very wide furnaces, and also with those that are quite deep. It is particularly suited for grates up to twelve feet in depth, which makes it a very economical fuel for certain work. The coal can be spread evenly over this large grate surface, and if spread uniformly it does not have to be worked and manipulated in order to get the fire even throughout. In this respect the buckwheat has an advantage over some of the larger sizes which must be raked and poked about at intervals to secure uniform heat. In ordinary shaking grates the small sizes cause more or less trouble and extra labor. In small grates, shaking and poking may prove satisfactory in cleaning the fires, but this will hardly answer in grates exceeding eight feet in width, in which case dumping must be resorted to. If the grate is provided with a good shaking and dumping arrangement, a fire can be kept clean and bright for long periods, and then, when needed, the grate can be dumped without materially cooling the fires for any great length of time.

Small anthracite is burned most successfully in plants with chimneys 200 feet or more in hight without forced draft, but in chimneys less than 100 feet some system of forced draft is usually necessary. It is even considered advisable in some cases to use forced draft where the chimneys are very tall, just to overcome weather conditions. In such cases the forced draft is not used except on such days as the weather makes burning with natural draft somewhat difficult. The cost of the forced-draft equipment is insignificant considering the results and the efficiency and economy obtained. Where the coal tends to form bad clinkers the forced draft should be supplemented by jets of steam passing through the fuel bed; this increases the efficiency of the boiler and saves time and labor in the cleaning.

There is quite a wide difference in the quality of small anthracite. Some will clinker badly under any but the most favorable conditions, and some grades will burn satisfactorily under very unfavorable conditions. This accounts in a measure for the difference in results obtained by plants which burn buckwheat coal; one will show excellent results without many of the modern improvements, and another will show poor results. It is the difference in the burning quality of the coal. For this reason the greatest care should be exercised in obtaining a good grade of coal at all times. The difference in the cost sometimes more than counterbalances the difference in the burning qualities.

A Remarkable Overload Boiler Test

The power plant for the repair shops of the New York Central Railroad at West Albany, N. Y., has recently been nearly doubled in capacity. The original boiler installation, consisting of four 500-horsepower Franklin water-tube boilers equipped with Taylor gravity underfeed stokers, has been supplemented by the addition of three 600-horsepower Edge Moor water-tube boilers also equipped with Taylor stokers. Two 500-kilowatt Western Electric alternating-current generators direct connected to 750-horsepower Ball & Wood horizontal cross-compound engines were installed at the same time. The original generating units consisted of two 600-kilowatt General Electric alternating-current generators driven by 900-horsepower Ball & Wood engines.

In order to meet the demands for power in the repair shops it is often necessary to overload the boilers greatly and this overload is likely to continue for some time. Accordingly, it was thought advisable to subject the new units to a very severe test to determine their capacity for handling a long continued excess load. To this end one of the new boilers located at the extreme south end of the boiler room and known as boiler No. 7 was tested for 16 hours under an average load of 1120 horsepower or 186 per cent. of the builder's rating. Furthermore, during the first 14 hours of the test the average horsepower developed was 1158, corresponding to 193 per cent. of the rating. The extreme severity of this test both on the boiler and the stoker may best be appreciated when it is considered that ordinary acceptance tests rarely exceed eight hours in length and the horsepower developed seldom exceeds 50 per cent. above normal rating. In general, for tests at higher rating, the time is cut down to six or even four hours' duration.

The test was conducted by the mechanical engineering force of the railroad from 9:15 a.m. on October 11 to 1:15 a.m., October 12. All the coal used was carefully measured on platform scales and the amount of water used was determined by means of calibrated barrels. The Hempel apparatus was used for analyzing the flue gases. Forced draft is obtained for this installation by means of a fan blower.

The principal dimensions and proportions of the boiler and stoker are as follows: Water-heating surface, 6129 square feet; grate surface, exclusive of area of the dumping plates, 70 square feet; number of tubes, 308; size of tubes, 4 inches in diameter by 18 feet long; spacing of tubes, 12 high by 20 and 21 wide; width of stoker grate, 12 feet 7 inches; width of furnace above stoker, 13 feet 4½ inches; length of furnace to the bridge-wall, 7 feet 3 inches.

The stoker used in connection with this boiler is of the seven-tuyer style; that is, there are seven coal-feeding chutes, each operated by a separate pair of plungers. The coal is fed in underneath the fuel bed and becomes thoroughly coked before reaching the surface of the fire. As the air supply is governed automatically by the speed of the stoker, there is no necessity for adjustment at different loads.

The principal reported data on this test follow:

CONDITIONS

	For 16 Hours	For First 14 Hours
Steam pressure, lb. gage	177.[illegible]	177
Draft in chimney, in. water	[illegible]	[illegible]
Draft over fire, in. water	—0.1	[illegible]
Draft in uptake, in. water	[illegible]	[illegible]

Methods of Governing Steam Engines

By John Davidson

Serial with article under the above caption in the February 21 issue. In this instalment are discussed combined throttle and variable expansion governors and expansion governors for actuating trip gears.

Combined Throttle and Variable-expansion Governing

Most modern high-speed engines are now controlled by means of a combination of both throttling and variable expansion. The governor is fixed to the crank shaft, and actuates a throttle valve in the usual way, but in addition to this, it also controls the cutoff by slightly rotating the piston valve in such a way as to alter the lead. The piston valve for engines governed in this way is necessarily of special design, and is provided with ports of angular shape arranged to engage with corresponding ports in the liner.

Fig. 13 is an elevation of a high-speed engine showing the governing gear, and Fig. 14 is a detailed view of the spring box employed for the purpose of allowing the throttle valve to act quickly and independently of the cutoff mechanism. Fig. 15 shows the developments of the valve and liner surfaces. Referring to Fig. 13, governor *A* is fixed to the engine crank shaft and is inclosed by a casing *C*. The rocking shaft *D* of the governor carries two operating arms *E* and *F*, the former controlling the throttle valve through rod *G*, and the latter the cutoff. The lever *E* is provided with a spring attachment *J* at its outer end for the purpose of regulating the action of the governor. The end of the lever *F* works in a box *K* (see detail, Fig. 14), inside of which there is a spring *M*, in compression between the end of the box and a cap on the end of the lever. When the lever *F* is moved from right to left by the action of the governor, the spring *M* is compressed and through lever *O* causes the vertical shaft *N* to rotate. As this shaft rotates through a small angle, it actuates the system of levers, shown in the small plan view, which is similar to a Stanhope lever. This lever is connected to a shaft passing through the end of the valve chamber, which, in turn, is fixed to a spider *S* mounted on an extension on the slide valve *T*. Thus the movement of the governor balls causes the angular adjustment of the piston valve *T*, and this effects the acceleration or retardation of the cutoff in the following manner:

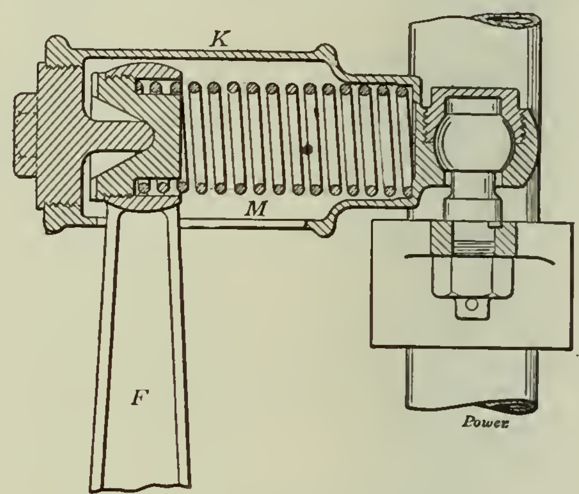

Fig. 14. Spring Box

The valve *T* is arranged to slide in the liners *U*, located at the top and bottom of the valve casing, these liners being provided with triangular ports *V*, while the valve itself has inclined cutting-off edges *W*. The triangular port is in the form of right triangle with the hypotenuse, which forms the steam edge of the port, inclined at 45 degrees. The cutting-off edges of the valve are also inclined at 45 degrees, so that an axial motion of the piston valve moves the cutting-off edges of the valve parallel with the inclined edges of the ports. The relative positions of these cutting-off

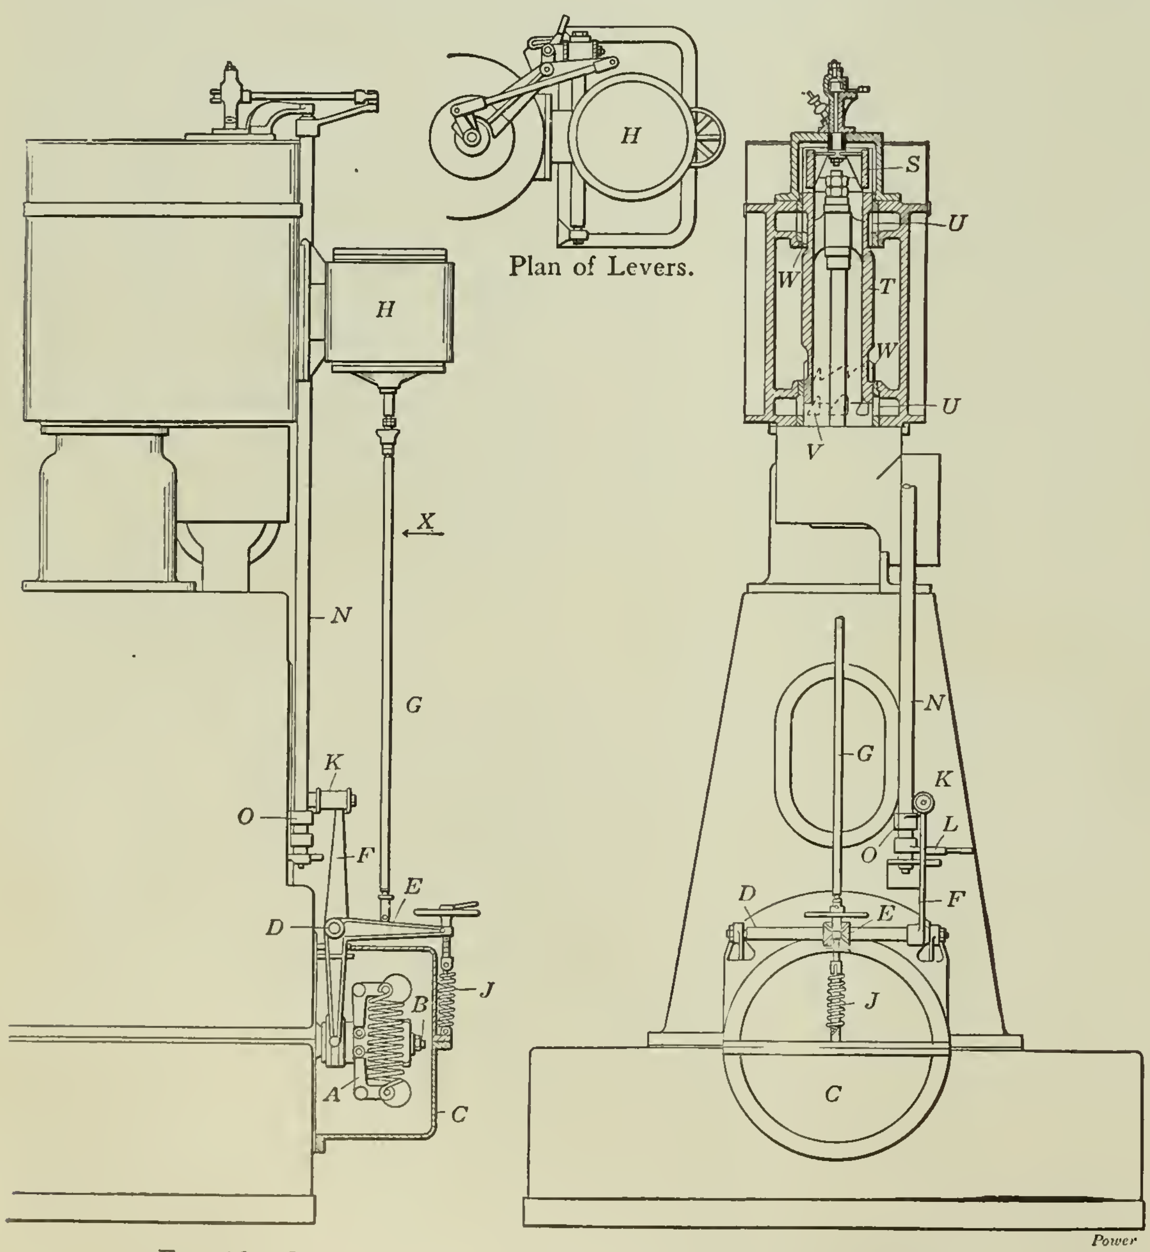

Fig. 13. Governing Gear for Small High-speed Engines

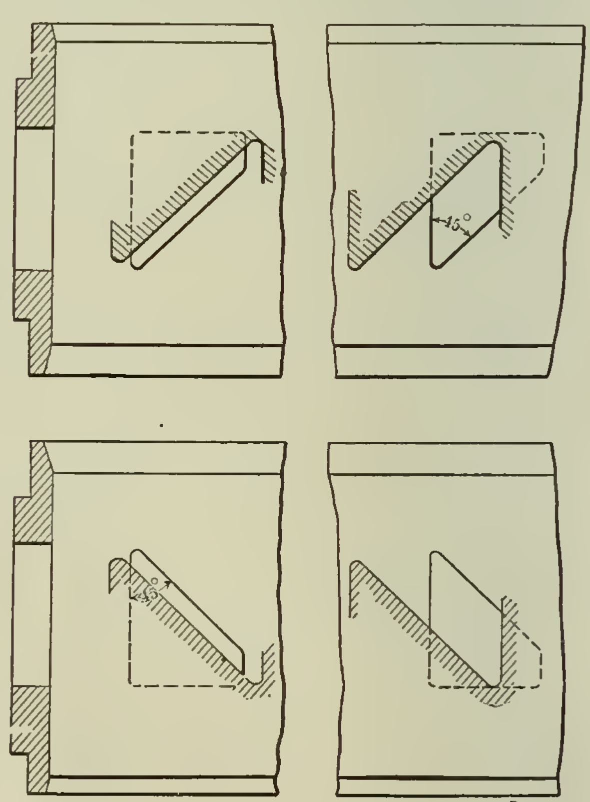

Fig. 15. Valve and Liner Surfaces

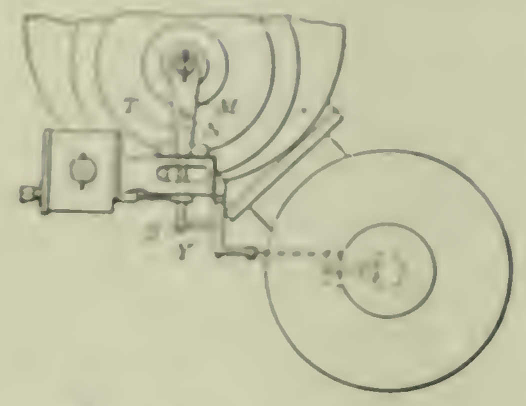
edges and ports are shown in Fig. 15, in which the left-hand view represents the relative positions when the valve is set to give the earliest cutoff, and the right-hand view the relative positions when the valve is set for the latest cutoff, these positions being taken at the same point in the travel of the valve. In order to cut off steam, the valve is required to move through a greater distance axially when in the latter position than when in the former. Also in the left-hand position the lead will be smaller than in the right-hand position, and the lap will be correspondingly greater. It has been found that with high-speed engines this reduction in the lead is no disadvantage, but has the effect of making the engine run more smoothly.

The operation of the gear is as follows: Assume first that the load has suddenly been taken off the engine. The consequent increase in speed will cause the governor balls to fly out and throttle the steam by means of the throttle valve in the casing H, Fig. 13. Meanwhile, the rotation of the slide valve will be much slower, owing to the intervention of the spring. The valve will, at first, be rotated through a considerable angle till that position is reached at which the speed is normal. When the point of earliest cutoff is reached, the engine is further governed wholly by throttling.

Now assume that the slide valve is at the point of earliest cutoff, the throttle valve is throttling the steam and the load is increased; the effect of this increase in load will be to open the throttle valve; meanwhile, the slide valve is not appreciably changed, owing to the action of the levers Q and P, but the throttle valve will continue to open until it ceases to throttle the steam. The arrangement of levers is so designed as to produce a material change in the position of the slide valve only after the throttle valve has ceased to throttle the steam. In this way the engine is governed at low loads by throttling, and at high loads by varying the expansion. By means of this gear it is possible to arrange for a variation in cutoff from 40 to 80 per cent. of the stroke.



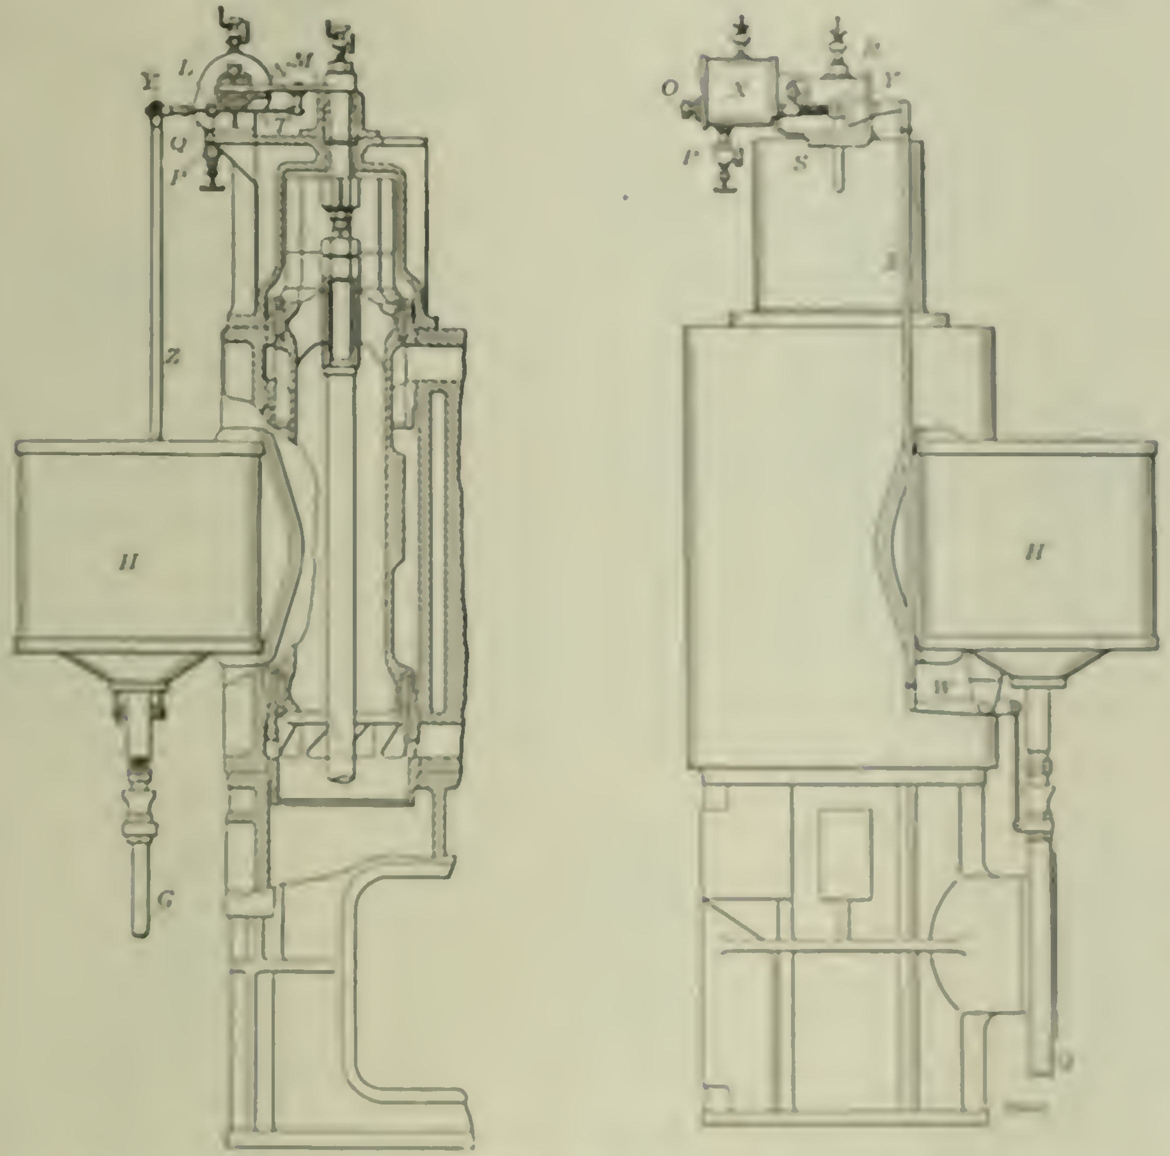


Fig. 16. Arrangement for Regulating Cutoff through Relay Piston

With large engines, it is usual to operate the cutoff valve through a relay cylinder, thus greatly relieving the governor, as it has then only to actuate a small piston valve in connection with the relay piston cylinder. Instead of using a spring and Stanhope lever, the gear illustrated in Fig. 18 is used. Here the spring is replaced by a small relay cylinder X and the Stanhope lever by a cam Y. The upward movement of the link G causes, through lever W, a downward motion of link Z which is connected to an extension on the cam Y. While this is taking place, the throttle valve in H is moved as in the case previously described. The motion of the pivoted cam at first produces no effect upon the cutoff because the cam is in the form of an arc with its center at the pivot. When, however, the throttle valve has been opened to such an extent that further movement has no effect upon the control of the engine, a raised portion R on the cam comes opposite a follower S, held in place by a spring. The follower is attached by means of a lever T to the

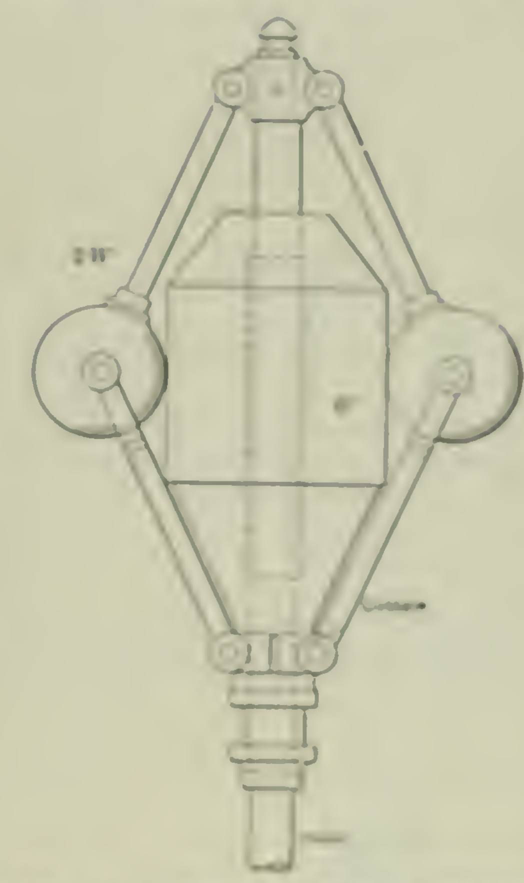

Fig. 17. Original Porter Governor

spindle L of a slide valve, which controls the admission of steam to the relay cylinder. Steam enters the valve casing Q by pipe P, and exhausts by pipe O.

The lever M is connected to the main slide valve of the engine, or, if the engine is of the multiple-expansion type, to the high-pressure slide valve, so that the valve is turned and controls the cutoff as described in the preceding case.

Lever T, which carries the cam follower, is pivoted at the end of spindle L and also at N to the lever M. As the lever M is moved in a counterclockwise direction under the action of the relay piston, and the follower S is moved clockwise under the action of the cam, the motion of the slide valve in the casing Q is made slower, and more accurate adjustment of the engine slide valve is rendered possible. In this manner, at light loads the engine is governed by throttling and at heavy loads it is governed by the cutoff.

Variable-expansion Governors for Actuating Trip Gears

The governor most commonly used for this purpose is the original Porter governor, illustrated in Fig. 17, but many firms have adopted a modified form of

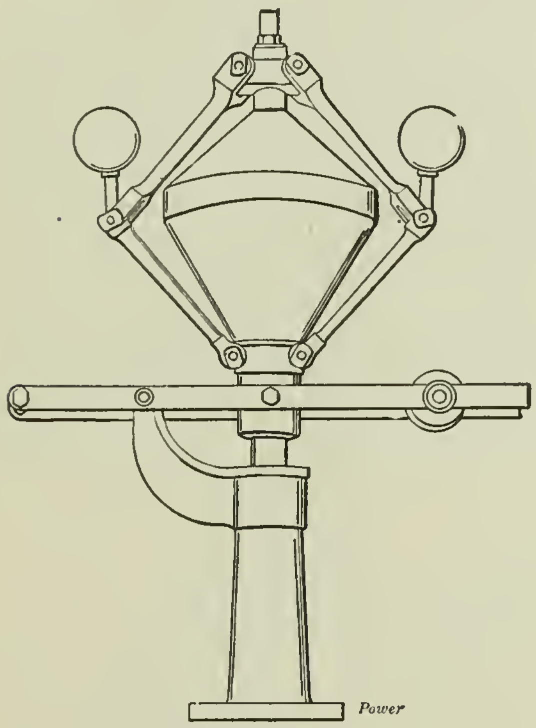

Fig. 18. Modified Proell Governor

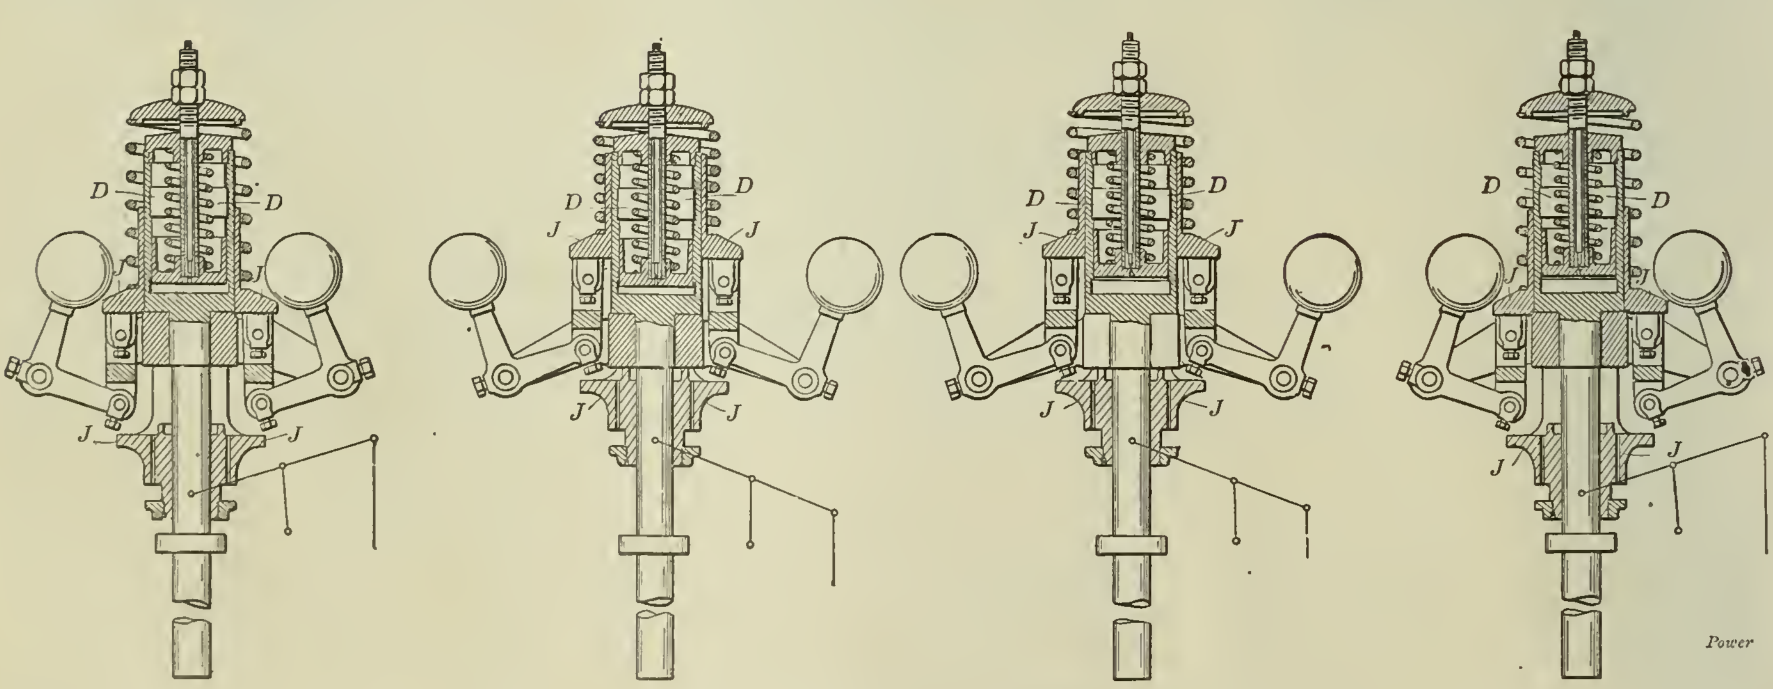
Proell governor as illustrated in Fig. 18. The latter is very sensitive but does not possess much controlling power.

The Proell governor itself, which is illustrated in Fig. 19 is much more powerful, and at the same time is very sensitive. The governor flange D, which is secured to the top of the stand, has a



Figs. 20-23. Whitehead Governor in Various Positions

cylindrical sleeve, into which is fitted the hollow spindle A. This spindle has lugs at E and F, from which are suspended two hanging straps H_1 and H_2, carrying at E' and F' two pendulums P_1 and P_2 which, at their lower ends B and C, are pivoted to the movable sleeve S. By this peculiar suspension of the governor balls, they are guided in a straight line, and, when revolved, describe a plane, not an arc or spherical surface, as is the case with all other governors. The straps H_1 and H_2 are continued at their upper ends as bell cranks, and these carry the cross bridge R, at K_1 and K_2, on hardened knife edges. Into the center of the cross bridge and into the bottom of the spindle A are fitted two spring holders T_1 and T_2 which hold between them a strong spiral spring in tension; this counteracts the centrifugal force of the governor balls. Many governors have been constructed on the principle of balancing centrifugal force against spring power, but as the balls open in an arc, an equal angular opening does not vary the centrifugal force in the same ratio as the compression of the spring. In the Proell governor the increase or decrease of centrifugal force is proportionate to the increase or decrease of spring power, to whatever angle the governor may be opened. This construction, therefore, secures the most sensitive regulation obtainable, while the strength of the spring and the heavy weight of the balls exert great power. With the exception of the support D, the whole governor is revolved by the bevel gear W.

A governor, which is very quick in responding to changes of load and pressure, and at the same time maintains the speed of the engine constant, is the Whitehead governor llustrated in Figs. 20, 21, 22 and 23. The balls and bell cranks are mounted on and driven by a yoke or cross bar by means of the spindle, which, in turn, is actuated by gearing or belting. The top of the spindle is a cylinder, in which a piston works, the hollow piston rod passing through the cylinder cover. The cylinder is filled with oil, which is allowed to flow from one side of the piston to the other through passages provided for that purpose. The rate of flow is controlled by the spindle acting as a valve and by the set screw at the top of the piston rod, there being a small spring at the lower end of the spindle which tends to lift the valve off its seat when the set screw is released. This combination acts as a dashpot.

The essential feature of this governor is the employment of two springs, one compressed between the sliding collar

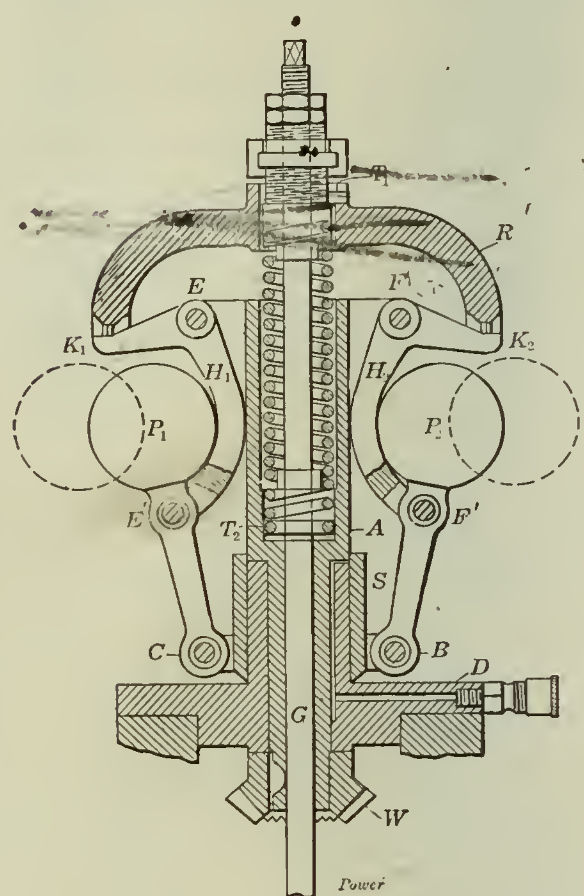


Fig. 19. Regular Proell Governor

and the plate, and the other between the piston and the cover of the cylinder. As both springs exert a pressure in opposite directions upon the plate, which is free to move under their influence, it is obvious that the two springs must have the same degree of compression, provided the oil in the cylinder permits a movement of the piston to take place; which will, of course, occur so long as any passage exists for the flow of the oil from one side to the other of the piston.

All ordinary governors, whether high or slow speed, sensitive or sluggish, must be designed to give a certain percentage of speed variation between no load and full load; that is, the speed at which the

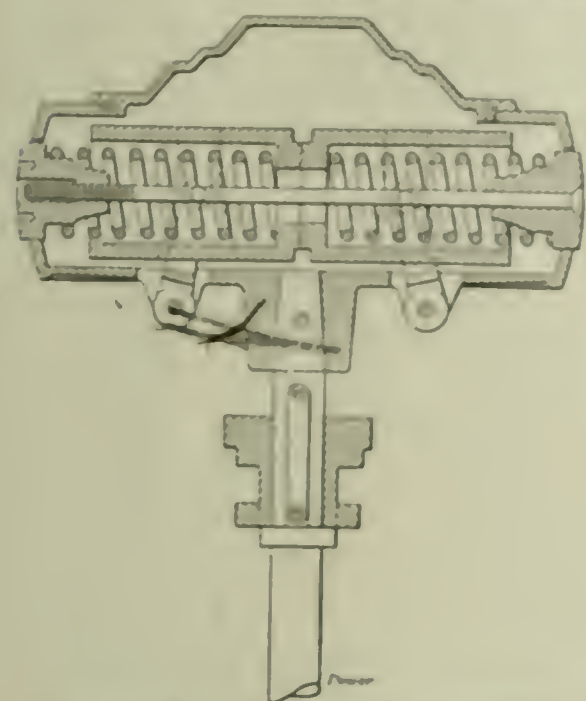

Fig. 24. Hartung Spring Governor

engine will work without hunting must always be higher with light than with heavy loads, for with light loads the engine must run faster than its normal speed in order to maintain the balls in a position to restrict the steam supply. On the other hand, the engine will slow down below the normal speed when an extra-heavy load comes on, so that in reality it maintains a normal speed at one load and steam pressure only, and is only approximately correct at all other loads or pressures.

The Whitehead governor, assuming that the outer spring only is in action, would have a variation of 12 per cent. between the bottom and top positions of the sleeve, but, owing to the equilibrium sought between the two springs, this 12 per cent. of variation is eliminated, and the governor is absolutely isochronous. In order to vary the speed of a spring-loaded governor, it is usual to slacken the spring if the engine is required to run slower and to tighten it if required to run faster. Upon this fact is based the operation of the Whitehead governor.

Fig. 20 shows the governor with the balls and the sliding collar in the bottom position giving steam to the engine. Assuming the governor is set to run at 200 revolutions per minute when the engine is running at its normal speed, the springs when working together exactly balance the centrifugal force of the balls at 200 revolutions in any position; therefore, the balls do not begin to spread or move outward until they attain that speed. Presuming that the load is suddenly thrown off the engine, the speed rises and the balls spread out, due to their centrifugal force. This lifts the sliding collar until it is in its top position, as shown in Fig. 21, thereby compressing the outside spring. If it were possible then to prevent the inside spring from compressing, and the top plate from moving upward, the governor, in order to keep the balls spread out, would have to run 6 per cent. faster, or 212 revolutions per minute; but, as the compression of the main spring transmits pressure through the piston rod and piston to the inside spring, the latter will compress and the piston will move up to the position shown in Fig. 22, thereby slackening the outside, which has the effect of producing a slower speed.

It was pointed out that the two springs together exactly balance the centrifugal force of the balls in all positions; therefore, when the inside spring has finished compressing, it will have relieved the outside spring so that a speed of 200 revolutions per minute will main the balls in their new position and the speed of the engine will again be normal.

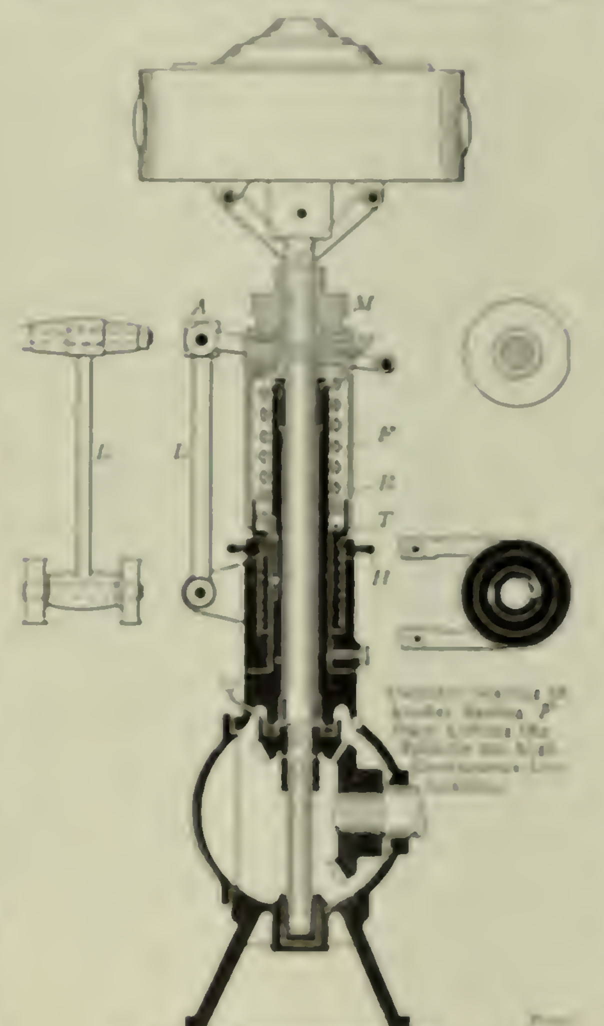

Fig. 25. Templin Governor

Presuming now that the full load is suddenly put on again, the balls drop back and the sleeve falls to the bottom position, as in Fig. 23. In this position the inside spring is still compressed as in Fig. 22 and, therefore, the outside spring is slackened until the speed drops 6 per cent., or to 188 revolutions; then the inside spring expands, and brings down the top of the outside spring until it is again in the position shown in Fig. 20, when the speed will have risen again to 200 revolutions.

In the foregoing explanation, in order to illustrate the action as clearly as possible, it was purposely said that the inside spring begins to move after the outside spring has been compressed or expanded by reason of the balls respectively spreading or coming in, so as to prove that the governor has its outside or governing spring automatically slackened or tightened by the inside or regulating spring. This statement, however, must be modified by stating that as soon as the outside spring has its pressure increased the inside spring feels the effect of this, and at once begins to compress. It is only prevented from doing so simultaneously with the outside spring by the necessity for the oil in the chamber having to pass to the opposite side of the piston; thus the inside spring lags slightly and only completes its movement after the outside spring has come to a state of rest. In this way any extraordinary excursion of the balls is checked and all hunting is obviated.

Hartung's Patent Spring Governor

A type of governor largely used on the Continent is the Hartung, illustrated in Fig. 24. This governor, although very sensitive, is extremely powerful. It has two hollow cylindrical weights revolving in a plane perpendicular to the axis of rotation, and inside these weights are two compression springs. The weights are hinged on bent levers which engage at their other ends with the governor sleeve, the weights thus being kept in their positions relative to the springs when revolving. In this way the action of the centrifugal force is opposed directly by the spring, so that no pressure

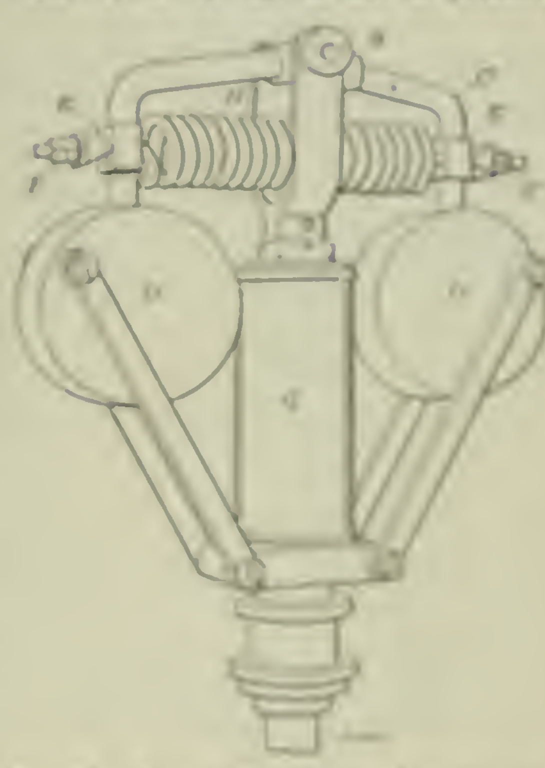

Fig. 26. [illegible] Governor Adapted to Engines of This Type

due to either of these forces acts upon the levers. In this way the friction is reduced to a minimum, and the wear in the sleeves themselves is due only to the action of the force necessary to alter the trip gear, and not by any undue pressure from the springs or centrifugal force of the weights. The governor is entirely inclosed in a circular casing which gives it a neat appearance, and at the same time, prevents dirt and dust from getting into the interior.

Another governor with weights arranged in a similar manner is "Temples

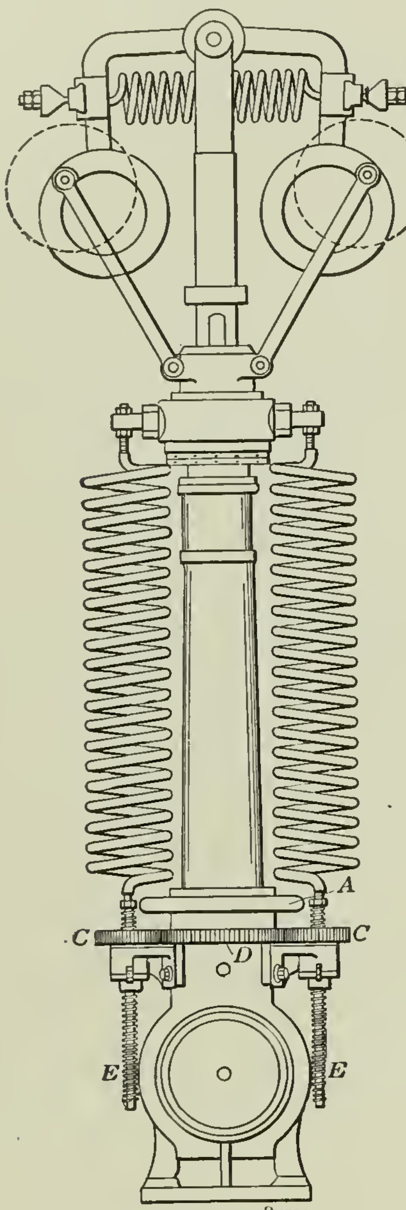

FIG. 27. TOLDES GOVERNOR FOR VARIABLE SPEEDS

patent," illustrated in Fig. 25. A change in speed is effected by means of a spring *F* coiled around the shaft of the governor; the lower end of this spring be-

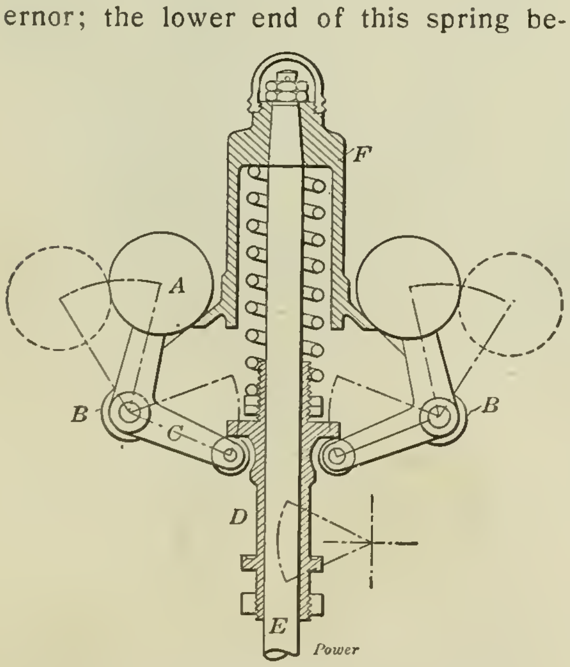

FIG. 28. HARTNELL GOVERNOR FOR SINGLE-SPEED ENGINES

ing secured by the cup *T* and the handwheel *H*, by means of which it may be more or less tightened.

The gear lever is secured by means of rod *L*, and the sliding ring can only move with the sleeve in a straight line. It is worthy of note that by this arrangement, the higher the number of revolutions, the lower the pressure of the spring, and *vice versa.* The wear of the sliding surfaces of the ring and the sleeve *M* is thus reduced to a minimum. In most other systems the loading of the sleeve has quite a different effect, for the greatest pressure corresponds to the greatest number of revolutions, which

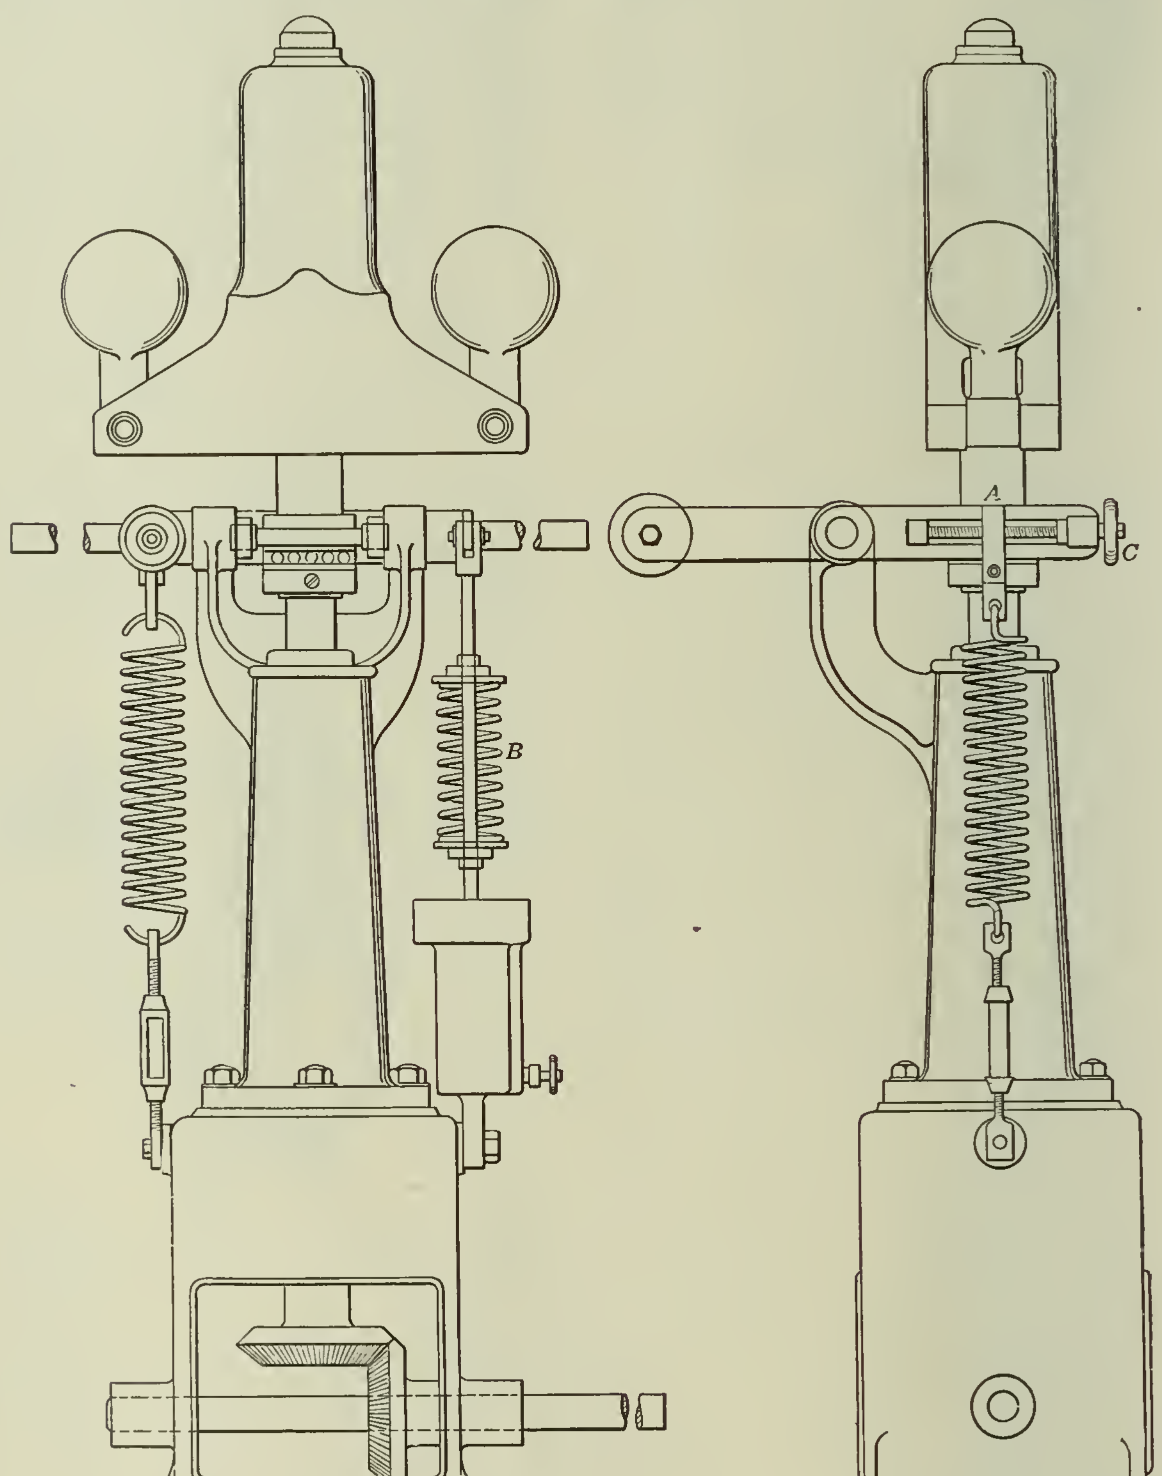

FIG. 29. HARTNELL GOVERNOR FOR VARIABLE SPEEDS

causes both heating of the sliding ring and quick wear.

Another type in which a large variation in speed is possible, is the Toldes patent governor, shown in Fig. 26, and made by Theodor Wiede's Maschinenfabrik, Saxony. The principal claim for this governor is that any change of the load on the spindle, tending to alter the speed within predetermined limits, does not affect the character of the governor in any way; that is, the degree of variation remains the same for every newly adjusted speed.

The governor consists of two weights *D D* suspended from a central pivot *B* by two bent arms *C*. The centrifugal force of the weights is balanced by the coiled steel spring *D* which acts through the knife edges *E*, the tension on the spring being adjusted by the nuts *F*. In the central casing *G* there is a smaller spring which acts on the central sleeve. If this spring is tightened the speed and energy of the governor are increased without in any way altering the degree of speed variation. If, on the other hand, the adjustment of the horizontal spring *D* is changed, the degree of variation is increased or decreased.

The governor illustrated in Fig. 26 is adapted for engines running at one speed only. When a considerable range in speed is desired, the central spring is replaced by two, as shown in Fig. 27, the two being adjustable simultaneously by means of the handwheel *A* actuating the gears *C C* through the central gear wheel *D*.

In Fig. 28 is illustrated a Hartnell governor. This is of the spring type and is very largely used. At *B* are pivoted the weights *A*, formed in one piece with the arms *C*, to the end of which are fixed rollers engaging a sleeve *D*; the latter slides on the vertical spindle *E*. The main governor spring is of the compression type, and is fitted between the sleeve and the cap *F*, to which are cast the lugs carrying the fulcrum pin *B*. Governors of this design are powerful and at the same time can be made very sensitive, in many instances the actual speed variation does not exceed 1 per cent.

For ordinary purposes, where an engine is only required to run at one speed, this arrangement of the governor is adequate. But where it is desired to vary the speed of the governor within moderate limits a spring is attached, as shown at *A*, Fig. 29. When the governor is used for actuating an expansion gear which will throw a reciprocating force on the governor, a dashpot is necessary; also, governors fitted to engines driving irregular loads, such as for rolling mills, etc., must not be very sensitive, and are better fitted with dashpots.

In cases where not only the speed of the governor has to be varied, but also the sensitiveness, it is necessary to vary the point of attachment of the spring. This is effected as shown at *A*, where the speeder spring is attached to a sliding block fixed to the arm, its position being adjusted by means of the small handwheel *C*.

In a few difficult cases, such as where the flywheel of an engine is small, or where there is a compound engine with a throttle valve, or with large intermediate space, or both, and where at the same time the mean speed of the engine must not vary to any extent, the governor spring is generally arranged to give a variation of, say 1½ per cent. from the mean speed. In addition there is a spring connected to the dashpot, as shown at *B*, and calculated to cause about 5 per cent. variation from the mean speed. Then, if the load be instantly taken off, the governor is at first controlled by the outer and inner spring and a considerable variation of load may take place, but as the dashpot yields the outside spring ceases to act and the engine returns to the mean speed, due to the governor only. In this case the dashpot also has a regulating screw.

All governors of the Hartnell type when used for electric-lighting purposes and where sensitive governing is required for considerable periods without stopping, are fitted throughout with ball bearings.

Modern Coal and Ash Handling System

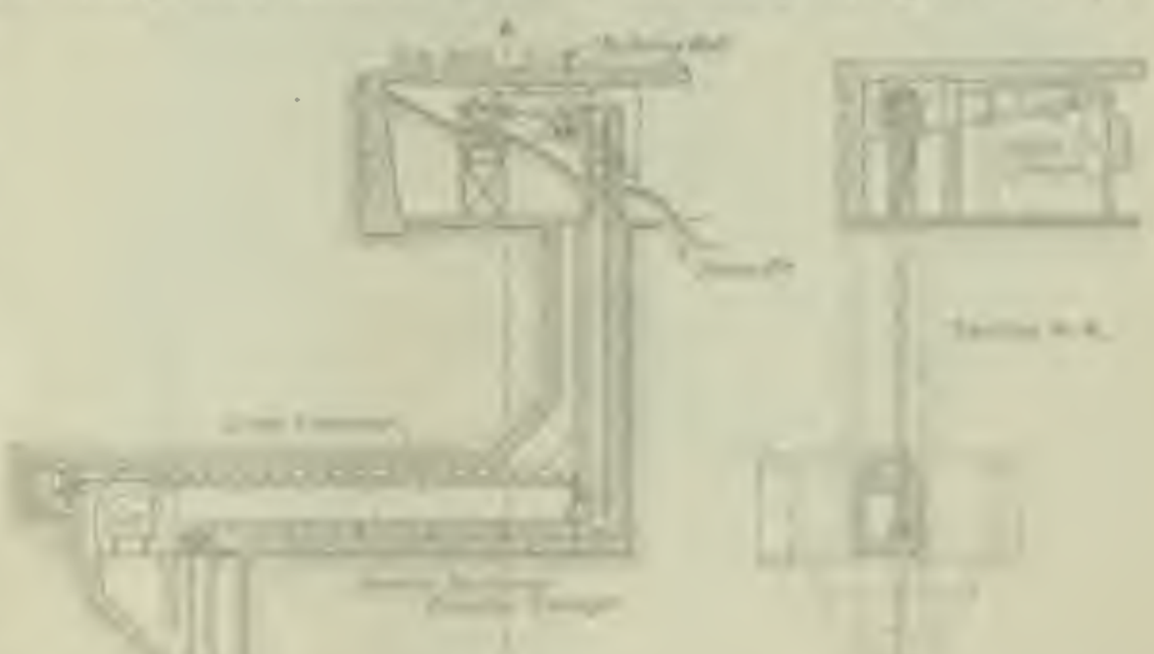
A combination coal and ash handling equipment taking coal from tunnel cars 45 feet below the street level and delivering it to the boiler room of an office building.

In the boiler room of the Merchants' Loan and Trust Company building, of Chicago, there has recently been installed a system of coal and ash handling which, although in a cramped space, shows a good efficiency.

The coal is delivered to the building in steel cars traveling in a branch of the Illinois tunnel 45 feet below the street level; these cars discharging into a concrete pit, from which the coal is taken by a gravity-discharge bucket elevator and conveyer. This machine is equipped with V-shaped buckets secured every 2 feet with malleable-iron attachments, to two endless conveyer chains; the speed of the buckets, when in operation, being 100 feet per minute. Referring to the illustration, it will be noted that the buckets, when traveling horizontally, push the material along in a steel trough and, when traveling vertically, automatically adjust themselves and lift it as does a bucket elevator.

The machine first lifts the coal 12 feet to the tunnel level, and conveys it to a point 30 feet away where it is again lifted 35 feet to the boiler room and discharged into the trough of a flight conveyer running at right angles to and in front of the boilers. The latter conveyer consists of a single endless chain running over two sprockets, placed at 30-foot centers and mounted on a steel frame. Fastened to the chain are steel flights, 2 feet apart, which, on the lower run, push the coal along in a trough. The coal is discharged through an opening in the trough and spouted to the storage pile in front of the boilers.

The present boiler equipment necessitates firing by hand, hence the storage pile. It is intended, however, to install new boilers equipped with mechanical stokers and the same conveying system will be adaptable to the new arrangement. The short flight conveyer will be removed and the gravity-discharge conveyer will be run up over the boilers and discharge into a 200-ton storage hopper, thence down and under the boilers where it will receive the ashes and convey them to the grating above the concrete chute shown in the illustration. The single machine will then be delivering the coal and hauling away the ashes in the most efficient manner possible, and this will practically do away with all manual labor in handling coal and ashes.



Elevation of Conveyor

At the present time the ashes are shoveled onto a grating through which they pass into the concrete chute, discharging into a special 16-inch cast-iron screw conveyer; this, in turn, conveys the ashes to the tunnel, where they are delivered into cars. This conveyer is equipped with a sliding steel trough at the tunnel end, which may be run out directly over the cars.

The gravity-discharge elevator and conveyer and the flight conveyer, are both driven through two gear trains by an electric motor, which is fitted with a rawhide pinion to eliminate the noise.

The present equipment is capable of handling 40 tons of coal per hour and was designed and manufactured by the Stephens-Adamson Manufacturing Company, of Aurora, Ill.

Electrical Department

Especially conducted to be of interest and service to the men in charge of the electrical equipment

Jones; Trouble Killer

Second Talk on Power Factor

"Now this matter of power factor is simple enough," said Jones, when he and the engineer got back from dinner, "when you once get the hang of it, but I'll admit that it isn't easy to get the hang of it."

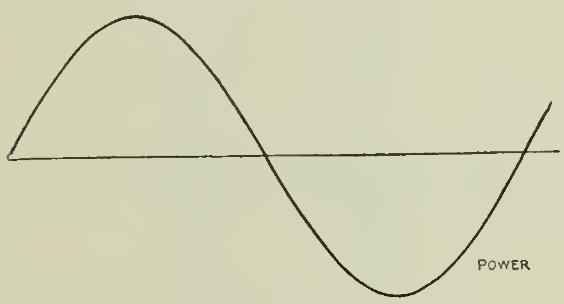


Fig. 2.

He fished out his loose-leaf book and turned over to a page of diagrams. Pointing out one that looked like Fig. 2, he said:

"You know what that is, of course."

"Sine curve," said the engineer, with conscious pride.

"Negative Power is Power Delivered to the Generator from the Circuit."

"Right. What does it represent?"

"An e.m.f. wave," said the engineer, swelling still more.

"What's an e.m.f. wave?" demanded Jones, regarding the engineer with a lively twinkle in his eyes.

"A—a—it's a wave of—a—wa—"

"A wave of electromotive force, eh?" suggested Jones with good-natured sarcasm. "It naturally wouldn't be a wave of sea water, now would it?"

The engineer rubbed his nose and dug hard into his mental recesses but they refused to deliver any inspiration. He shook his head slowly.

"I know," he said, "but I don't know how to say it."

"I know you know," said Jones, "and you know how to say it, too, but you're rattled a little, that's all. Tell me this: How many times does the e.m.f. represented by that curve rise to its maximum value?"

"Twice; once positive and once negative."

"All right. Now, what is it that is made up of a rise to positive maximum, a drop to zero, a rise to negative maximum and another drop to zero? What does that constitute?"

"One cycle."

"Of course. Then this sine curve representing an e.m.f. wave is a curve showing what?"

"The changes of pressure during one cycle," hastily replied the engineer.

"Now you're on the job," said Jones, with an approving extension of his grin. "You know that if a recording voltmeter could follow the changes of pressure exactly as they occur, it would draw a diagram like that for every cycle, don't you?"

The engineer nodded. "Just like a steam-engine indicator draws a diagram of steam-pressure changes that happen in the cylinder," he suggested.

"Correct," said Jones. "Of course, no voltmeter is sensitive enough to follow the changes of e.m.f. through a cycle, because of the inertia of its parts, and it couldn't be made to follow 'em accurately anyhow, the way voltmeters are made, even if it had no inertia. But that curve corresponds exactly to the steam-pressure curve drawn by an indicator."

"But what's that got to do with the power factor?" asked the engineer.

"Keep your shirt on; I'm coming to that as fast as you'll let me," responded Jones.

"If a recording voltmeter could be made to draw the e.m.f. curve showing the changes during each cycle," he resumed, "a recording ammeter made just like it would draw the same sort of a curve to represent the rise and fall of current in the circuit, wouldn't it?"

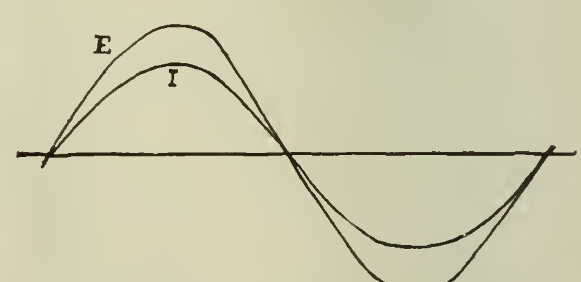

Fig. 3. Jones' Sketch

"Of course," agreed the engineer.

"And if you could arrange 'em to draw the two curves on the same sheet of paper at the same time, the diagram would look something like this, wouldn't it?" asked Jones, drawing Fig. 3.

"I dunno, but I sh'd think so," said the engineer dubiously.

"Well, it would," Jones assured him, "*provided*—now mind what I'm saying—

provided the e.m.f. and the current were in phase or in 'step' with each other."

The engineer nodded.

"But suppose the current lagged behind the e.m.f. in its rising and falling —didn't reach its highest point until after the electromotive force had passed its highest point and was falling. What kind of a diagram would your voltmeter and ammeter draw?"

The engineer brightened up. He had been rereading the old Electrical Catechism printed in POWER ten years ago and his memory was clearing.

"About like this," he suggested, drawing Fig. 4, "if the difference in phase wasn't very big."

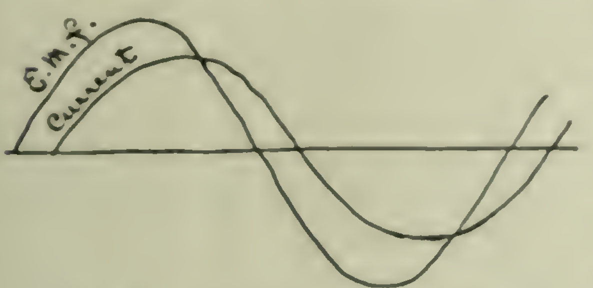

FIG. 4. THE ENGINEER'S SKETCH

"Good boy," Jones ejaculated, "you're getting close to the throne." Thumbing over the leaves of his book he pulled out another diagram, which is reproduced in Fig. 5.

"Here's a diagram of lagging current all scaled up for convenience in figuring the effects of the lag. Before going into that, though, do you understand why I've got the e.m.f. cycle scaled in three hundred and sixty divisions?"

"Because a cycle's got three hundred and sixty degrees, like a circle," ventured the engineer.

"Well, that's not exactly the right answer. A cycle hasn't any degrees, and there is no physical reason why it should be divided into three hundred and sixty any more than a hundred or a thousand or any other number. It is divided into three hundred and sixty degrees for purely mathematical reasons—merely because it makes easy figuring to consider a cycle as though it were a circle, which you know was divided into three hundred and sixty degrees for astronomical reasons."

"Dunno anything about that," protested the engineer, beginning to feel that he was over his head.

"You don't need to," said Jones reassuringly, "that's just a little off the track."

The engineer grinned. It was seldom he caught Jones in anything bordering on bad judgment and he enjoyed it.

"Well," resumed Jones, "as the cycle has been divided into three hundred and sixty degrees for scientific convenience, we may as well stick to that arrangement in talking about the physical part of the game. A half cycle, then, is what?"

"One hundred and eighty degrees," replied the engineer promptly.

"Right. Now look at my diagram and tell me how much the current is supposed to lag behind the e.m.f. in that diagram."

"Thirty degrees."

"What part of a cycle?"

The engineer scribbled on his scratch pad as follows:

$$30 \text{ degrees} = \frac{30}{360} \text{ of a cycle}$$

$$\frac{30}{360} = \frac{3}{36} \text{ and } \frac{3}{36} = \frac{1}{12}$$

"A twelfth," he announced.

"Right. Now, when the e.m.f. is at its maximum, which is a hundred and fifty volts, where is the current?"

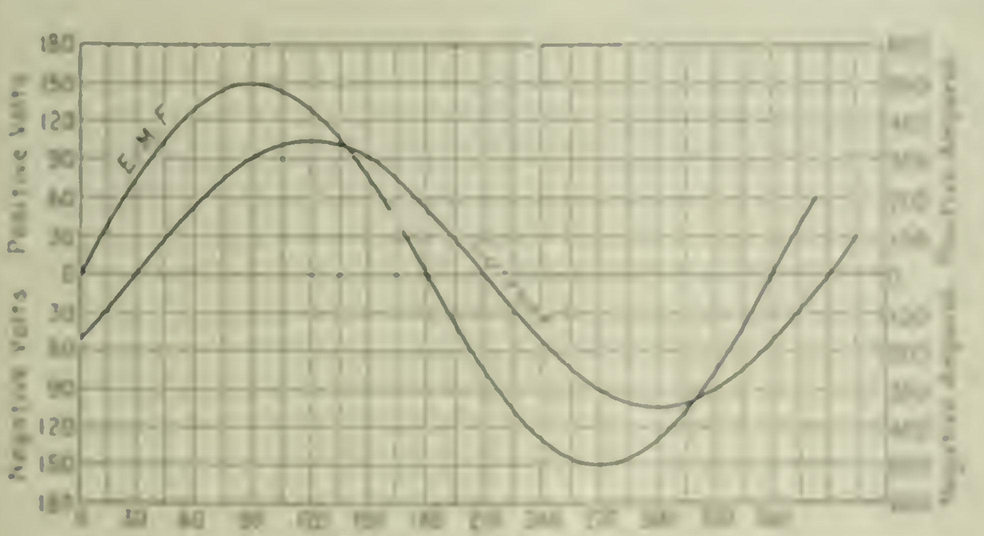

FIG. 5. E.M.F. AND CURRENT CURVES; CURRENT LAGGING 30 DEGREES

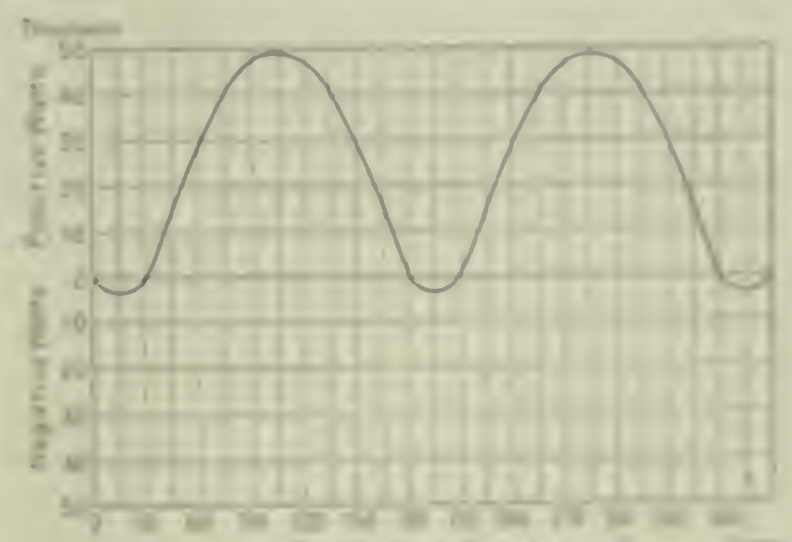

FIG. 6. POWER CURVE CORRESPONDING TO THE CURVES OF FIG. 5

The engineer scrutinized the diagram closely, and tried to find the scale value opposite which the current curve crossed the ninety-degree line.

"The current's three hundred and fifty amperes at the top o' the wave 'n' it looks like three hundred at the ninety-degree line," he said, "but I can't measure it fine enough."

Jones chuckled.

"Of course you can't," he said; "I just wanted to work you a little. Here's a list of the e.m.f., current and power values at each fifteen-degree division of the e.m.f. cycle," and he turned the diagram sheet over, showing on the back of the sheet the following table:

MOMENTARY VALUES OF VOLTAGE, CURRENT AND POWER, WITH CURRENT LAGGING 30 DEGREES

Point in the Cycle	Momentary Values		
	Volts	Amperes	Watts
Beginning	0	—175	0
At 15 degrees	+ 38.82	— 90.59	—3,517
At 30 degrees	75.00	0	0
At 45 degrees	+106.07	+ 90.59	+ 9,609
At 60 degrees	129.90	175.00	22,733
At 75 degrees	144.89	247.49	35,857
At 90 degrees	150.00	303.11	45,467
At 105 degrees	144.89	338.07	48,984
At 120 degrees	129.90	350.00	45,467
At 135 degrees	106.07	338.07	35,857
At 150 degrees	75.00	303.11	22,733
At 165 degrees	38.82	247.49	9,608
At 180 degrees	0	+175.00	0
At 195 degrees	—38.82	+ 90.59	—3,517
At 210 degrees	75.00		0
At 225 degrees	—106.07	— 90.59	+ 9,609
At 240 degrees	129.90	175.00	22,733
At 255 degrees	144.89	247.49	35,857
At 270 degrees	150.00	303.11	45,467
At 285 degrees	144.89	338.07	48,984
At 300 degrees	129.90	350.00	45,467
At 315 degrees	106.07	338.07	35,857
At 330 degrees	75.00	303.11	22,733
At 345 degrees	38.82	247.49	9,608
At 360 degrees	0	175.00	0

The engineer turned the sheet over and back several times, comparing the table with the diagram.

"Let's see," he began, a little uncertainly, "at fifteen degrees the e.m.f. is thirty-eight point eighty-two volts 'n' the current is ninety 'n' fifty-nine hundredths; multiplyin' one by the other gives thirty-five hundred 'n' seventeen watts—that right?"

"Not even warm," asserted Jones more enthusiastically than elegantly.

"But the watts go down to zero at thirty degrees from the beginning," said the engineer. "How's that?"

"What's the current at that point?" asked Jones.

"Zero—oh! You can't have any watts without both factors, of course," sheepishly. "Well," he continued, "what's a power table but it don't tell me much about power factor."

"It will if you look at this diagram at the same time," said Jones, producing Fig. 6. "That curve is what you'd get if you plotted the momentary power values given in the fourth column of the table."

"What do the little loops below the zero line mean?" asked the engineer.

"Negative power;" replied Jones, "that is, power that is delivered to the generator from the circuit."

The engineer stared at him, dumfounded.

"Look at the other diagram," said Jones. "During the first thirty degrees of the cycle the current curve is below the zero line, isn't it?"

"Yes."

"And the voltage curve is above, isn't it?"

"Yes."

"Well, what do those locations mean—what polarities?"

"Positive above and negative below," promptly.

"Right. Now, if you multiply a positive quantity by a negative quantity the product is negative, isn't it?"

"Yes, but ——"

"Never mind butting. Positive volts multiplied by negative amperes make negative watts. Negative watts mean power transferred from the line to the generator. Now look at the table and tell me what the maximum watts are during the first thirty degrees."

"Thirty-five hundred and seventeen," replied the engineer.

"That's negative power," said Jones, "that's why it's fenced off from the rest of the figures with the line across the table. You'll find another period of negative power during the first thirty degrees of the second half of the cycle; that's ruled off, too."

The engineer scanned the table and compared the diagrams with it.

"Then from the beginnin' of the cycle to the thirty-degree point the power's negative," he ventured inquiringly; "from there to the one hundred and eighty-degree point it's positive; from one hundred and eighty to two hundred and ten degrees it's negative again, and positive the rest of the cycle?"

Jones dealt him an approving thump on the back and nearly cut his own head off with his expanding grin.

"You're commencing to show signs of human intelligence again," he said. "Now tell me what's the biggest value of positive watts in the table."

"Forty-eight thousand nine hundred and eighty-three," replied the engineer, "and it happens at one hundred and five 'n' two hundred and eighty-five degrees."

"Right you are. Now what's the *average* positive watts?" he demanded, regardless of grammar.

"D'you mean the effective value?" asked the engineer.

Jones nodded.

"Forty-eight thousand nine hundred and eighty-three multiplied by point seven nought seven," began the engineer ——

"Hold on; the effective watts aren't figured that way," said Jones.

The engineer scratched his head and studied Jones' countenance for enlightenment, without success.

"Ain't the effective voltage seven-tenths of the maximum voltage?" he asked.

"It sure is," agreed Jones.

"Then ain't the effective power seven-tenths of the maximum power?"

"It sure is *not,*" said Jones.

"Give it up then," said the engineer in disgust. "I thought I did know that."

"You won't give it up, either," said Jones. "Suppose, for a moment, that the current and e.m.f. were in phase. The maximum watts would be figured how?"

"Maximum volts multiplied by maximum amperes."

"All right. Now reduce 'em to effective values."

"Effective watts are effective volts times effective amperes."

"Go on; what are effective volts and effective amperes?"

The engineer searched his partly confused brain. Then he got his pad and scribbled as follows:

effec. volts = 0.707 × max. volts
effec. amps. = 0.707 × max. amps.
Effec. watts = effec. volts × effec. amps.
Effec. volts × effec. amps. =
0.707 × max. volts × 0.707 × max. amps.

and submitted it to Jones.

"Correct," said that cheerful person. "Now multiply your two numbers together to make one factor of 'em."

So the engineer proceeded as follows:

0.707 × 0.707 = 0.5
Effec. watts = 0.5 × max. volts × max amps.
" " = 0.5 × maximum watts.

"Well I'll be ——"

"You probably will, sooner or later," interrupted Jones. "Now, get a move on you and follow out the power-factor business. Effective watts are equal to ——?"

"Half of the maximum watts."

"Then in the two diagrams and the table the effective positive power is what?"

"Half of forty-eight thousand nine hundred and eighty-three ——" scribbling on his pad —— "Twenty-four thousand four hundred and ninety-one and a half watts."

"Put it down on a clean spot. What's the effective negative power?"

"Half of thirty-five hundred and seventeen ——" more scribbling——"Seventeen hundred and fifty-eight and a half watts."

"Put it down under the other figure—that twenty-four thousand and something. Now don't you see that if the generator delivers power to the circuit part of the time and the circuit delivers power to the generator part of the time, the watts that get to the lamps and do work in the motors are the difference between the two?"

"It looks that way," admitted the engineer, thoughtfully gazing at the table and the diagrams. "But I don't get that power-factor thing yet."

"You're 'most there now," said Jones encouragingly. "Subtract the effective negative watts from the effective positive watts."

The engineer made the subtraction and showed the following to Jones:

24,491½
1758½
22733

"All right. Remember that's the real power—the true watts actually delivered to the circuit and requiring mechanical power to drive the generator. Now, the maximum voltage is one hundred and fifty and the maximum current is three hundred and fifty amperes; what is the *apparent* power in the circuit—the effective volt-amperes?"

The engineer made the following calculation:

350 max. amperes
150 max. volts
17500
35
2)52500 max. volt-amperes
26,250 effec. volt-amperes

"Twenty-six thousand two hundred and fifty volt-amperes; good. That, you understand, is what you mean when you talk about apparent power in a circuit."

The engineer nodded. "And the power factor's the real power divided by this," he said.

"You're on," said Jones, "figure it out."

The engineer divided 22,733 by 26,250.

"Eight hundred and sixty-six thousandths," he announced.

"Express that as a percentage and it's your power factor," said Jones.

The engineer fidgeted uncomfortably.

"What's the matter?" asked Jones.

"How do you express thousandths as a percentage?" asked the engineer.

"What does per cent. mean, baby?" demanded Jones somewhat impatiently.

"Per hundred," answered the engineer.

"Well, if you have eight hundred and sixty-six parts out of a thousand, how many is that per hundred?"

"One-tenth as much."

"Well?"

"Eighty-six and six-tenths?"

"Of course. Write it down in fractional form and you'll see it plain as the nose on your face."

So the engineer wrote:

$0.866 = \frac{866}{1000}$

and $\frac{866}{1000} = \frac{86.6}{100.0}$

and $\frac{86.6}{100} = 86.6$ per cent.

"Now," said Jones, "look at the table; tell me what the current is when the voltage is at its highest point?"

"At ninety degrees," said the engineer, following down the columns of the table with his finger, "the voltage is one hundred and fifty and the current is three hundred and three and eleven-hundredths."

"And your highest current is ——?"

"Three hundred and fifty amperes."

"All right. Divide three hundred and three and eleven-hundredths by three hundred and fifty and tell me the answer."

The engineer performed the division, hesitated, glanced at Jones and then went over the division again to make sure he was right.

"Well," he said, "it's the same as the power factor, but I don't see why."

"Just think what it means," advised Jones. "When you divided the momentary current that exists when the voltage is maximum by the maximum current, you got the same result as when you divided the true watts by the volt-amperes, didn't you?"

The engineer agreed that he did.

"Then it follows that *the power factor is the proportion of maximum current which exists when the voltage is at its maximum.* See?"

The engineer saw.

"Yes;" he said, "it's coming through slow. If the voltage and current were in step like this," indicating Fig. 3, "they'd reach the top at the same time, and you'd get all the power there was ——."

"Careful," cautioned Jones, "you get all the power there is anyhow, but the power used in the circuit is greatest when the voltage and current are in step. When they are not, the power is less because the product of momentary volts and amperes at any point in the cycle is less than it would be if they were in step."

"I can see that," said the engineer, "by lookin' at the thirty-degree point in this diagram," taking up Fig. 5. "The current's zero here at thirty degrees but if they were in step it would be something, anyhow—I dunno how much."

"Right you are," said Jones. "It would be one hundred and seventy-five amperes at that point. Now get your tables of sines, cosines and so on."

The engineer took a copy of Trautwine from his bookshelf.

"Find the cosine of thirty degrees," directed Jones.

"Naught, point, eight, six—well, I'll be hornswaggled," exclaimed the engineer, "that's the power factor of this diagram, too. How many more things figure out that way?"

Jones grinned.

"You knew that before," he said, "but you've forgotten most of your early training. How many degrees is the current behind the e.m.f. in that diagram?"

"Thirty."

"And the cosine of thirty degrees is naught, point, eight, six, six, isn't it?"

"Yes, and so's the power factor," said the engineer.

"Of course. The power factor of any circuit or machine is the cosine of the number of degrees by which the current lags behind the e.m.f. That is called the angle of lag, for mathematical convenience."

"But you just said the power factor was the proportion of maximum current that exists when the voltage is maximum," protested the engineer.

"So it is," said Jones. "Didn't you just figure it? That's the physical definition of it; this cosine business is the mathematical definition, and connecting the two gives you this rule: *The cosine of the number of degrees by which the current lags behind the e.m.f. is the proportion of maximum current that exists when the voltage is maximum; it is therefore the power factor.*"

The engineer gasped.

"That's an awful mixup of words to remember," he said feebly.

"Surest thing you know," agreed Jones, with bland indifference. "Don't try to remember 'em; put 'em down where you can get at 'em when you want to, sort of like a formula, so: Power factor is equal to cosine of the angle of lag; also equal to proportion of maximum amperes that exists momentarily when voltage is maximum."

"Well," said the engineer, writing the rule on the fly leaf of his copy of Foster's "Pocketbook," "I ain't quite sound on that angle of lag business."

"Give you that some other time," promised Jones, removing his heels from the engineer's desk and reaching for his data sheets.

"Wait a minute," said the engineer, pointing at the small loops in Fig. 5. "You didn't tell me how that negative power gets back from the circuit into the generator."

"That's another story and a long one," answered Jones, replacing the diagrams in his book, "and I've got to get over to Uniontown this afternoon. So long."

Railroad cars loaded with snow are not an unusual sight at crowded terminals where it is necessary to ship the snow out in order to dispose of it. One of the disadvantages of snow shipments has been the necessity of unloading the cars. The Illinois Central has, however, discovered a unique method of dealing with the unloading problem. They ship the snow far enough South to melt it on the way. The empty cars used in this manner are ready to bring coal back to Chicago at the termination of their Southern trip, so that the work of unloading the snow is dispensed with.

Storage Batteries in Alternating Current Stations

By W. H. Radcliffe

The storage battery from the very beginning of its commercial career in the early eighties has been a direct-current station adjunct, and only within the last decade has it become useful in strictly alternating-current stations. Its chief value in this important but rather unusual field lies in its reserve power being used as a protection against the failure in supply of the direct current used to excite the field magnets of the alternators. Although the direct-current dynamos used as exciters in alternating-current stations seldom go wrong, the increasing seriousness of an interruption in service makes it advisable to leave no stone unturned to insure continuous operation. Under modern conditions of everyday life an interruption of lighting or power current may produce public calamity; that is why central-station managers strive to provide against the possibility of even a temporary shutdown.

In the large power stations built within recent years the parallel and independent groups of coal compartments, boilers, pumps, engines, generators and switchboard panels have become characteristic features. Considering here merely the provision made for insuring against exciter breakdown, it might appear at first thought that the addition of one or two reserve direct-current machines would be preferable to installing the more expensive storage battery of equal capacity, and this would be the case where shutdowns of short duration would be tolerated, as in small power stations carrying light loads; but in a large station the reserve machines, if installed, would have to be kept in motion continuously in order to insure absolutely uninterrupted exciter service in case the regular exciters failed.

With a storage battery permanently "floated" across the exciter busbars, the instant an exciter breaks down the battery automatically comes to the rescue, so that the current supply is not interrupted at all. The exciting voltage may fall slightly on account of the drop in the battery when it first takes up the load, but the voltage can quickly be brought up to normal by advancing the number of active end cells or by means of the alternator field rheostats.

Storage batteries for use in the manner described may be of either the Faure (pasted plate) or the Planté type. The pasted plate retains its charge remarkably well when used only occasionally, costs considerably less and occupies less space than the equivalent Planté plate. Owing to its smaller weight and bulk it is also cheaper to install.

Gas Power Department

Everything worth while in the gas engine and producer industry will be treated here in a way that can be of use to practical men

Compression and Expansion Ratios

By Cecil P. Poole

What is the compression ratio of a gas engine? What is the expansion ratio? Nearly every man operating one probably thinks he knows the answer until he "gets down to brass tacks" and starts to give it. The compression ratio is not the clearance percentage, nor the ratio of compression to admission pressures; nor is it anything else except a simple ratio of volumes. The expansion ratio is also a ratio of volumes.

Compression Ratio

If you measure the cubic inches of space in front of a piston when it is ready to begin the compression stroke, then measure the cubic inches of space between the piston and the cylinder head when the compression stroke is completed, then divide the larger volume by the smaller, the result will be the compression ratio. That is all there is to it. It is not affected by valve setting, mixture variation or any other adjustment unless the adjustment changes the length of piston stroke or the volume of the clearance space.

For example, suppose the volume under the piston shown in Fig. 1 to be 12 cubic feet and that the piston is forced downward until the volume under it is reduced to 2 cubic feet, as indicated in Fig. 2. Dividing the volume before compression by the volume after compression gives

$$\frac{12}{2} = 6$$

which is the compression ratio.

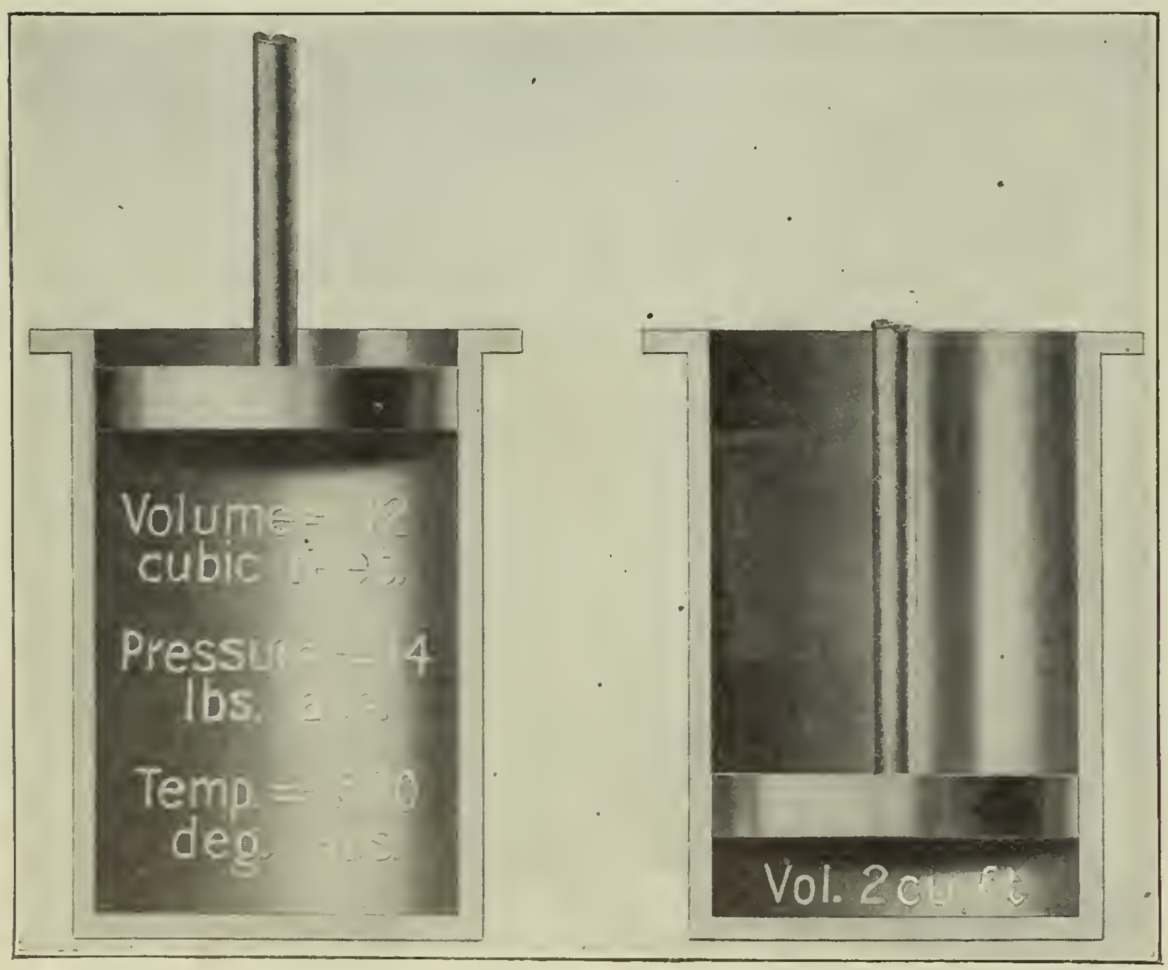

Fig. 1. Maximum Volume Fig. 2. Compressed Volume

If the pressure in the cylinder is 14 pounds absolute (0.7 of a pound below atmospheric) before compression it will be increased to about 150 pounds at the end of the compression stroke, if no more heat escapes through the wall than is usual with gas engines. The temperature will also increase, but not so greatly as the pressure; if the absolute temperature is 500 degrees absolute before compression it will be about 900 degrees absolute after compression. But the pressure and temperature changes do not affect the compression ratio; they are *results* of it.

In the case just assumed, the compression ratio is 6, the pressure ratio due to compression is about 10.7 and the temperature ratio about 1¾. Under certain operating conditions, however, the pressure ratio could easily be 9½ or 10 and the corresponding temperature ratio 1.59 or 1.67, although the compression ratio would remain 6.

Expansion Ratio

If the exhaust valve opened at the end of the piston stroke instead of a little in advance of the end, the expansion ratio would be exactly the same as the compression ratio because the cylinder volumes at the ends of the stroke are the same in both cases. In other words, the volume of gases would increase exactly as much during expansion as it decreased during compression. If four cubic feet were compressed to one, then the one cubic foot would expand to four during the outstroke.

For example, if the cylinder in Fig. 2 contained a mixture of gas and air and the mixture were lighted with the piston in the position shown and the crank on the dead center, the pressure and temperature would rise rapidly—almost instantaneously. As soon as the crank passed the dead center the gases would push the piston outward, and if the exhaust valve opened wide when the piston reached the position in Fig. 1, at which compression began, the expansion ratio would be

$$\frac{12}{2} = 6$$

exactly equal to the compression ratio.

The exhaust valve does not open at the extreme end of the expansion stroke, however, and the expansion ratio therefore is less than the compression ratio in all modern engines working on the four-stroke cycle.

Fig. 3 illustrates this difference. At *A* the piston is shown at the beginning of the compression stroke; at *B* it is at the other end of the stroke, the crank then being on the opposite dead center; at *C*, just before the piston reaches the end of the outward stroke, which is indicated by the dotted line, the exhaust valve is supposed to open.

The volume in the cylinder at *A* (represented by the symbol V_a) is assumed to be 0.45 of a cubic foot; at *B* it has been reduced by compression to 0.1 of a cubic foot, making the compression ratio

$$\frac{0.45}{0.1} = 4\tfrac{1}{2}$$

When the piston moves outward from the B position to that at C, where the exhaust valve opens, the volume V_c (0.1 of a cubic foot) increased to V_e, which measures 0.41 of a cubic foot. The expansion ratio, therefore, is mechanically

$$\frac{0.41}{0.1} = 4\tfrac{1}{10}$$

Effectively, it is a little greater because the exhaust valve does not open wide all at once and even when it is wide open the port is not large enough to allow

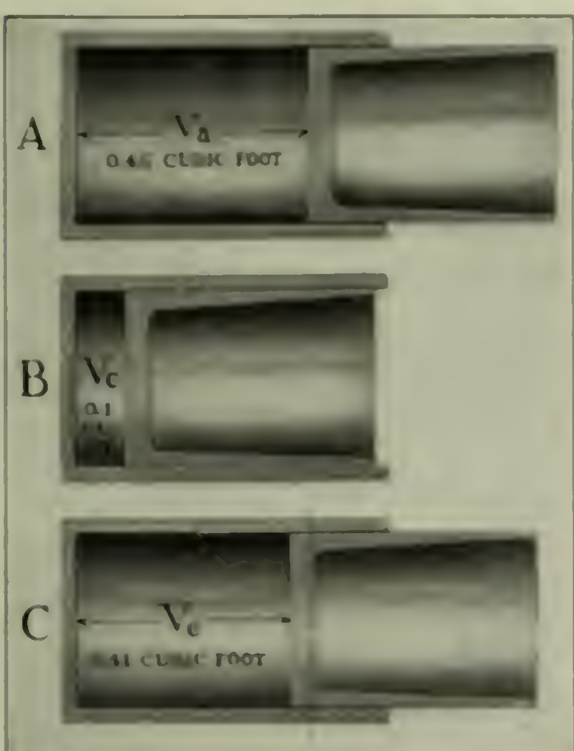

FIG. 3. ILLUSTRATING DIFFERENCE BETWEEN COMPRESSION AND EXPANSION RATIOS

the gases to fall instantaneously to atmospheric.

RELATION BETWEEN COMPRESSION AND EXPANSION RATIOS

However, the effect of the exhaust valve's movement may as well be ignored just now. The important fact to be remembered is that the compression and expansion ratios are "tied together," hard and fast, in the ordinary four-stroke engine.

Referring to Fig. 3 again, suppose the stroke of that engine were increased one-seventh. As it is represented here, the piston displacement is 0.35 of a cubic foot, the clearance being 0.1 and the maximum volume (displacement + clearance) 0.45 of a cubic foot. If the stroke be increased one-seventh without changing anything else, the piston displacement will be increased from 0.35 to 0.4 of a cubic foot. The maximum volume (displacement + clearance) will then be

$$0.4 + 0.1 = 0.5,$$

or one-half cubic foot and the compression ratio will be increased to

$$\frac{0.5}{0.1} = 5.$$

If the exhaust valve opens when the piston has traveled the same percentage of its stroke as in the first case, the volume V_e will be 0.4543 of a cubic foot and the mechanical expansion ratio will be

$$\frac{0.4543}{0.1} = 4.543$$

as compared with 4.1 in the first case.

In other words, the expansion ratio in the first case was

$$\frac{0.41}{0.45} = 0.91$$

(or 91 per cent.) of the compression ratio; in the second case, the expansion ratio is

$$\frac{0.4543}{0.5} = 0.909$$

(or practically 91 per cent.) of the compression ratio.

The only way in which the relation between the compression and expansion ratios can be changed appreciably is by altering the timing of the exhaust-valve opening. If the exhaust valve opens in all cases when the piston has traveled the same percentage of the expansion stroke, the relation between the expansion and compression ratios must remain practically constant no matter what the compression ratio may be. With a compression ratio of 4 and the exhaust valve opening at nine-tenths stroke, the expansion ratio is 3.7, or 92½ per cent. of the compression ratio; with a compression ratio of 8, which is seldom if ever used, the expansion ratio would be 91¼ per cent. of the compression ratio.

In other words, the ratio of expansion to compression is only 1.35 per cent. smaller with a compression ratio of 8 than it is with one-half that ratio. Moreover, instead of obtaining a relative increase in expansion, which would give lower release pressure and temperature, the increase in expansion is less than the increase in compression, so that the pressure and temperature at release would be higher, notwithstanding the increase in the expansion ratio.

With the same compression ratio and the same exhaust-valve timing, the relation between the compression and expansion ratios is absolutely unchangeable, no matter what the size of the cylinder, relation of stroke to bore, or other features or conditions. It is impossible to obtain a greater expansion of gases unless the compression is increased and if that is done, the temperature and pressure of the gases at the moment of release will be raised.

EXAMPLES

To illustrate by figures instead of reasoning, suppose there were three gasoline engines, one 4x4 inches with a compression ratio of 3½; one 4x5 inches with the same ratio and one 4x4 inches with a ratio of 4. Further, suppose that all three engines work under the following conditions:

Pressure in cylinder before compression	[illegible]
Compression-curve exponent	[illegible]
Rise of pressure due to combustion*	[illegible]
Expansion-curve exponent	[illegible]
Portion of expansion stroke completed when exhaust valve opens	[illegible]

A normal cycle in the three cylinders would work out about as follows:

Engine	A	B	C
Bore and stroke	[illegible]	[illegible]	[illegible]
Piston displacement, compression	[illegible]	[illegible]	[illegible]
Clearance volume	[illegible]	[illegible]	[illegible]
Compression ratio	[illegible]	[illegible]	[illegible]
Compression pressure†	[illegible]	[illegible]	[illegible]
Rise by combustion	[illegible]	[illegible]	[illegible]
Maximum pressure	[illegible]	[illegible]	[illegible]
Piston displacement, expansion	[illegible]	[illegible]	[illegible]
Expansion ratio	[illegible]	[illegible]	[illegible]
Release pressure	[illegible]	[illegible]	[illegible]

The comparison between A and B shows some of the results of increasing the stroke without changing the compression; the expansion ratio is not changed and, as the compression ratio is unchanged, the explosion pressure is also unchanged, giving exactly the same release pressure as before.

The comparison between B and C shows that increasing the compression by making the clearance smaller (the bore and stroke remaining the same) increases the expansion ratio, but it also causes the explosion pressure to go higher; consequently the greater expansion does not produce a lower release pressure. On the contrary, it is slightly increased.

The only way by which the expansion ratio can be made greater than the compression ratio is by making the compression stroke shorter than the expansion stroke. Although this is impractical mechanically, as the natural death of the Atkinson engine has demonstrated, the compressor effect of a shortened stroke can be obtained by holding the inlet valve open during the first part of the compression stroke and forcing some of the mixture out of the cylinder, or by cutting off the admission of mixture before the suction stroke is completed, as in the Sargent engine. Without the use of some such unusual method of operation the ratio of expansion must be slightly less than the ratio of compression in all engines working on the four-stroke cycle.

*The rise of pressure is greater with high compression than with low because [illegible]

†Since the exponent of the compression curve is taken at [illegible] [illegible]

[illegible]

Readers with Something to Say

Practical information from the man on the job. A letter good enough to print here will be paid for. Ideas, not mere words wanted

Water Hammer Burst Valve

A serious case of water hammer, caused by carelessness, occurred in the boiler room of a Government building in Washington, D. C., some time ago, which burst a 6-inch angle-stop valve on one of the boilers, seriously injuring a coal passer.

Orders had been given to an extra man on duty to slowly fire up No. 1 boiler, which had been out of service several weeks for repairs, and at the time he went off duty 20 pounds pressure showed on the gage. The 9-inch header passes over the front of the boilers, each of which is connected by a 6-inch long bend with a gate valve, without a bypass at the header, and a 6-inch angle valve at the boiler, both of which were shut when the fire was started.

The gate valve is 4½ inches lower than the globe valve, and such is the arrangement on all the boilers, and it is supposed that the section of pipe between the two valves was partly full of water.

Soon after the extra fireman went off duty, orders were given to the coal passer, who, by the way, was an ignorant colored man and had only been employed in the boiler room a short time, to go up and open one of these valves. Instead of opening the angle valve as he should have done, he opened the gate valve about two turns when a violent water hammer was heard by the fireman, who told him to shut the valve, but for some reason he opened it wider and the second or third hammer burst the angle valve, as shown at *A* and *B*, the unshaded portion being the shape of the piece that was broken out of either side. The coal passer was knocked off the boilers and badly bruised and burned.

All of the boilers were connected to the header in the same manner, as shown in the figure, and without a bypass or bleeder between the valves.

In cutting out a boiler it has been customary in this plant to close both valves on the branch and to open the angle valve when the fire is first started to raise steam, but in this case it was overlooked by the fireman and the boiler was cut into the line by means of the gate valve. Even with the angle valve open the pipe will not drain, because it is 4½ inches lower at the header than at the angle valve. This leaves a pipe full, or nearly so, of water, the result being that the water goes into the steam line when the gate valve is opened and there is danger of breaking the 9x9x6-inch tee. The gate valve should never be closed except in case of emergency or repairs to the angle valve and the boiler should be cut in by means of the angle valve only.

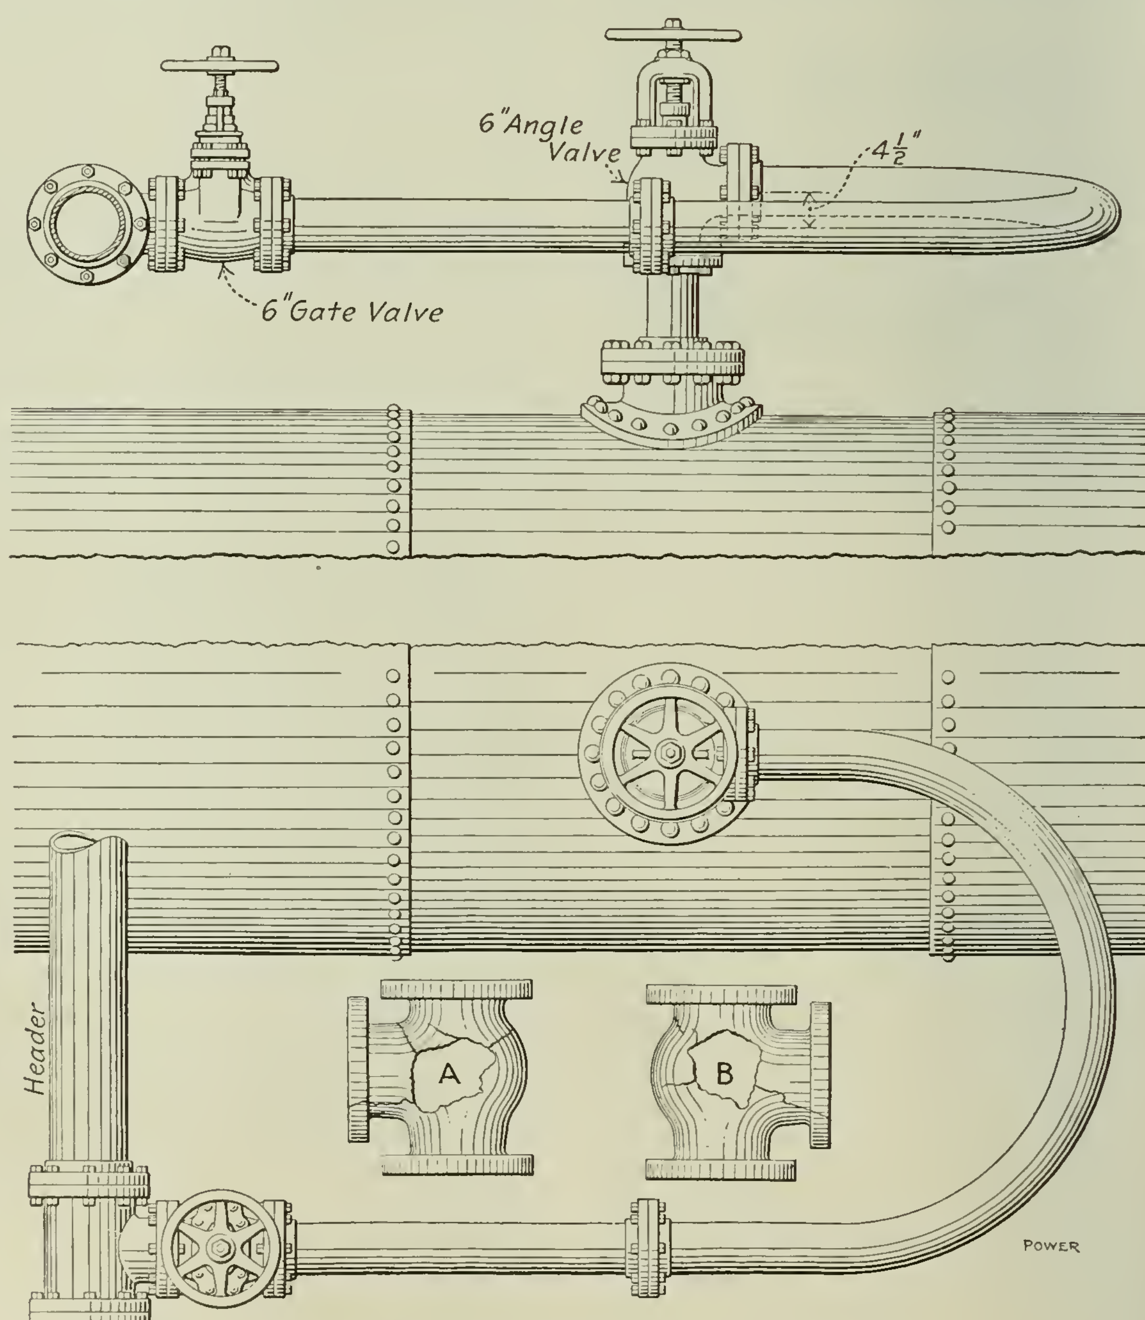
Hyattsville, Md.



Arrangement of Piping and Valves

Connecting Ammonia Compressors

I am engineer in a refrigerating plant and a consulting engineer advised me to connect a 50-ton and a 35-ton machine to one condenser.

The large machine compresses through a 2-inch, three-way valve into a 2-inch header; the coils are also of 2-inch pipe. The small machine has the same size discharge pipe expanded into a 5-inch header at the condenser and does better work than the large machine.

Will these machines do good work if they are connected to the same condenser through the 2-inch, three-way valve? The condenser has a capacity of 54 cubic feet.

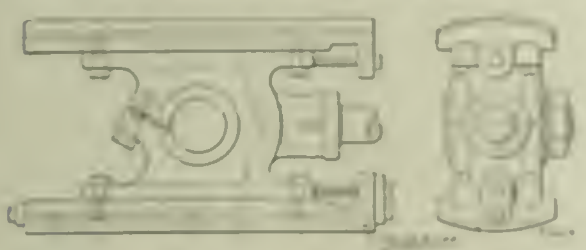
H. S. Free.

Harrisburg, Penn.

Loose Crosshead Shoe

The crosshead shoe of a large steam engine worked loose one night while the engine was carrying the peak load. As this was the main engine it was necessary to repair it at once.

I disconnected the shoe from the crosshead and drilled six 1½-inch holes through the babbitt and shoe body, and countersunk the holes in the babbitt with a drill ground for the job. Next, some copper rivets were made with which to rivet the babbitt to the shoe, as shown.



How Shoe was Fixed

To make sure of the job, two stops were made and fastened to the shoe, each overlapping the babbitt about ½ inch.

This repair job proved very effectual and is still doing as good service as when repaired six months ago.

Damper Regulators

I would be glad to hear from experienced engineers as to what has been found the best practice regarding the use of damper regulators.

In some cases, equipment of this kind is, no doubt, essential to good economy in boiler-plant operations and I would like to know what conditions would justify such an installation.

Some time ago, I consulted one engineer on this subject who stated that there are certain kinds of operation and conditions where regulators would be detrimental rather than otherwise, citing as an instance a boiler plant supplying steam to hoisting machinery where steam at a maximum pressure and volume is needed very quickly and at irregular intervals. He believed that a regulator in such a case would not operate quickly enough to be of any benefit.

Then, again, there are plants that supply steam to electric generating engines having constant loads where no great surges of steam occur and where there is no necessity for the safety valves blowing off.

I can readily see the advantage of proper damper regulation where there are a number of steam consumers scattered throughout a plant driving mill machinery that has varying loads and that uses a maximum amount of steam only intermittently. In such a case it would be rather difficult to maintain a constant steam pressure in the boilers without such an equipment.

[illegible]

Pittsburg, Penn.

Boiler Setting and Steam Jet

I would like to know the opinion of engineers regarding my boiler setting which is illustrated in the accompanying sketch. Could I burn anthracite coal with any degree of economy? Run-of-mine coal is used and the analysis shows 12,880 B.t.u. per pound; it costs $2.70 a ton, delivered at the plant. Anthracite pea coal will cost $5.40 a ton, delivered, or double the cost of bituminous. Will a ton of the Pennsylvania anthracite pea coal produce as much heat as a ton of bituminous run-of-mine coal?

There is not much chance to make a saving in fuel, as the plant only operates about three months each year, but as the factory puts up a food product, I would like to burn anthracite coal so as to do away with the smoke, soot and dust of bituminous coal.

I would also like to see suggestions published on how to keep a boiler room clean. I use a tube blower, and it does good work as far as cleaning the flues is concerned, but it blows soot and fine ashes all over the room every time it is used. Our fronts do not fit very tight and I thought possibly a good steam blower in the stack would create enough draft to overcome the trouble. If so, how large should the steam pipe be; should it have a jet around the nozzle the same as the exhaust on locomotives, or will the nozzle in the uptake be sufficient?

I have a large, well ventilated boiler room and I like to see things kept neat and clean, but I want to let the fireman have time to read or otherwise employ himself instead of cleaning fronts all the time. I do not have to crowd the boilers. When the plant is working up to capacity, I burn from 10 to 12 tons in 24 hours.

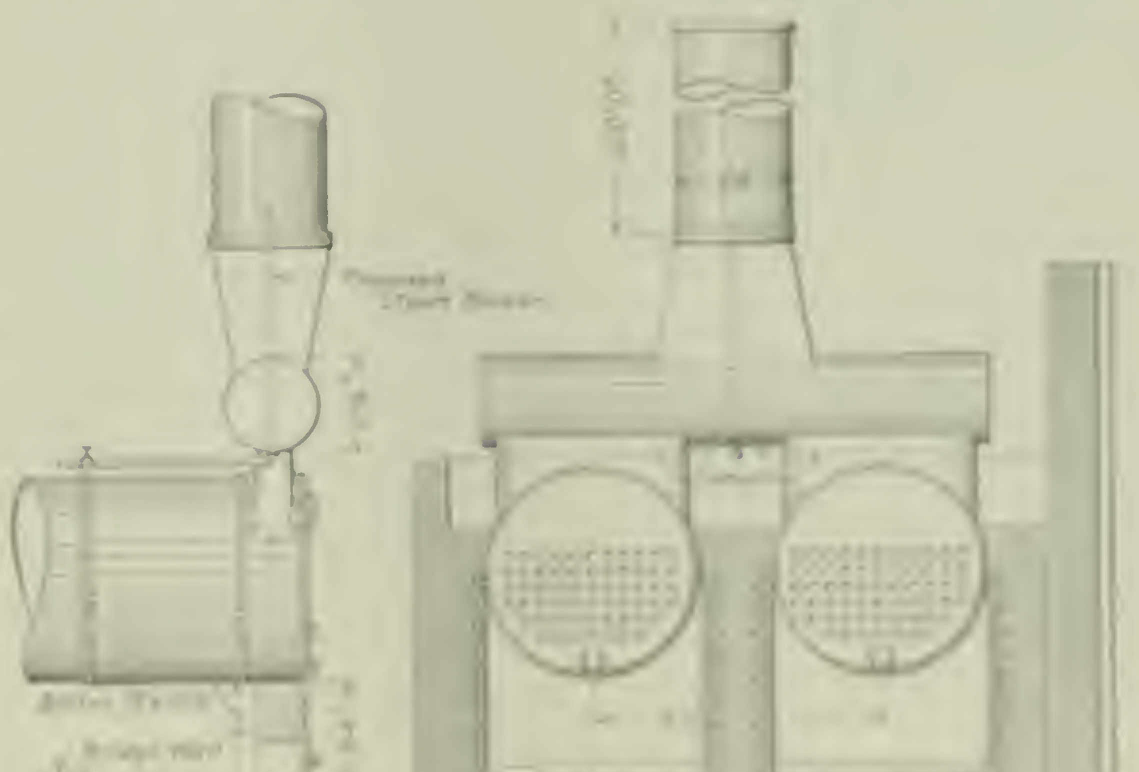
Washington, Ill.



Showing Boiler Setting and Steam Jet Arrangement

Scale in the Exhaust Pipe

There is a large open heater in the plant I am in charge of, that is fitted with the usual baffle plates for the water to flow over. The exhaust entrance was about midway between the heads and discharged to the atmosphere through a 6-inch pipe.

Soft scale collected very fast in the heater and had to be thoroughly cleaned out once a month. An overflow pipe connected at the bottom and extended above the water line. In case of a back pressure in the heater the water would blow out of this pipe as soon as the scale began to form in the openings through the heater. If a sudden, heavy load was thrown on, the water would overflow; cleaning the heater would always eliminate this trouble until the last cleaning, when it failed.

The top plate in the heater was so near the top of the opening in the heater that the exhaust outlet could not be seen, and the exhaust head prevented me from looking into the other end. After closing down at night, I went inside the exhaust head and put my hand into the 6-inch pipe and found it partly closed with scale. I took the pipe down the next Sunday and found that the scale had reduced the pipe opening to a 1½-inch hole from the bottom to the top.

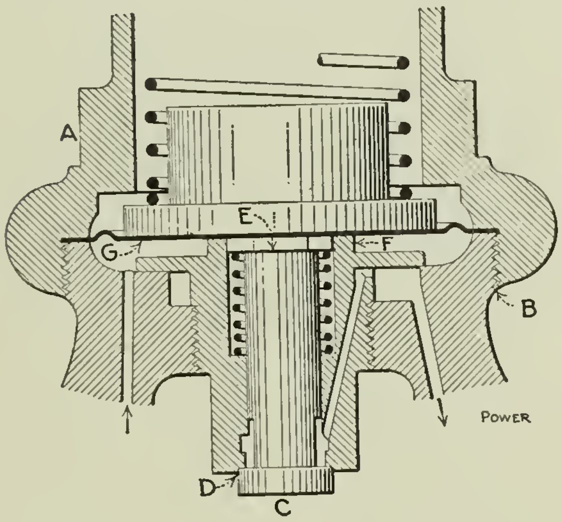
Los Angeles, Cal.

Reducing Valve Trouble

I once had occasion to overhaul several reducing valves which had been in use a long time. The valves were taken apart and cleaned and valves and seats reground. After reassembling them they were tested and all worked nicely with the exception of two which would not reduce the pressure in the least. These two were taken apart again and seemed to be all right, but upon a second trial they still refused to work.

With steam on the valve a wrench was put on the bonnet *A*, which was unscrewed a little, when the valve started



Sectional View of Reducing Valve

to work as it should, but steam escaped from the joint *B*.

After a little thinking I took the valves apart again and found that repeated grinding of the auxiliary valve *C* had worn down the seat *D* so that the nut *E* projected to far above the shoulder *F* and when the bonnet *A* was screwed down tight the diaphragm *G* would force the auxiliary open and hold it open, thus preventing the reduction of pressure.

The top of the nut *E* was filed enough to make up for the metal removed at *D* and the valves then worked satisfactorily.

Foxboro, Mass.

Loose Stud Caused Click

A Corliss engine in a factory had an unaccountable click in the cylinder for a long time. Various conjectures were offered from time to time as to the probable cause.

It was not until a breakdown occurred, however, that the real cause was found.

A stud had broken off in the piston at the end of the threads, tearing about two inches of its length loose in the hole.

Apparently a little bur was all that held the loose stud from dropping out of the piston into the cylinder as the engine passed over the head-end center. It would come partly out during the travel of the piston toward the crank center; then, upon the reversal of the piston travel, it would slip back to place, making the mysterious click.

The crisis came at last when the supposed bur wore away and the stud dropped into the cylinder. The cylinder head was not knocked out, although the engine was considerably damaged. The loose stud lodged in the exhaust port where the lower edge of the piston struck it and bent the stem. The piston rod was also too badly bent to be packed steam tight.

Edward T. Binns.

Philadelphia, Penn.

Preserving Bolt Heads

A good substitute for expensive brass heads for bolts, where chemical action prevents the use of iron, has been found in babbitt.

A mold is made and a rack to hold the bolts in a vertical position. The babbitt is then poured around the iron head and allowed to cool.

F. H. Stacey.

Montreal, Can.

Dash Pot Troubles

I have frequently seen the question asking why a Corliss engine will govern perfectly with a normal load, but will race more or less when the load is light. The answer usually given is that the governor is not properly adjusted.

This trouble occurs more frequently with engines equipped with multi-ported valves, and the trouble is due to the action of the dashpots and not to that of the governor. A Corliss dashpot must lift quite a distance in order to produce sufficient vacuum to close the valve quickly. In the single-ported type, the valves usually have much more lap than the multi-ported valve, and in order to open the valves the dashpot plunger must be lifted about 9/16 inch with a 30x48-inch engine. In a multi-ported engine of the same size the lap will frequently be not more than ¼ inch.

A dashpot plunger must ordinarily lift at least ½ inch in order to produce a prompt cutoff. If the plunger does not drop its full stroke the valve will remain slightly open until the hook returns to pick up for the next stroke, when the valve will be closed by the hook pushing down on the dashpot rod. Of course, so long as the steam port is open, steam will follow the piston and the engine will race.

Multi-ported valves are more prone to leak than single-ported valves, on account of the smaller amount of lap. It is quite evident that the more lap a valve has the less will be the leakage.

I have sometimes thought that where an engine runs under a very variable load and a condenser is available that it would be a good plan to connect the vacuum chamber of the dashpots to the condenser, having check valves in the connections so that the dashpots would operate when the condenser was shut down. This would give a pretty constant pull on the dashpots; regardless of the lift. This scheme could only be applied where the dashpot has a cushion chamber separated from the vacuum cylinder.

Cleveland, O.

Regrinding Valves

A short time ago it became necessary to reface the valve seats in a boiler-feed pump, as they were badly pitted. As the reseating machine could not be used

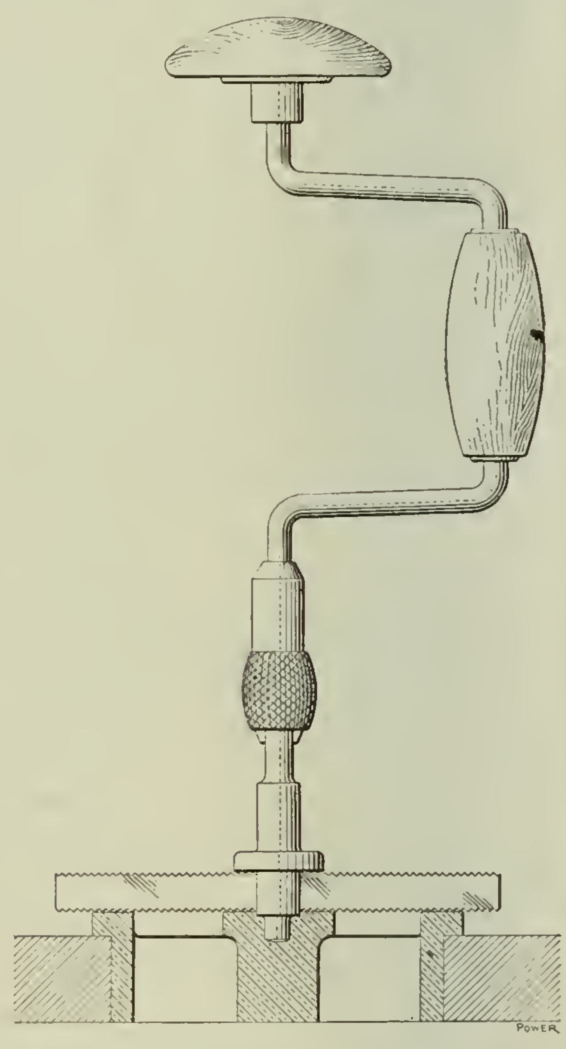

Fig. 1. Regrinding a Valve Seat

on the valve decks without some kind of special rig to hold it, the method described herewith was tried.

A second-cut-file was annealed and a piece cut off a little longer than the diameter of the valve seats. A hole, the size of the valve stud, was drilled and tapped in the center to hold the spindle which went into the stud hole. Then I hardened the file cutter. The spindle fitted in the

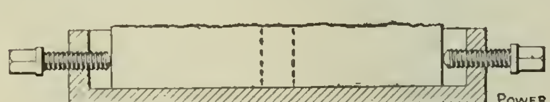

Fig. 2. Worn Valve in Holder

hole in the cutter and was held in a bit stock at the other end. The cutter was turned, thus facing off the seat.

I then thought that truing up the valve would help, so a holder was made, as shown in Fig. 2, which is a box fitted with a set screw to prevent the valve from turning. The box is held in a vise while the valves are being faced.

Questions Before the House

Comment, criticism, suggestions and debate upon various articles, letters and editorials which have appeared in previous issues

Leakage through Piston Valve

I read with interest the articles discussing the report published in the October 11, 1910, number of the piston-leakage tests by Mr. Mitchell. I agree with Mr. Schoemaker in the January 3 issue that the pressure-plate valve leaks as much as, if not more than, the piston valve.

In the January 11 number, Mr. McGahey gives further examples of valve leakage. I think that Mr. Schoemaker and Mr. McGahey have lost sight of the fact that the amount of leakage through a valve when it is in a state of rest is much less than when it is in operation, and such a test, while showing the presence of valve leakage, does not indicate the amount under operating conditions.

Those interested in this matter may refer to *The Engineer* (London) for March 24, 1905, page 289, in which is given a report of the Brush Steam Engine Reseach Committee. It is there stated that the leakage through a slide valve is independent of the speed, but directly proportional to the difference in pressure on the two sides and that in most cases with perfectly balanced valves, the leakage is even greater than 20 per cent. of the steam entering the engine.

Asa P. Hyde.

Binghamton, N. Y.

Engineer and Machine

I differ with some points in the editorial in the February 14 issue entitled "The Engineer and the Machine." I wish to defend the supervising engineer—the "peripatetic supervisor." According to present practice the supervising engineer is engaged principally in looking after the operation of small private plants when there is no one who corresponds to the consulting mechanical engineer or the superintending engineer of the large power house or industrial plant. The only reason why he is "peripatetic" is because one private plant alone does not offer enough work *in his line* to keep him busy.

There are good men and bad. This applies to supervisors as well as to any other class of men. He who comes around and advises the boss that the engineer should be in line for a "cut" or is not needed at all is the one who is so set on "economy" that the plant will soon be on the high road to the scrap heap. This supervisor will sooner or later lose his job anyway, because he will become unpopular with the "boss."

There are honest supervisors doing business. Their work is to take certain responsibilities off the operator's shoulders and to help him bring the plant up in efficiency. If the supervisor and the engineer work together and realize that they can help each other and the boss better results can be obtained than were ever before dreamed of.

H. B. Lance.

New York City.

Where Do You Stand?

An advertisement in a recent issue of Power calls attention to a condition which is prevalent, judging from the evidence found in the advertising pages of all of the technical papers of the day. Briefly, the situation is this: A consideration, in the form of a "present," a "prize" or a "premium" is often used to influence the recommendation of the man who knows.

It reminds me of a story. We had changed from one brand of boiler compound to another and thought that we were getting better results when a salesman for the discarded brand dropped in and said that we had a condition which I would probably like to investigate after he had given me a tip.

I told him to unburden himself.

He said, "You know your engineer has been using our preparation with good results and now he has substituted So-and-So's and can give no good reason for so doing. I just want to tell you that it is a very common custom to pass a V or an X over the shoulder or under the coat tail to obtain desired results in selling boiler compound."

I replied that I knew that such things were done, but was not much interested. I had seen some literature sent out privately to engineers by a company which had an Eastern representative who was given a certain sum for advertising and who thought that the best way in which to advertise was to distribute the advertising money among the engineers in the form of presents, jewelry, etc.

Dismissing the salesman, I went down to see the old engineer. He hated me from the bottom of his heart, cordially and frankly, and I knew it and he knew that I knew it and neither of us cared; I also knew that he was honest and I would take a good beating rather than let anyone tell me that he was a crook. Nevertheless, I asked him if he was in the habit of accepting presents in consideration of his specifying any certain boiler compound.

He said, "No, but I just had a good chance to."

If your wife should go to the grocery and buy a pound of tea with a twenty-five-cent cup and saucer thrown in for sixty cents, she would get thirty-five cents worth of tea and that would be her business. If she should get a pound for her neighbor, keep the cup and saucer and give her neighbor the pound of tea in exchange for her sixty cents, there probably would be two women folks who would not speak to each other any more.

Enough said.

W. R. Smith.

Alton, Ill.

Small Refrigerating System

I read with interest the communication of R. C. Turner in the January 31 issue regarding a small refrigerating system. He describes the refrigerant as "Pictet" fluid. Presumably, he meant the Pictet mixture of sulphur dioxide with 3 per cent. of carbon dioxide.

As all compression-refrigerating machines depend for their operation upon the same thermodynamic principles, and differ by only comparatively small amounts in efficiencies when the various refrigerating mediums are employed, we may expect this small machine, of excellent mechanical efficiency, to produce refrigeration with an efficiency of 60 to 80 per cent. of that of the large machines, small machines being in general inferior to larger ones by some such ratio. The work required to make one ton of ice in the large ammonia machine being 2½ to 3 horsepower for 24 hours, this machine would hardly make 1 ton of ice for less than 3 to 5 horsepower; wherefore, we must conclude either that the 2-horsepower motor was greatly overloaded, or that Mr. Turner meant to say that the machine produced a refrigerating effect equal to that produced by the melting of one ton of ice—commonly called "a ton of refrigeration." In that case, the horsepower developed by the motor would probably need to be 60 per cent. of 2 to 3, or say, 1½ to 2 and, giving the machine the benefit of the more favorable figure, we may conclude that the 2-horsepower motor was working, at least, something under its full rating.

Mr. Turner gives 12 kilowatt-hours as costing 36 cents, an evident rate of 3 cents per kilowatt-hour. As a 2-horsepower motor will hardly have an efficiency better than 80 per cent. at full load, we may calculate a probable electrical input of

$2 \div 0.80 = 2\frac{1}{2}$ *electrical horsepower,*

equal to $1\frac{7}{8}$ kilowatts. Electricity at the rate of $1\frac{7}{8}$ kilowatts for 24 hours would cost, at 3 cents per kilowatt-hour, $1.35, which is the power cost of the ton of *refrigeration*, not of a ton of ice, which would cost about

$1\frac{2}{3} \times \$1.35 = \$2.23.$

Adding the labor cost of 25 cents and a depreciation and interest charge of only 10 per cent. on a probable first cost of $600, equal to $6\frac{2}{3}$ cents per day, we find the total cost of one ton of refrigeration to be $1.66 nearly, and of a ton of ice, $2.75.

Even at that, the machine furnishes refrigeration equal in cost to ice purchased at $8\frac{1}{2}$ cents per hundred pounds ($1.70 per ton)—which ought to satisfy any reasonable man content with mechanical possibilities.

S. H. Bunnell.

New York City.

Binding "Power"

I have just finished binding my 1910 copies of Power according to the method described by Mr. Lambowin in the issue of January 10, except that, finding that his method did not produce volumes that would probably stand the service to which I expected to subject them, I reinforced them by putting two wire staples clear through each.

As it was difficult to punch the holes and put the staples through a whole volume at once I made a gage out of sheet iron by taking a strip as long as a copy of Power and about ¾ inch wide and bending ⅛ inch over at one side and one end. I then punched holes through it so as to locate the staples about ¼ inch from the edge and about 1½ inches from the top and the bottom. With this gage I punched holes for the staples in each copy separately. The staples I made of No. 20 gage wire. I then strung the papers on the staples one at a time as I glued them together, beginning with the first copy of the first month and going right through to the last copy of the last month of the volume. I chose to put only two months' issues in a volume. After all were glued together I clinched the staples and put on the backs and covers as described by Mr. Lambowin.

After I had the binding completed I printed labels on the typewriter to put on the backs. These labels show the months and the pages in each volume and the volume containing the index is indicated.

G. E. Miles.

Salida, Colo.

Boiler Operation

I read in Power for January 31 the "Confessions of an Engineer," by R. O. Warren. He states that fuel can be saved by cutting out one boiler and running the remaining ones with open drafts and dampers. I have had fifteen years' experience in firing and I wish to say that with more boiler room, and when steam can be kept with dampers closed, much more fuel is saved than when the boilers are strained to their full limit and when in order to keep the steam pressure the dampers have to be open all the time.

F. Van Valkenburg.

Chichester, N. Y.

Water Gages

I think that H. F. Heyrodt is too severe with C. R. McGahey in his letter in the February 7 issue under the above title. I do not think that Mr. McGahey meant that the water column should be set as shown in the sketch. His letter explains that the lowest water line should not be less than 3 inches above the top row of tubes. I may not understand Mr. McGahey's letter correctly, but I cannot find anything wrong with it.

Mr. Heyrodt considers the use of gate valves on water columns poor engineering; I consider the use of globe valves on water columns poor engineering, and no valves at all a great deal worse.

William Swope.

Tiffin, O.

Homemade Belt Dressing

In the February 14 issue, Mr. Van Antwerp gives a recipe for making belt dressing.

I have had some experience with rosin as a belt dressing. It is efficient in making a belt stick to the pulley while it lasts. But, an application of rosin to a slipping belt will last only a short time. It has been my experience that where a leather belt is dressed with rosin it soon becomes hard and rotten and cracks and the holes where the belt is laced soon pull out. With canvas and rubber belting I never noticed any depreciating effects.

If anyone has a large, expensive leather belt that is giving him trouble, I would advise the use of some good oil, such as castor or neatsfoot. This makes the belt soft and pliable so that it conforms to the shape of the pulley and adds to the life of the belt.

Edgar Altmann.

Cincinnati, O.

On Lending a Hand

The first-page editorials in Power for January 17 and January 24 bear close analogy, they go hand in hand and are distinctly applicable to the element, found in all walks of life, that "isn't telling all it knows." Dealing with the power business, the engineer that gets "results" such as depicted in the later issue, the extremely "practical" man, who has little use for any literature regarding his profession, who scoffs at technical papers and sneers at the advertisements contained in them, is usually the one who "won't help the other fellow," and who is keeping all he knows to himself—as a rule, this is very little. This is the class that "knows it all." From the engineer of this type we learn much of "past performances," of what he has done and what he has been through and in full completion there is often a missing link, "how." But this is the secret, it fails to appear either because it is as much of a conundrum to himself as to the other fellow or because the other fellow might accidentally glean a kink. When anything goes wrong he is the one who is the quickest to blame it on another operator. I am acquainted with a very "practical" man who has adorned the engine room with a patent safe, a breadbox fitted with a padlock; into this is placed his "records and private data"; the desk, supplied by the company, is too public and the engineer on the following watch might see something. To have a motto, "Let the other fellow learn the way I did," isn't showing full appreciation of the fact that possibly you learned considerable from someone yourself; it must be excessively hard to go through life in this frame of mind.

To a man of character and business sense, there is nothing like extending a helping hand; because one man's experience is not on a par with another's, is no disgrace; none of us can ever know too much, and when we begin to realize that we can learn something, that we do not "know it all," it is the first signs of judiciousness. The young engineer, the man trying to make progress in his chosen profession, should be assisted and encouraged, not discouraged; when mistakes occur, he should be shown where he has erred, not taunted; he should be helped on, not held back. Nothing will have such a demoralizing effect upon the fellow trying to learn, as the man with the big head and infused with self-conceit; it downs him in his purpose and ambition, and makes him impressed with "What's the use"?

There is an old saying, "Chickens come home to roost," and its full significance should be understood. Power points out that there is a feeling of great satisfaction to the man who knows he has helped another and there is certainly no comparison between this and that other sensation, "he didn't get any information from me."

L. R. W. Allison.

Los Angeles, Cal.

Specialists

I sometimes wonder, from the letters occasionally printed in these columns, if there are any experts alive. I often read letters from some dinky little one-horse engineer like myself telling how he had to put the bricklayers right with their mortar, etc., although probably the men had been doing boiler brickwork for years. Then, the machine erecters changed their plans when shown where they were wrong. Next, the men putting up the shafting were shown a point or two, and so on. Not one of these experts was right—at least, so our engineer will inform us at three "plunks" or so per column. Any right-minded man should know that such contributions must be from some gassy engineer spouting rot. No man is perfect, but the erecters and experts sent out by manufacturers seldom make many mistakes at this date.

To say that any man, even a chief in a first-class plant, is an expert in all branches of steam engineering is wrong.

C. F. Scott, of the American Institute of Electrical Engineers, said (in 1908) that if all the studies were included that had been suggested as essential or desirable in the training of an engineering student, the college period would need to be 30 years in length. This is 1911, so I guess it would mean 40 years by now.

Prof. L. B. Stillwell, in the same year, said that men who rise highest in the engineering profession, generally speaking, are the men of broader education. Employers have little trouble in finding draftsmen and competent calculators, but the demand for "all-round men" always exceeds the supply. Now, if he meant men with several college degrees and 10 or 15 years' practical experience, anyone would know as much without being told. But, if employers who require good all-round men, that is, men with good practical experience and some technical knowledge, will put a two-line ad in Power, I venture to predict that they will get hundreds of answers from real good men, always providing that the salary is adequate for a good man, say $2500 to $4000 per year. Surely a man is worth that who has spent probably half a lifetime to make himself as proficient as possible.

James Scotch.

Toronto, Ont.

Steam for Preventing Clinkers

Referring to the February 7 issue, in which Charles H. Parson makes comments in regard to the reply to a question asking if steam jets under the grates will prevent the formation of clinkers and if their use is economical practice, I think the answer which the editor gave to the question is as nearly correct as could be stated.

Mr. Parson's statement that ash does not melt at all is entirely wrong, and he contradicts himself by saying, "Clinkers are caused by the fusing of certain elements in the fuel. These elements may be sand, silica, sulphur, etc." If sand, silica, etc., are not ash, what are they?

It is generally believed that as steam passes through a fuel bed, the steam is decomposed into hydrogen and oxygen and absorbs heat from that part of the fuel bed where the decomposition takes place. The hydrogen formed from the decomposition of steam in the fuel bed is probably burned above the bed and, hence, the furnace temperature as usually measured may be very little different than that obtained when the steam jet is not in use.

E. G. Bailey.

Boston, Mass.

Smoke Abatement

Henry D. Jackson, in a recent issue, offered his solution of the problem of smoke prevention. Several very good suggestions were given. He suggests the old coking method of firing for the prevention of smoke. But, how many men are there who are physically able to fire in such a manner; also, how many plants are there in which such a plan could be followed without losing the steam pressure? How can better results be obtained than by the spreading method of firing? Some of the most skilled firemen use the alternate method. Is it not true that the percentage CO_2 depends greatly upon the temperature of the fire; also, that greater capacity can be secured by firing lightly, evenly and often? Then, why do so many indorse the coking method when the spreading method is used in perhaps nine cases in every ten?

I certainly approve of paying a fireman all that he is worth. In addition, I am much in favor of the bonus plan. It engenders enthusiasm and vigilance which are kept up because the bonus must be earned, whereas an increase in wages only serves as a temporary stimulant.

Waldo Weaver.

Middletown, O.

Burning Pulverized Coal

I was much interested in the article in a recent issue on burning pulverized coal. There were two items in the results of the test that seemed peculiar.

The duration of the trial was only six hours. This is entirely too short for a boiler test if any dependence is to be placed on the results.

The temperature of the flue gases as given, 380 degrees Fahrenheit, is extremely low when it is taken into consideration that the temperature of the steam at the pressure given would be about 371 degrees Fahrenheit, there being a difference of only 13 degrees in temperature between the flue gases and the steam. No mention was made of an economizer. An explanation of this temperature should prove highly beneficial to those of us who are interested in boiler economy, even if we do have to burn lump coal.

John Bailey.

Milwaukee, Wis.

Writers Among Engineers

As has been stated, the starting bar or a monkey wrench is a far handier tool than a pen in the hands of most engineers. To buckle down and compose a four- or five-hundred word article which will be rewritten two or three times before it is considered sufficiently good to trust to the tender mercies of the editor, and then go around in a cold sweat for the next two weeks expecting every mail to bring it back marked "N. G." or "not available," is more than most engineers can stand.

Some men write for the pleasure it gives them to lend a helping hand. Some write just to see their names in print. Others write for the money to be gained, which is very acceptable to all.

I find that there are from 20 to 30 articles in each issue of Power which are from one-half to one and one-half columns in length each that I would take to be written by the men "on the job." I also find that the circulation is about 33,000. Suppose 13,000 copies go to libraries, professors, retired engineers, students, etc., leaving 20,000 to go to the men on the job. Of these 20,000 men there should be at least 10,000 who could write at least two articles per year on some accident, kink, saving, or what not that he has had to deal with during the year. This would give us a little over 380 articles per issue as compared with 20 or 30 now. Of course, such a number could not be used, but this shows what a small amount of writing it would take to make a rousing old paper out of our friend Power.

I think that if the editor would give us a few front-page talks on the writing of articles, and the most acceptable subjects, going into detail on some of the points connected therewith, some of these days, very soon, such a pile of letters would drop at 505 Pearl street that someone would have to dig the whole office force out.

Indicator Diagram Defects

A suggestion in reply to Mr. Binns in the February 7 issue: Perhaps the piston is traveling past the indicator hole. I have had trouble of my own in this respect.

Also, was a spring of the right scale used?

J. L. KEZER.

Bradford, Penn.

Referring to the indicator diagram submitted by Edward T. Binns and published in the February 7 issue, when admission occurs at the head end, the pressure causes the indicator piston to rise abnormally high, due to excessive lead. As the piston is well balanced, that is, it moves with perfect freedom, the vibrations due to inertia are set up.

The reason why vibrations are not present in the crank end is because there is not so much lead.

J. P. COLTON.

The Position "Higher Up"

The question asked by Mr. Richmond in the February 14 issue is answered in the various editorials in POWER and in the little squibs tucked away in the corners of the pages.

I stepped out of the fire room into my first job as chief. How I did it may be interesting but I have always accepted it as a matter of course. I had been firing a pair of boilers for over three years and had got the trick down so fine that the boiler manufacturer noticed it and used to borrow me once in a while to fire boilers for him when they were under test. I always got as high an evaporation as the coal and boiler would stand and the boiler man always got his money.

While going out on these jobs, I noticed the men who were conducting the tests taking indicator diagrams. This interested me and, although I was working seven days a week and twelve hours a day for $40 per month, I managed to save enough money to buy a cheap indicator and to find time in which to indicate engines wherever I had acquaintances.

One day the mechanical engineer who built the plant dropped in as I was taking some diagrams from our engines. He looked at the diagrams and asked me if I knew what I had when I got one. I told him that I did and showed him some diagrams from about twenty other engines on which I had laid out the point of cutoff and the theoretical expansion curve. He seemed to be impressed and, after a while, told me that he had a pair of Corliss engines in another plant that were not doing very good work and that if I would set the valves and bring him diagrams, taken before and after setting the valves, all figured up, he would give me $20. I took a day off, indicated the engines, set the valves and spent the night figuring up the diagrams. The next day, I got an hour off and took the diagrams to him, got my $20 and went back to work at my firing job.

But that experience taught me something. There was a vast difference between $20 for a day's work and $20 for two weeks' work. So I got busy, saving money to buy books and more instruments and nearly had nervous prostration from studying and experimenting. I think the only time I ever lost from work, when I wanted to work, was at this time, when I had to go to a hospital to have my eyes treated and later on when I went to a hospital to get some burns treated which I received while trying to conduct a fire test of a sample of oil with a homemade flash pot and a gasolene torch.

Some time after indicating those two engines my mechanical-engineer friend came around and said that in a plant somewhat similar to the one in which I was firing the chief engineer was due to walk the plank. He asked me if I thought that I could handle the job. The wages were to be $21 per week, only five and a half working days per week. Although the offer nearly took the breath out of me, I told him that if he was willing to try me I was willing to take a chance and that if I failed it would not be because I had not tried.

The long and short of it is that he gave me the position, and I have held that and similar positions almost without interruption ever since.

One of the principal requirements of a chief engineer is executive ability and this is hard to acquire. Another qualification is fair bookkeeping ability. I studied probably all of the technical journals for ten years and could figure out any of the problems relating to a stationary engineer's work. Then I saw a new light. Today, I do not believe that I could figure out the horsepower of a boiler or engine or do any of the lever safety-valve problems without consulting a book. But, I can figure out the cost per kilowatt-hour of every item entering into the daily operation of the plant, lay out the load curve, figure the load factor and the boiler performance, show the difference between the last twenty-four hours' operation and that of the preceding day and account for that difference. Any or all of the foregoing information I can put on the manager's desk by ten o'clock in the forenoon. Such things are what really count and are what the company wants.

I am not a paragon of virtues and meet engineers every day to whom I take off my hat. In fact, I have had them working under me and have in several instances managed to turn over my job to them when I got ready to quit. I never noticed an engine-room clock except to see that it was correct and still running, for I always considered that I was paid for twenty-four hours per day. I have always respected my employer if I did not respect the man. I have never asked for a raise in salary in my life and my employer has always paid me *all* of the salary I received.

I work hard and long and expect the men and machines under me to operate at as near full capacity as possible. In return for the coöperation of the men, I see to it that they get all the money that the company will stand for and I do not work them on twelve-hour shifts. It may sound strange, but I have found that a sure way in which to bring down the cost per kilowatt-hour, and that is all that I think and dream about, is to see that the men get all the money within reach and work short shifts.

EDWARD ADAMS.

Reading, Penn.

Under the above head in the issue of February 14, Oscar J. Richmond wishes suggestions on the matter of obtaining better positions.

It is generally admitted that the first move is self-education, which results in increased personal efficiency. A difficulty mentioned, and it is a real one, is the fact that a power-plant engineer is tied down for the greater part of every day with a minimum chance for meeting influential men and thus furthering his ends. He has, however, the same use of the United States mails as his employer. All "improved" engineers are conscientious readers. In reading they are continually noting the affairs of others and news with regard to new undertakings. If in search of an opening, many ideas should be gleaned in this way. New power plants in the course of construction will soon need engineers. Improvements in old plants will need better talent. New companies forming will need expert talent. A card index or other means of tabulating should be instituted and business methods applied to the subject in hand—that of getting a better job.

Letters should be written by the dozen and the replies graded as to prospect. It must be remembered that letters are proxies and as such should truly represent the writer. A slovenly letter may not always indicate a slovenly man, but in the absence of other evidence the effect is the same. The rent of a typewriter would amount to a few dollars a month, and a little practice makes one fairly proficient. And if the end is worth having at all, the typewriter is a part of the job-getting business. Another way would be to turn the letters over to a friend who is a stenographer, or still another, have them copied by a public stenographer. In the quest of a position, do not send a letter written in long hand to a stranger; in most cases it is suicidal.

Blind advertising is all right in the search for men, but as a means of obtaining a position it is practically useless. The head of a plant has too many opportunities to reach people directly, and the blind advertisement carries with it an atmosphere of distrust.

Engineering societies and clubs do much to raise the standing of men who take active part. There are those whose fortunes were made by this method, sometimes called "self-advertising."

Above all things, if you really want a new job, go after it in a whole-hearted manner. You cannot leave a stone unturned and do justice to yourself.

L. F. WILSON.

Chicago, Ill.

Binding "Powers"

In the February 7 issue, Mr. Levy tells how he takes care of his copies of POWER.

I have been a regular subscriber to POWER for a number of years and I have every copy that was ever sent to me. I have a case in the engine room for them; in it I place each copy after I have read it. I can get any number I want without the slightest trouble. I keep the titles of such articles as I need in a ledger. I think I have a better method than any I have seen described.

E. O. FOULK.

Pioneer, La.

Vacuum for Reciprocating Engines

I take exception to the opinion expressed in the article under the above in the issue for January 31. The old-fashioned and impractical idea of 26 inches of vacuum being the limit for economical engine performance should be discarded with the innumerable other practices now obsolete in engineering.

Why should the author, as is customary with engineers discussing the subject from the same viewpoint, base his figures on the steam delivered to the low-pressure cylinder? If the steam requires more volume with the higher vacuum than is provided in this cylinder, why not change the cutoff in the high-pressure cylinder and adjust the receiver pressure accordingly? The decreased back pressure will allow of a shorter cutoff for the same power output. After putting the condensing apparatus into first-class shape and obtaining the highest vacuum possible, the valve setting should be adjusted to correspond. In some plant-betterment work, which I conducted recently, the vacuum for the engines was changed from 25 and 26 inches to 27 and 28 inches with marked improvement in the coal consumption per kilowatt-hour. The dashpots in several cases acted badly under the new conditions but the trouble with the *dashpots* was eliminated by better adjustment.

Parallel with this mistaken idea is the practice in many plants of dropping the steam pressure during the light load at the noon hour. The reason for this generally is on account of the poor regulation under the lighter load with the short cutoff. There is no excuse for this in a reputable engine and it will usually be found that a better adjustment of the governor, dashpots and valve gear will eliminate the trouble.

Let us forget obsolete practices!

THOMAS J. WALSH.

Boston, Mass.

Change of Cutoff

In a recent issue a correspondent wanted to know how to change the cutoff of a Brown engine.

The engine takes steam while the valve is going up. If the engine will stand a little more lead, a later cutoff will be obtained by increasing the lead, and an earlier cutoff by decreasing the lead.

I have an idea that the engine is overloaded and that a little later cutoff is desired.

H. JONES.

Wylam, Ala.

Central Station vs. Factory Plant

The instances of greater cost of power obtained from central-station current than of power produced by the independent factory plant cited by Henry D. Jackson in the issue of February 14, are but examples of scores of cases where the central-station agent would "never have gotten further than a look in" had the owners gone to the small trouble and expense of having a disinterested examination made of the actual conditions and of the possibilities of saving power, or money, by changing from the belt drives of a factory plant to electrical power and transmission. Saving of space, greater cleanliness and greater convenience are advantages possessed by electric power and transmission over the ordinary factory-plant belt drives that can be turned to good account in almost any manufacturing establishment; but the power which will be saved by the elimination of belt transmission is usually much overestimated.

Electric-line losses and losses due to imperfect insulation of motors rarely amount to less than 5 per cent and, placing the average working efficiency of motors at 85 per cent, it can be seen that the electrical horsepower read at the switchboard must be about 20 per cent in excess of the net power delivered by the motors.

From an experience of testing many hundreds of factory plants, I can testify to the fact that shafting friction in nearly all lines of manufacture has been found to be nearer 10 per cent, than 20 per cent, of the total power required, in many cases being less than 10 per cent, of the power that would have to be delivered to the same points by motors.

In the average factory, shafting, pulleys and belting are the most conspicuous features of the power plant, and to the uninitiated they are impressive of the idea that they absorb most of the power required for the whole establishment. It is no wonder that owners are profoundly impressed with arguments of savings of power that are to be realized by the employment of electrical transmission, especially if they are not "wise" to losses that are inevitable in the conversion of electrical power at the switchboard into actual power.

In a case where it is proposed to change from belt transmission to electric driving and where cost of power is a consideration, it will pay to make careful tests to determine the power loss in transmission, and it is of equal importance to demand guarantees of motor and line efficiencies. The loss or saving resulting from the installation of electric motors can then be determined in advance in place of waiting until after the central-station service bills are presented and the plant has been equipped with a lot of expensive motors.

Quite recently I was called in to consider a case where the proprietors of a plant were greatly disappointed to find that the central-station charges for current supplied to the motors amounted to nearly double their former cost of power generated by the old factory plant. Enormous savings had been looked for. Transmission by belts had been replaced by electric motors installed in groups, main belt drives abandoned, a good Corliss engine power plant shut down, the engineer discharged and only a fireman retained for making the steam necessary for the manufacturing processes and for warming the buildings with live steam.

The only improvement was in one department where the speed was more uniform than formerly. In this case the old transmission had been by vertical belt and the condition of the lower pulley showed that slippage took place on account of the belt dropping away from the driving pulley, a trouble which any millwright engineer would have corrected by giving slope to the belt or by equipment of a ready-made belt tightener for less than 5 per cent. of the cost of the new electrical equipment. In this case electric motors were employed for driving the old line shafts. The only transmission that had been dispensed with was the jack shafts which I am satisfied would not have absorbed more than about 3 per cent. of the power which they transmitted.

This was a case where the claim of saving power by electrical transmission was absurd and the central-station rates will have to be materially reduced in order to meet the cost of operating the old plant.

Paterson, N. J.

Inquiries of General Interest

Questions are not answered unless accompanied by the name and address of the inquirer. This page is for you when stuck—use it

Horsepower of Gas Engine

Is there a formula for estimating the horsepower developed by a gas engine?

E. D. R.

For a four-stroke cycle engine using illuminating gas or gasolene the output that will probably be obtained is given by the formula:

$$\frac{d^2 s n}{12{,}500} = \textit{horsepower}$$

in which

d = Diameter of piston in inches;
s = Length of stroke in inches;
n = Number of revolutions per minute

For a two-stroke cycle engine use 8000 instead of 12,500 for the divisor.

Pressure Required to Compress Air

What pressure per square inch will be required to compress air to ⅔ and also to ½ its original volume?

P. C. A.

The volume of a gas varies inversely as its pressure and the product of pressure into volume is constant, provided the temperature remains constant. To compress a given volume of air to ⅔ of the original volume will require $\frac{3}{2}$ of the original pressure and to ½ the original volume will require twice the original pressure. If the air to be compressed is at atmospheric pressure the pressures will be

$$3/2 \times 14.7 = 22.05 \textit{ pounds absolute}$$

and

$$2 \times 14.7 = 29.4 \textit{ pounds absolute}$$

respectively.

At any pressure other than that of the atmosphere the method will be the same.

Efficiency of Boiler and Furnace

How is the efficiency of a boiler and furnace determined?

E. O. B.

By dividing the heat transmitted to the water by the heat in the fuel.

Brass and Babbitt Bearings

Which is better for engine-shaft bearings, brass or babbitt metal?

B. E. B.

Under all ordinary conditions babbitt metal is preferable.

Dead Weight Safety Valve

What is a dead-weight safety valve?

D. W. S.

It is one in which the valve is loaded by weights acting directly on the valve without the interposition of a lever.

Cause of Reversed Rotation

What would cause an engine to run backward?

R. C. R.

A sufficient change in the position of the eccentric.

Point of Cutoff

At what point in the stroke will cutoff take place in an engine of 20 inches stroke, valve travel 5 inches and outside lap 1⅜ inches?

P. O. C.

The point of cutoff will vary slightly with the lead. With 5/16-inch lead the period of admission will continue through 62 per cent. of the stroke.

$$20 \times 0.62 = 12.4 \textit{ inches}$$

With no lead, cutoff will occur at 66.6 per cent. of the stroke.

$$20 \times 0.666 = 13.32 \textit{ inches}$$

A valve having the lap and travel as stated would give a port opening of 1⅛ inches.

Pohle Air-lift Pump

Will you please explain the construction and operation of the air-lift pump?

P. A. L.

The air-lift pump consists of a vertical water pipe the lower end of which is submerged in the water of a deep well, and a smaller pipe delivering air into the lower end of the water pipe. The air rises in bubbles, and the column of air and water inside the pipe being lighter than the solid water outside, it is forced upward by the unbalanced pressure.

Vacuum Gage on Suction Line

Kindly explain the theory and use of a vacuum gage on the suction line of a cold-water pump. Is it proper to locate the gage on the suction gas chamber? Will its showing be the same there as on the main suction line? Explain the gage reading; what it should read on, say, a 20-foot suction lift, and what information does the engineer get from the reading that is of practical use to him in operating the pump?

G. S. L.

A vacuum gage on the suction pipe from a pump may give much or little information to the pump operator, depending entirely on the conditions under which the pump is working. Attached near the pump it tells the vacuum required to draw water to the pump at all times. With clean water and steady service this may not be much, but with the suction pipe drawing water from a source filled with seaweed, dead leaves or grass, the strainer may become clogged and the vacuum gage tells that the supply is being restricted long enough before the pump fails to allow for cleaning. It is proper to attach the gage to the suction chamber, and it will read the same as though attached to the main pipe near the pump; but the farther from the pump it is attached, the lower the reading will be. With a large suction pipe and a slow running pump, the gage should read 18 inches for a 20-foot lift, but with a long pipe with numerous ells and with the pump running at a high rate of speed, it may read as high as 28 inches.

Factor of Safety of Old Boilers

What rule is followed by boiler inspectors in reducing the working pressure on horizontal tubular boilers with lap seams on account of age?

T. M. D.

Boiler inspectors follow no general or regular rule in reducing the allowable working pressure on a boiler due to its age. They rely upon their judgment and experience. The Board of Boiler Rules of the State of Massachusetts prescribes that the lowest factor of safety used for boilers, the shells or drums of which are exposed to the products of combustion and the longitudinal joints of which are lap-riveted construction, shall be

5 for boilers not over 10 years old;
5½ for boilers over 10 and not over 15 years old;
5¾ for boilers over 15 years old and not 20 years old;
6 for boilers over 20 years old.

These factors are considered by many engineers to be altogether too small, and that 6 should be the lowest factor of safety allowed on a new lap-seam boiler and that the factor should be increased each year to such an extent that it will put the boiler out of use at the end of 10 years.

Reduced Grate Area at Light Loads

It is generally conceded that with a properly designed furnace the highest grate efficiency is obtained when burning the maximum amount of coal per square foot, consistent with complete combustion. Opposed to this, however, is the efficiency of the boiler itself. With a fixed heating surface, increased combustion is accompanied by a higher stack temperature and this means increased heat losses. There is a mean between the boiler and the furnace efficiencies and in good design this point should represent the rated capacity. Boilers are often forced considerably beyond their ratings, with only a slight loss in economy, but this is explained by the introduction of other factors, such as increased velocity of the gases, etc.

On the other hand, through lack of judgment or to meet certain conditions, boilers are often installed having a rated capacity far in excess of the load to be carried. In such cases it is customary to reduce the draft to suit the load; this results in more or less incomplete combustion and tends to lower the efficiency of the unit. Here it would be much better to reduce the grate area and maintain a high rate of combustion. Instances are on record where this has lowered the fuel consumption as much as five per cent.

The Cost of Power

To one who got his knowledge and impressions of the subject from the recent joint meeting of the American Institute of Electrical Engineers, and the American Society of Mechanical Engineers, the man who runs an engine and generator when he can buy current from a central station would appear a blithering idiot.

It is not surprising that a meeting, all of the papers for which were written by central-station men and most of the prearranged discussion prepared by their friends, should have turned out so preponderatingly and exaggeratedly onesided as to have excited the risibility even of central-station sympathizers; but it is surprising that the managements of the societies involved should have turned the forum of American engineering into an arena for the mental gymnastics of the central-station enthusiasts, and the "proceedings" of a great national professional society into a reference book for him who seeks to justify high rates.

To the engineer whose interests are not involved with those of the central station it is quite possible to conceive a condition where the owner of a department store, hotel or office building having to have steam plant anyway for heating and other purposes, can put in an extra engine, run it as a reducing valve between his high-pressure boilers and his heating or low-pressure service and make what current he needs more cheaply than a central station can make and deliver it to him at a profit. In fact there are records available where such a thing has been done. In fact, again, there is something very exceptional about a case where an industrial establishment or building of size worth considering cannot be run on less money, when heating is as much of a factor as it ordinarily is in any but southern latitudes, if it makes its own electric current than if it buys it.

Try the shoe upon the other foot. There are people whose interests are with the isolated plant rather than with the central station: manufacturers and salesmen of engines and generators and power-plant supplies, consulting engineers who have advised against central-station service when it appeared to them that their clients could make current cheaper, engineers of public plants shut down by the usurpation of the central station, high-class operative engineers of the professional type who are in charge of large installations and know what it costs to run them. Suppose that some of these wanted a meeting held under the auspices of one of the great national professional societies to present their side of the case.

Could they get it?

Having got it, would there be any kind of a howl if they monopolized the meeting with the perverted statements of the most unreasoning of their adherents; watch and gavel in hand, would shut anybody who approached the subject from the other side; if, after all their ammunition had been spent, many of the audience had left and all were ready to go they threw the discussion open at a minute a head, and then published the performance as the "proceedings" of a national scientific institution?

We know of nothing which would be more interesting and profitable than a dignified professional discussion of "The

Cost of Industrial Power," backed by statements of initial cost and of actual accomplishment. There is plenty of information of this kind to be had. There are plenty of men who are qualified to discuss it intelligently, even the accountants' side of it. It ought to be discussed without prejudice and with no more warmth than the interest warrants, from a purely engineering point of view; and when one class of men claim that they can make a kilowatt-hour for a cent and another class claim that it is really costing them fifteen but that they do not know it, there ought to be enough brains in a free-for-all meeting to find out whether the difference is one of fact or of bookkeeping.

We should like to see such a meeting arranged, in the interest of the truth; not organized for and by those whose aim is to boost the popular conception (and especially the Public Service Commission conception) of the cost of power nor of him whose interest lies in reducing that conception, but for the manufacturer, the engineer, the power user who wants to get at the facts in the matter.

Pending such a meeting the columns of POWER are open to any who have real information upon the subject.

Interest and Sinking Fund

If the life of an installation of power plant is assumed to be twenty years, then it would appear at the first glance as though there must be charged against operation one-twentieth, or five per cent., of its cost each year, as it uses up that amount of plant each year on the average, as well as coal and other supplies. But if five per cent. of a sum be set aside each year and be put at compound interest at six per cent. it will amount to 184 per cent. of the original sum at the end of the twenty years. It is necessary to set aside only 2.7 per cent. in order that the full sum may accumulate and accrue and be ready to replace the plant at the end of its assumed lifetime.

At the recent New York meeting of the American Institute of Electrical Engineers, held to discuss power costs, one of the central-station solicitors maintained that it was not right to so reduce the sinking-fund charge because inquiry upon his part had revealed the fact that nobody invested the money thus charged annually to the plant at compound interest.

Well, what do they do with it? They don't put it in a safety-deposit vault, or soak it away in a stocking. They keep turning it over in their business and make it earn twenty or thirty per cent. If the steam plant were credited with that rate of interest its sinking-fund charge would be low indeed. But that would not be fair, for the owner could borrow at six per cent. for his commercial or manufacturing operations.

And in the face of this refusal to credit the plant with ordinary interest upon money which they insist it shall earn and set aside for its own replacement, the central-station men want the man who is considering the installation of an isolated plant as against buying current to virtually charge the plant with interest at the rate of profit in his most profitable department, upon the plea that he had better use the money there than to put it into power plant if the plant cannot beat the most profitable department as a money maker; which would be true if the department were capable of such extension as to absorb all the capital and the owner were "broke."

Inertia

Inertia is defined as the inability of matter to set itself in motion, or of a moving body to change the rate or direction of its motion. A broader application of this definition covers those peculiar attributes of the human mind which induce many to bury themselves in a rut or a ditch so deep that their horizon is limited by the blank wall in front of them. When study for improvement is suggested, it is often met with the abject confession, "I didn't have much schooling an' those things are beyond me." No man's education ceases at the school door unless he wilfully shuts his eyes and his ears when he tosses his school books aside. In fact, the largest part of anyone's education comes outside of books. Some of the most ignorant men have had all of the advantages afforded by schools and colleges and have failed to profit thereby, while some of the best educated men in the world have been entirely self-taught. A man's education commences the instant he begins to see and only stops when he ceases to see. In this he is governed by his own inertia or his lack of it—the inertia that prevents a man from advancing himself, the initiative which prompts a man to seek out the explanation of those phenomena which daily life presents.

At the close of his paper on the "Art of Cutting Metals," presented by F. W. Taylor, when retiring from the presidency of the American Society of Mechanical Engineers, are found the following words:

"And let me point out that the most important lessons taught by these experiments, particularly to the younger men, are that several men when heartily cooperating, even if of only everyday caliber, can accomplish what would be next to impossible for any one man even of exceptional ability.

"Expensive experiments can be successfully carried on by men without money, and the most difficult mathematical problems can be solved by very ordinary mathematicians; provided only they are willing to pay the price in time, patience and hard work. The old adage is again made good that 'All things come to him who waits,' if he only works hard enough in the mean time."

The same amount of time and energy that the average man devotes to memorizing the standing of the different baseball clubs and the players would, devoted to a subject connected with his occupation, render him an authority on that line.

The corrosion of condenser tubes is one of the serious items of expense and trouble about a power station. In one of the large New York stations the surface condensers have to be entirely retubed after a service of not more than three years. It is pleasing to learn, therefore, that the Institute of Metals, of Great Britain, has appointed a committee to investigate the subject of corrosion, and that the first subject which they will take up is that of condenser tubes. Sir Gerard Muntz, the president of the Institute, is naturally much interested in the subject, and G. D. Bengough, of the metallurgical department of Liverpool University, is in charge of the scientific work.

That a chain is no stronger than its weakest link is an old and familiar maxim. The same reasoning applies to many other things besides chains. One weak spot in the insulation of an armature, for example, can cause the destruction of an otherwise sound generator. A set screw of insufficient size or "bite" can wreck the finest steam engine ever built, by allowing the key to back out of the connecting-rod strap. A cheap, unreliable ignition system will "kill" a $100,000 gas engine just as effectually as the use of rotten material in the crank shaft, though equal mechanical damage would not be caused.

Having awakened to the advantages of electric ignition ten years late, our British cousins are about to make the parallel discovery that the hit-and-miss method does not embody all of the cardinal virtues of regulation for gas engines of moderate output.

But those same English cousins have keenness of vision when it comes to discerning the buttered side of a slice of bread. They don't figure crank pins and such with a margin of $2\frac{9}{16}$ per cent.

The National Assembly of Panama has recently voted $100,000 in aid of the proposed world's fair to be held in Panama City in 1915. The more, the merrier, providing it does not interfere with Louisville or San Francisco.

If everybody had the moral courage to tell the whole truth always, we'd all know "where we're at" and everybody would be really more contented.

Notes on the Cost of Industrial Power

Two papers and the discussion of them at a joint meeting of the American Society of Mechanical Engineers and the American Institute of Electrical Engineers. The original papers deal with methods to be used in arriving at the cost of power in isolated plants as viewed from the central station standpoint.

On Friday evening, March 10, the American Society of Mechanical Engineers and the American Institute of Electrical Engineers held a joint meeting at which were presented several papers upon the cost of producing power.

John C. Parker, of the Rochester Railway and Lighting Company, delivered a paper entitled "Comments on Fixed Costs in Industrial Power Plants." Beginning with the initial investment he pointed out the necessity of including the cost of real estate, building, equipment and all labor involved in connection with the erection of a plant, depreciation being charged against the labor and supervision items as well as the equipment itself. It was shown that boilers depreciate more rapidly than engines which, in turn, depreciate faster than buildings and so on; hence, a separate rate should be applied to each, the basis for calculation being that the life of any plant is the length of time for which it can be run economically.

Regarding insurance, if the installation of a plant increases the fire hazard on the property as a whole, the net increase of insurance should be charged against the plant which occasioned the increase. Furthermore, to the ordinary fire insurance must be added accident and liability insurance. This expense is existent whether such insurance is actually carried, or not, as a sum equal to the insurance premiums must be laid aside to provide for such contingencies for which the insurance is carried.

An "obsolescence" charge, meaning the supersession of the apparatus initially installed by a more efficient piece of apparatus which may be developed before the initial apparatus has reached the scrapping stage, was not considered important, even though the supersession take place under stress of competition. For this would not be undertaken unless the new apparatus could save enough to justify the expense, in which case the saving must take care of that much of the new investment as is not already covered by the sinking fund.

Mr. Parker laid considerable stress upon what he termed the "marginal principle." This, briefly stated, is to the effect that if any part of a business requires time, material or investment which could have been utilized in any other part of the business, the cost thereof should be taken as the amount such time, material or investment would have earned if applied to the most profitable part of the business which is capable of extension. To illustrate this he cited the case of a department store in which, for every $1000 invested in the china department, a yearly profit of only $100 is made, whereas each $1000 invested in the clothing department yields a yearly profit of $300. Hence, according to the marginal principle, the $1000 invested in china actually showed a loss of $200 per annum which should be charged against the china department. If, then, an enterprise is making a net profit of 10 per cent. per annum on the average—and not less and probably more than this on certain details of the business—[illegible]

is at least a 10 per cent. loss per annum on the investment of money in a power plant, if the money earns only the fixed items of taxes, insurance, interest, depreciation and supervision, and the amount lost is just what could have been gained by the investment of such a sum in the most profitable part of the business.

As an illustration of the methods laid down, Mr. Parker appended figures intended to show the cost of supplying a large mercantile establishment with power from an isolated plant as compared with central-station service. The plant selected was of 150 kilowatts capacity and the fixed charges were assumed at the rates given in Table 1.

The second paper of the evening was by Aldis E. Hibner, of the Toronto Electric Light Company, and was in part as follows:

There are in general three factors involved in every industrial-power problem: the investment charges, operating charges and the cost of heating or the use of low-pressure steam. The investment charges are understood to cover the interest, amortization, insurance, taxes and profit on the capital invested in the plant. The operating charges include coal, labor, repairs and supplies. The cost of heating is the investment and operating charges of the boiler plant necessary for heating the building and supplying steam for manufacturing processes.

TABLE 2.

Heating Plant Investment.		
Boiler, piping and auxiliaries (A)	$1,500.00	
Building and stack (B)	2,500.00	
Total investment	$4,000.00	
Fixed Cost.		
Interest 6 per cent. on $4000	$240.00	
Insurance and taxes, 2 per cent. on $4000	80.00	
Amortization on A, 4½ per cent., 15 year life	67.50	
Amortization on B, ½ per cent., 50 year life	12.50	
		$400.00
Operating Cost.		
Coal, 475 tons @ $3.00	$1425.00	
Fireman @ $15.00 per week	780.00	
Supplies and repairs	100.00	
		2305.00
Total cost		$2705.00

Assume as a typical example of the conditions ordinarily found, the Blank Shoe Company, which has outgrown its present quarters and has decided to build a new factory having a floor area of 60,000 square feet and a cubical content of 750,000 cubic feet.

One of the first things which must be determined before starting construction is whether power shall be purchased or supplied from a private plant. The first step in the solution of this problem is to determine the cost of heating the building. A heating plant is necessary in any case, as the conditions of manufacture are such that the temperature of the building must be kept above fifty degrees during the winter months.

The coal consumption is based on an evaporation of seven pounds of water per pound of coal, one change of air per hour in the factory and the supplying of radiation losses. During zero weather 90 boiler horsepower will be required. Having determined the size of boiler plant necessary the next step is to take up the cost of heating. Table 2 gives the investment necessary, together with the fixed and operating costs of the plant.

Replacement of the plant has been provided for by a sinking fund drawing 5 per cent. interest compounded semi-annually, based on a life of the various parts of the plant as given in the table. The time of the fireman has been figured for the entire year, as steam at high pressure is required the entire year for industrial purposes. It is of interest to note that the cost of coal represents only a little over 50 per cent. of the total cost of heating, and that a variation of 25 per cent. in the amount of coal burned causes only 13 per cent. variation in the total cost.

Having determined the expense which is absolutely necessary in connection with the power requirements, the question asked is whether it is advisable to go a step further and make the additional investment necessary for generating power, or whether it shall be purchased from a power company. The answer, obviously, depends upon the additional cost of producing this power and the rate at which power can be purchased. Having determined the former, the rate at which power can be purchased to advantage is fixed.

The concern under consideration has a maximum demand for 100 kilowatts of power. The average load is 80 kilowatts, giving an 80 per cent. ten-hour load factor. The engine is of the Corliss noncondensing type, requiring 30 pounds of steam per indicated horsepower-hour. The boiler evaporation is taken at seven pounds of water per pound of coal, giving a coal consumption of 4.3 pounds per indicated horsepower-hour. The efficiency from steam cylinder to switchboard is 78 per cent., giving a coal consumption of 7.39 pounds per kilowatt-hour or 5.51 pounds per horsepower-hour at the switchboard. The factory runs 300 days per year.

Table 3 gives the investment cost, fixed cost and operating cost of the plant, allowance being made for the cost of heating, as calculated.

Among the items of fixed cost will be found one covering a profit on the additional investment required for a power plant. It is clear that a concern is not justified in investing in a power plant unless the capital so invested returns the same profit as if invested in the most profitable part of the business still capable of extension. When the added risk is taken into consideration, this could safely be raised to 10 or 15 per cent. It is evident from these results that if power can be purchased for 2.3 cents per kilowatt-hour there is no advantage in installing a steam-power plant.

TABLE 3.

Complete Power Plant Investment.		
Capacity, 100 kilowatts.		
Engine, generator, switchboard, wiring (A)	$5,500.00	
Boilers, steam piping, auxiliaries (B)	5,000.00	
Building, foundations, stack (C)	5,000.00	
		$15,500.00
Steam-heating plant		4,000.00
Additional for power		$11,500.00
Fixed Cost of Power Plant.		
Interest, 6 per cent. on $15,500	$930.00	
Profit, 5 per cent. on $11,500	575.00	
Insurance and taxes, 2 per cent. on $15,500	310.00	
Amortization on (A), 3 per cent. (20-year life)	165.00	
Amortization on (B), 4½ per cent. (15-year life)	225.00	
Amortization on (C), ½ per cent. (50-year life)	25.00	
		$2,230.00
Fixed cost on heating plant		400.00
Additional for power		$1,830.00
Operating Cost of Power Plant.		
240,000 kilowatt-hours.		
Coal @ 7.39 pounds, 887 tons @ $3.00	$2,661.00	
Banking, 181 tons @ $3.00	543.00	
Night heating, 202 tons @ $3.00	606.00	
Engineer @ $18.00 per week	936.00	
Fireman @ $15.00 per week	780.00	
Water	100.00	
Oil, waste, supplies	150.00	
Repairs	200.00	
		$5,976.00
Operating cost of heating plant		2,305.00
Additional for power		$3,671.00
Total additional for power		5,501.00
Cost per kilowatt-hour		0.0229
Cost per horsepower year		51.40

At the present time, however, an engineer would scarcely make any decision without investigating the cost of producing power by means of a gas-producer plant. The most active competitor of the steam engine for power production is the gas-producer plant. This type of plant, which has developed since 1900, has shown remarkable economy of coal consumption when handled by experienced operators. The United States Geological Survey report on gas-producer plant shows that for an average of a great many tests the noncondensing steam plant requires 2.7 times as much coal per unit as the producer plant. Their results give a thermal efficiency at the switchboard of 4.86 per cent. for the steam plant and 13.5 per cent. for the producer plant. The maximum attainable efficiency is probably 10.3 per cent. for the steam plant and 21.5 per cent. for the gas producer under present conditions. In view of this known economy a great many producer plants have been installed in the last few years.

For the factory under consideration the conditions will require the installation of a 175-horsepower engine and producer, and in addition a heating plant for heating the building. As this heating plant is required in any event, the cost of heating is eliminated as a comparative factor in the problem. The investment, fixed costs and operating costs of this plant are given in Table 4. The cost of the plant is somewhat higher than the corresponding steam plant. The life of the plant is also shorter. This gives a higher fixed cost than for the steam plant.

TABLE 4

GAS PRODUCER PLANT

INVESTMENT		
Engine and producer (A)	$11,900 00	
Generator, switchboard, wiring (B)	2,500 00	
Building (C)	2,500 00	
	$16,900 00	
FIXED COST		
Interest, 6 per cent on $16,900	$1,014 00	
Profit, 5 per cent on $16,900	845 00	
Insurance and taxes, 2 per cent on $16,900	338 00	
Amortization on A, 15-year life, 4½ per cent	535 00	
Amortization on B, 20-year life, 3 per cent	75 00	
Amortization on C, 50-year life, ½ per cent	12 50	
		$2,819 50
OPERATING COST		
240,000 kilowatt-hours		
Coal, 3 pounds per kilowatt-hour at $4.00 per ton, 360 tons	$1,440 00	
Engineer at $18.00 per week	936 00	
Oil and waste	125 00	
Repairs	300 00	
Water	133 00	
Emergency service	300 00	
		$3,234 00
Total		$6,053 50
Cost per kilowatt-hour		0 025
Cost per horsepower-year		56 20

The operating costs of the producer plant are only about one-half that of the steam plant. This, however, is counterbalanced by the cost of heating. The final result gives a slightly higher cost for the gas-producer plant. The ratio of the fixed cost to operating cost in the two cases, however, produces a very marked effect where the load factor is poor. The only items affected by the output of the plant are coal and water. These represent only about 27 per cent of the total cost, as against 50 per cent with the steam plant, the result being a very much higher cost for the gas producer at low load factors. The poor fuel economy on light loads would further exaggerate this effect.

DISCUSSION

Mr. Moses: I think Mr. Parker's paper is typical of the central-station point of view, in that it exaggerates each item of the cost and the result is a great exaggeration. He says that since the installation of a plant costing $10,000 to $20,000 will constitute a physical improvement to the property, it is obvious that the taxes will be increased. I have installed a number of plants in this city and do not know of a single case where the taxes have been increased. Furthermore, I do not know of any cases where the taxes have been decreased, owing to a plant having been discontinued.

On the subject of insurance, Mr. Parker allows a charge of 3 per cent. In the modern fireproof building the insurance on the contents is about one-quarter of one per cent. In addition to this there is the liability and accident insurance. This, in New York State, under the new law is about 3 per cent. of the cost of labor, and of the labor in the boiler and engine rooms about one-half is chargeable to the heating. In a plant costing $20,000, the labor will be about $5000 per annum; hence, this charge would be about $75 per year, which is about three-quarters of one per cent. upon the investment.

Considering the cost of the equipment in the typical isolated plant selected by Mr. Parker, the cost of a 100-kilowatt engine and a 50-kilowatt engine is given as $4195. We recently purchased two 100-kilowatt engines for $3000.

Mr. Bolton: I wish to controvert the statements of the previous speaker in so far as they refer to conditions in this city. The insurance on hazardous labor has now risen in this State until it amounts to nearly 6 per cent. Mr. Parker has amortized his depreciation at a rate of compound interest which we are not able to get in this city, namely, 6 per cent. Referring to the table showing the rate of amortization, I would say that, capitalized at 3 per cent., which is the rate obtainable in most savings banks, the average would be more like 4.5 per cent. on the total; hence the figure given in Mr. Parker's table should be increased by about 2 per cent.

The use of exhaust steam as a byproduct depends upon climatic conditions; the nearer the plant is to the North Pole, the more efficient the use of the exhaust steam; and the nearer to the Equator, the less efficient its use becomes. The following statistics, showing the percentage of live steam used based upon the total steam supplied, are taken from the records of a large steam company in this city: October, 3.2 per cent.; November, 7.2 per cent.; December, 15.5 per cent.; January, 25.7 per cent.; February, 22.6 per cent.; March, 20.6 per cent.; April, 5.2 per cent. The corresponding figures for a large office building situated only a few blocks from the other plant, were as follows: October, 13.4 per cent.; November, 12.9 per cent.; December, 14.8 per cent.; January, 15 per cent.; February, 13.9 per cent.; March, 16.1 per cent.; April, 13.73 per cent. If anyone can make these fit together, I should be glad to know it.

Mr. Williams (New York Edison Company): I am compelled to take issue with Mr. Parker and Mr. Hibner; they have not placed the cost of current, at least under conditions existing in such a city as New York, at anywhere near its true value. In Mr. Hibner's paper the amount allowed for heating the building with an average steam-heating load of 62 horsepower is altogether too high; $2800 should cover the investment instead of $4000, and upon this basis the annual fixed cost upon the investment would be $300 and not $600. As to coal, for heating alone the cost appears overstated. Four hundred tons, for an average of 62 boiler horsepower for the heating season, would be sufficient, which, at $3 per ton, would cost $1200. In the matter of labor, a fireman's wages for a full year have been charged. Assuming that one would be sufficient, the wages chargeable to heating for thirty instead of fifty-two weeks would be $450. Making these changes, the yearly cost of heating the building would be about $2000 instead of $2705. I would summarize the fixed charges at 15 per cent., and, making this allowance, the final result becomes 5.5 cents per kilowatt-hour instead of 2.29 cents.

Referring to gas-producer plants, they are hardly more reliable in their operation and hardly longer in life than an automobile engine. Therefore, I would change the ratio of depreciation on the total investment to 20 per cent.

Mr. Parker estimates 2.03 per cent. as the annual depreciation, but I do not know of any case where annual depreciation is actually put aside in a fund upon which interest is accumulated from year to year. Therefore, I would change the general depreciation rate to 7.5 per cent. Two causes for depreciation have been given—obsolescence and physical life; however, there is a third, and that is, the moment that a competing service becomes available at a cost not exceeding the cost of operating the private plant, then the depreciation of that plant has become 100 per cent., and as long as its operation is continued, it must be apparent that operation is continued at a loss to the operator.

Some years ago Mr. Parsons presented a paper in which he gave the average number of pounds of coal consumed per kilowatt-hour in a number of plants. I believe there were three apartment houses, three hotels and three clubs, representing in these three classes the most difficult service with which a central station in a large city must compete. I have never seen the accuracy of Mr. Parsons' figures questioned, but I have seen them confirmed in many ways. They show as high as 25 pounds of coal per kilowatt-hour generated, including the coal required for heating. The average was 17.3 pounds, and the average of all, divided by the kilowatt-hours required, was 15.5 pounds of coal per kilowatt-hour. Contrasted with this it is customary to have preliminary estimates of from 6 to 7 pounds of coal per kilowatt-hour.

Mr. Kimble: In Mr. Hibner's paper the basis of profit is taken at 5 per cent. I do not think any manufacturer will go into business on the basis of a 5 per cent. profit, with the anxiety and worry and chance of failure, when that profit can be obtained by the purchase of any ordinary good bond on the market. I called up a half dozen manufacturers in Brooklyn and asked them what turnover they would consider it necessary to have on $15,000. The lowest man of the six gave a turnover of 15 per cent., on the basis of 5 per cent. for the use of the money, thus giving a net profit of 10 per cent., twice the amount given in the paper. The highest man of the lot gave a turnover of 30 per cent., stating that they turned over their money on an average of ten times a year, with a profit of 3 per cent. each time. Between these two extremes it would be safe to take 15 per cent. as a fair profit.

As to the amount of coal, my experience in plants of this size has shown that about ten pounds of coal per kilowatt-hour is a conservative figure. If that is taken into consideration, together with the increased profit, it will bring the cost per kilowatt-hour to 2.84 cents. If allowance is made for part of the manager's time, this, together with either of the other items, will bring the cost of power, based on Mr. Hibner's figures, to over three cents per kilowatt-hour. Any large public-service corporation would be very glad to supply power to such a plant for three cents per kilowatt-hour on a term contract.

Mr. Ripley: I would like to have it go on record that the Commonwealth Edison Company, of Chicago, to my own certain knowledge, owns and operates three isolated plants in the basements of buildings. If these industrial-plant owners need any further encouragement, as far as depending upon these certain engines is concerned, I will say that the Commonwealth Edison Company depends upon the Ideal engine and upon the Corliss engine, as well as high-speed engines, and I cannot see but that the owners of industrial plants can likewise depend on similar apparatus designed by the same people.

Mr. Fowler: When I received the notice of this meeting tonight it struck me that we were coming here to discuss a problem that was about as easily solved as it would be to discuss the size of a piece of chalk the length of a piece of string. It is a very easy thing to sit down and tell what a plant should do, but it is almost impossible to sit down in advance and tell what it actually will do. It is not difficult to go into a plant and make an analysis of what they are doing and get the figures, but to sit down in cold blood in an office and figure out what it is doing, with all the variables that must be taken into account, is almost an absolute impossibility.

Mr. Parker: I want to clear the ground ethically. Mr. Moses refers to the paper I offered as being characterized by central-station animus. I tried to keep it from that as much as possible. It is manifest that a central-station man would be decidedly idiotic if he attempted to exaggerate the claims at all in favor of himself. I answer that statement by the obvious statement that the only thing a central-station man can offer to do is to make his claims as reasonable as possible. Mr. Moses misunderstood the statement of the insurance charge. Insurance is not claimed to be 3 per cent.—taxes and insurance are said to be 3 per cent., and that would cover casualty insurance on both patrons and employees.

The rental value of the space is, I believe, absolutely right. The proprietor of the store acknowledged the figures used in the table as being right. The basement of a department store handles five-, ten-, twenty-five and thirty-cent articles, which sell with a tremendous margin of profit, and in tremendous volume. That is good rental space in a department store. The figures are given as representative of what obtained in the specific plant in question. I do not mean that the rental value for power-plant sites given in this table would apply to every type of building necessarily. The actual cost figures given are unquestionably large, but these prices were actually paid by responsible manufacturers for the plant delivered in place ready to operate. The figures for the engines cover the holding-down bolts, putting the engine together, limbering up and getting ready to turn over, and as to the latitude of the figures elsewhere, the point is made that synthetic plant costs are different from form quotations, which a man will make good on. Form quotations are 50 to 75 per cent. higher than the synthetical plant cost.

I cannot too heartily indorse what has been said in regard to the pernicious practice of retaining engineering service in connection with industrial-power work. Having a man work on salary for a public-service enterprise, or having him work on commission, is rather objectionable, because I know, personally, that with the best motives in the world a man finds it very hard not to be biased by his own personal interest. I believe that the salvation of such a situation will come in this way—that the industrial engineer employed by a public-utility company will recognize that the best interests of his company consist not in taking all the business there is in sight, but in taking only that business which he, as an independent consulting engineer, would recommend a client to take. The central-station engineer doing that will get away from the prejudicial results of his personal bias. The man in private practice should not work on commission; he should work for a retainer or for a fixed sum, and that sum should be amply large. I think that most of the industrial-engineering work today is being done for utterly miserable fees, and the result is that the pressure is very great on a man to sacrifice his highest ethical standard or to allow his judgment to be governed by his personal interest in the way of trying to bolster up his commissions.

The written discussion, which was not given at the meeting, will follow in a later issue.

Blowoff Tank Accident

The bottom of a cast-steel blowoff tank was blown out, on February 21, at the Pittsfield Y. M. C. A. building and the engineer was badly scalded. The plant consists of two 54-inch boilers, two turbines and auxiliaries and apparatus for filtering the swimming-pool water and lighting and heating the building. One boiler was being blown down under 125 pounds pressure. The 2-inch blowoff pipes from the boilers united in the 2½-inch line which led to a 36x36-inch tank. The 2½-inch sewer outlet was sealed with water and there was a 2-inch vent to atmosphere as usual. The flat bottom of the tank apparently dropped out under pressure and the tank lifted, bending a steel I-beam above it and breaking several 3-inch water pipes. It is supposed that the bottom of the tank was filled with scale and so prevented the sewer outlet from working.

Coal Land Frauds

It is reported in the daily press that the Government investigation into alleged Alaskan coal-land frauds involving approximatelly 48,000 acres of land, valued at more than $50,000,000, has resulted in the issuance on March 6 of an indictment by the Federal grand jury at Detroit, charging seven individuals with conspiracy against the United States.

The contention of the Government is that the defendants conspired to induce between 200 and 300 individuals to become stockholders in the Michigan-Alaska Company by making fraudulent and fictitious locations of certain Alaska coal lands," thereby violating the land-entry laws of 1910, which made it illegal for more than four persons to form a company for locating Alaska coal lands and taking out patents on more than 640 acres. It is alleged that several stockholders or coal-land claimants were led to believe that they were locating the lands for their exclusive use, "but in truth and in fact for the use and benefit of the seven defendants and the Michigan-Alaska Development Company."

The Michigan-Alaska Development Company was organized under the laws of Arizona. W. W. McAlpine is the president. The coal lands involved are situated at Juneau, Alaska, and several contiguous tracts in the vicinity of Homer, upon the westerly end of Kenai peninsula, bordering upon Cook inlet. The claims are said to have been located by about two hundred Detroit and Michigan residents and a hundred other claimants from New York, Chicago, San Francisco, Seattle and other points.

Donkey Engine Boiler Explodes and Kills Seven

On March 4, the boiler of a donkey engine in the logging yard at the river mill of the Portland Railway, Light and Power Company near Estacada, Ore., exploded and caused the instant death of five men, the injury and subsequent death of two others and the serious injury of still another. The boiler rose 500 feet in the air and fell to the ground a quarter of a mile away. For several days, it is said, the safety valve on the boiler had not been working satisfactorily and experiments had been carried on with a number of improvised devices. On the very morning of the explosion one of the contractors had started for Portland with the express intention of providing a new valve, but he had only gone a few miles when reports of the explosion caused him to retrace his steps.

Wisconsin Engine Company Makes Extensive Additions

The Wisconsin Engine Company, of Corliss, Wis., which is about twenty miles from Milwaukee, has just made a considerable addition to its equipment and working capital. Hitherto the company has been controlled by strong Pittsburg interests, but on account of its location it became desirable to bring Milwaukee capital into the company, and two of the new directorate are prominent business men of the latter city. E. T. Adams has been made president of the company.

Heretofore the principal business of the Wisconsin Engine Company has been the manufacture of Wisconsin Corliss engines. It is the purpose of the new organization to foster and to build up the existing Corliss-engine business, but the addition of new capital and new equipment is chiefly for the purpose of enabling the company to enter extensively into new lines of manufacture. Chief of these will be the Adams gas engines, which will be manufactured in sizes from 200 to 8000 horsepower in a single unit. It is stated that the company has already secured orders for upward of 10,000 horsepower of the Adams engines, and increased shop facilities and new equipments are now being installed to permit the rapid and economical production of this additional line of manufacture.

E. T. Adams, the new president of the company, has been identified with the manufacture of heavy machinery for many years, dating back to the early days of the Edward P. Ellis Company, of Milwaukee, where, under Mr. Reynolds, he was connected with the design and installation of most of the important power and pumping installations in the country. Mr. Adams was a pioneer in the heavy gas-engine business in the United States, being identified with the first large gas engine put out by the Westinghouse company and later the manager and chief engineer of the gas- and mill-engine department of the Allis-Chalmers Company. It is probable that considerably over half of the large gas engines now in operation in this country are of Mr. Adams' design, including the Allis-Chalmers engines in the plant of the Steel Corporation at Gary, Ind.

Second Monthly Meeting of Engineers' Institute

The second regular monthly meeting of the proposed Institute of Operating Engineers was held at the Engineering Societies building, New York City, on March 9. About 150 members and friends of the temporary organization were present.

Prof. W. D. Ennis, of the Brooklyn Polytechnic Institute, delivered a paper entitled "The Commercial Aspect of the Work of the Operating Engineer." An abstract of this paper will be published in a following issue, together with an abstract of the discussion which was offered by Willis Lawrence.

Cast Iron Elbow Bursts

On February 27, a cast-iron elbow in the blowoff pipe of a 135-horsepower horizontal tubular boiler in the plant of the La Porte Electric Company burst while the boiler was being fired up. A pressure of 40 pounds was on the boiler at the time. The boiler was shaken in the setting and the brickwork considerably damaged. Had the accident occurred after the boiler had been cut in the battery with the six other boilers at 125 pounds, there is not much doubt that the accident would have been more serious. The boiler had been washed out and inspected on February 10 and had not been used since that time. This is only one more reason why cast-iron fittings should not be used.

On February 17, Governor Dix sent a special message to the legislature recommending that a resolution be passed urging upon Congress careful consideration of two bills now before that body relating to the use of hydraulic power of the Niagara river and confirming a legislative grant for hydraulic development of the St. Lawrence river by the Long Sault Development Company. These measures are known respectively as the Alexander and Oliver bills.

A bill has been introduced in the Ohio State legislature providing for the formation of a State department of boiler inspection. A chief inspector at $2400 and six deputies at $1800 per annum are authorized. This department is to have supervision of all stationary boilers except those used for heating plants and very small boilers. An inspection fee of $5 is to be charged.

PERSONAL

C. W. Van Blarcom, New York representative of Noonan Brothers, of Troy, for the past fifteen years, died suddenly on March 7. Mr. Van Blarcom was 40 years of age and leaves a widow.

Moses Nelson Baker, editor of *Engineering News*, was the speaker of the evening at the charter-day exercises of the fifteenth anniversary of the Thomas S. Clarkson Memorial School of Technology, held on March 17. The topic chosen by Mr. Baker was "The Engineer and Social Service."

George Q. Palmer, formerly vice-president, has been made president of the Alberger Condenser Company and the Alberger Pump Company. Mr. Palmer is succeeded as vice-president in the Alberger Condenser Company by D. H. Chester, and in the Alberger Pump Company by W. S. Doran.

On March 18, John W. Lane, formerly an engineer of Providence and for some time editor of the *National Engineer*, the official organ of the National Association of Stationary Engineers, was tendered a reception by Rhode Island No. 1. He was greeted by a large number of friends from Rhode Island and Massachusetts.

NEW PUBLICATIONS

A bulletin describing the Moore patent automatic fuel-oil regulating system and entitled "Unnecessary Losses in Firing Fuel Oil and an Automatic System for Eliminating Them," is being issued by Charles C. Moore & Co. It can be obtained upon request from the offices of the company at San Francisco, Los Angeles, Seattle, Portland and Salt Lake City.

The system controls the supply of oil to all burners, the supply of the atomizing agent to all burners, and the supply of air for combustion, for any number of boilers, all from a central point. The results claimed are: Increased boiler-plant efficiency, the practical prevention of smoke, and the decrease in the maintenance cost of boiler equipment, due to a more uniform manner of firing. Such a system was first installed at the Redondo plant of the Pacific Light and Power Company in 1907. Here the regulating system is used to control the entire plant of 16 boilers of 600 horsepower each, and the increased economy due to the uniform rate of firing is very evident.

Qualitative Chemical Analysis. By J. I. D. Hinds. Published by the Chemical Publishing Company, Easton, Penn., 1910. Cloth; 285 pages, 5½x9 inches. Price, $2.

A textbook treating the subject of qualitative analysis from the standpoint of ions, solubilities and mass action. By this method it is hoped that the student will be better prepared to take up the study of physical chemistry. The classification of the kations is similar to that used in other textbooks, but a systematic method of separating and identifying the anions is given, which should prove helpful to the beginner. There is a complete list of the reagents and the solutions, together with the methods of preparing them to a given concentration. Among the useful tables is one giving the solubility in water of most of the substances ordinarily met with as precipitates in the course of analysis.

BOOKS RECEIVED

Steam Turbines. By Rankin Kennedy. The Macmillan Company, New York. Cloth; 101 pages, 5½x8½ inches; 62 illustrations. Indexed.

Motion Study. By Frank B. Gilbreth. D. Van Nostrand Company, New York. Cloth; 116 pages, 5x7¾ inches; 44 illustrations; indexed. Price, $2.

Industrial Plants. By Charles Day. The Engineering Magazine, New York. Cloth; 294 pages, 5x7½ inches; 48 illustrations; indexed. Price, $3.

Water Turbine Plant. By Jens Orten-Böving. Raithby, Lawrence & Co., Ltd., London, W. C., England. Cloth; 197 pages, 8½x10¾ inches; 216 illustrations.

Mathematics for the Practical Man. By George Howe. D. Van Nostrand Company, New York. Cloth; 143 pages, 4½x7½ inches; 42 illustrations; tables; indexed. Price, $1.25.

Elements of Graphic Statics. By William L. Cathcart and J. Irvin Chaffee. D. Van Nostrand Company, New York. Cloth; 304 pages, 5½x9 inches; 159 illustrations; indexed. Price, $2.

NEW INVENTIONS

Printed copies of patents are furnished by the Patent Office at 5c. each. Address the Commissioner of Patents, Washington, D. C.

PRIME MOVERS

INTERNAL COMBUSTION MOTOR. Karl Fabel, Hamburg, Germany. 985,793.

ROTARY ENGINE. William M. Hoffman, Buffalo, N. Y., assignor to the Hoffman Patents, Ltd., a Corporation of Canada. 985,804.

ELASTIC-FLUID TURBINE. Charles G. Curtis, New York, N. Y., assignor, by mesne assignments, to General Electric Company, a Corporation of New York. 985,885.

ROTARY INTERNAL COMBUSTION ENGINE. Orsemus L. R. Jones, Detroit, Mich. 985,907.

EXPLOSIVE ENGINE. Mathew B. Morgan, Lansing, Mich., assignor of one-half to Oscar M. Springer, Detroit, Mich. 985,920.

ROTARY ENGINE. Hubert I. Call, Spokane, Wash., assignor to the Hercules Rotary Engine Company, Ltd., Wetaskiwin, Canada, a Corporation. 985,974.

ELASTIC-FLUID TURBINE. Charles G. Curtis, New York, N. Y., assignor, by mesne assignments, to General Electric Company, a Corporation of New York. 985,982.

STEAM ENGINE. Christopher F. Laufer, Richmond, Cal. 986,016.

ROTARY ENGINE. Frank Wyle, St. Louis, Mo. 986,116.

TURBINE. Henry F. Schmidt, Pittsburg, Penn., assignor to the Westinghouse Machine Company, a Corporation of Pennsylvania. 986,317.

INTERNAL COMBUSTION ENGINE. Andrew Betts Brown and William Albert Hickman, London, England; said Brown assignor to said Hickman. 986,353.

ELASTIC-FLUID TURBINE. Charles G. Curtis, New York, N. Y., assignor, by mesne assignments, to General Electric Company, a Corporation of New York. 986,368.

ELASTIC-FLUID TURBINE. Charles G. Curtis, New York, N. Y., assignor, by mesne assignments, to General Electric Company, a Corporation of New York. 986,368.

BOILERS, FURNACES AND GAS PRODUCERS

FURNACE. Roy E. Ashley, Muskegon, Mich. 985,878.

OIL BURNER. Adolf Klein, Vienna, Austria-Hungary. 986,067.

WATER-TUBE BOILER. Minott W. Sewall, Roselle, N. J., assignor to the Babcock & Wilcox Company, Bayonne, N. J., a Corporation of New Jersey. 986,089.

STEAM BOILER. Minott W. Sewall, Roselle, N. J., assignor to the Babcock & Wilcox Company, Bayonne, N. J., a Corporation of New Jersey. 986,090.

POWER PLANT AUXILIARIES AND APPLIANCES

FEED-WATER HEATER. Charles Caille, Le Perreux, France. 985,778.

FEED-WATER HEATER FOR PREVENTING PITTING. John C. Parker, Philadelphia, Penn. 985,834.

BALANCED VALVE. Baxter M. Aslakson, Salem, Ohio. 985,879.

GOVERNOR. Ernest L. Nance, St. Louis, Mo. 985,022.

REDUCING VALVE. John Graham and Archibald Graham, Jr., Glasgow, and David Auld Graham, Rutherglen, Scotland. 986,165.

WATER-GLASS GUARD. George Moser, Minneapolis, Minn. 986,199.

ASH DISCHARGER. Frederick P. Palen, Newport News, and William Burlingham, Hampton, Va. 986,208.

ROTARY VALVE. Charles H. Harkins, Derby, Kan. 986,284.

CONDENSER FEED LUBRICATOR. Chas. Cheers Wakefield, London, England. 986,330.

WATER TRAP. Joseph Joy, Donora, Penn. 986,394.

ELECTRICAL INVENTIONS AND APPLICATIONS

ELECTRICAL TERMINAL CONNECTOR. Ray H. Manson, Elyria, Ohio, assignor to the Dean Electric Company, Elyria, Ohio, a Corporation of Ohio. 985,821.

INDUCTION COIL. Richard Varley, Englewood, N. J., assignor to the Autocoil Company, a Corporation of New Jersey. 986,033.

ELECTRIC BATTERY. Carl Jaeger, Seattle, Wash. 986,064.

SYSTEM OF MOTOR CONTROL. William Siebenmorgen and Samuel H. Keefer, Plainfield, N. J., assignors to Niles-Bement-Pond Company, Jersey City, N. J., a Corporation of New Jersey. 986,091.

INSULATING CAP. James C. Phelps, Springfield, Mass. 986,213.

ELECTROPLATING MACHINE. Constantine G. Miller, Chicago, Ill., assignor to the Meaker Company, a Corporation of Illinois. 986,303.

THERMAL CIRCUIT CLOSER. Fredrick C. Guptill, Elgin, Ill., assignor of one-half to William F. Lynch, Elgin, Ill. 986,382.

POWER PLANT TOOLS

CHAIN PIPE WRENCH. George Amborn, New York, N. Y., assignor to J. H. Williams & Co., Brooklyn, N. Y., a Corporation of New York. 985,766.

WIRE-TIGHTENING DEVICE. Henry F. Heitmeyer, Friendship, Ind. 986,058.

WRENCH. John C. McLean, Cleveland, Ohio. 986,192.

ENGINEERING SOCIETIES

AMERICAN SOCIETY OF MECHANICAL ENGINEERS

Pres., Col. E. D. Meier; sec., Calvin W. Rice, Engineering Societies building, 29 West 39th St., New York. Monthly meetings in New York City. Spring meeting in Pittsburg, May 30 to June 2.

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS

Pres., Dugald C. Jackson; sec., Ralph W. Pope, 33 W. Thirty-ninth St., New York. Meetings monthly.

NATIONAL ELECTRIC LIGHT ASSOCIATION

Pres., Frank W. Frueauff; sec., T. C. Martin, 31 West Thirty-ninth St., New York. Next meeting in New York City, May 29 to June 2.

AMERICAN SOCIETY OF NAVAL ENGINEERS

Pres., Engineer-in-Chief Hutch I. Cone, U. S. N.; sec. and treas., Lieutenant Commander U. T. Holmes, U. S. N., Bureau of Steam Engineering, Navy Department, Washington, D. C.

AMERICAN BOILER MANUFACTURERS' ASSOCIATION

Pres., E. D. Meier, 11 Broadway, New York; sec., J. D. Farasey, cor. 37th St. and Erie Railroad, Cleveland, O. Next meeting to be held September, 1911, in Boston, Mass.

WESTERN SOCIETY OF ENGINEERS

Pres., O. P. Chamberlain; sec., J. H. Warder, 1735 Monadnock Block, Chicago, Ill. Meeting first Wednesday of each month.

ENGINEERS' SOCIETY OF WESTERN PENNSYLVANIA

Pres., Walter Riddle; sec., E. K. Hiles, Oliver building, Pittsburg, Penn. Meetings 1st and 3d Tuesdays.

AMERICAN SOCIETY OF HEATING AND VENTILATING ENGINEERS

Pres., R. P. Bolton; sec., W. W. Macon, 29 West Thirty-ninth street, New York City.

NATIONAL ASSOCIATION OF STATIONARY ENGINEERS

Pres., Carl S. Pearse, Denver, Colo.; sec., F. W. Raven, 325 Dearborn street, Chicago, Ill. Next convention, Cincinnati, Ohio, September 12-15, 1911.

AMERICAN ORDER OF STEAM ENGINEERS

Supr. Chief Engr., Frederick Markoe, Philadelphia, Pa.; Supr. Cor. Engr., William S. Wetzler, 753 N. Forty-fourth St., Philadelphia, Pa. Next meeting at Philadelphia, June 5-10, 1911.

NATIONAL MARINE ENGINEERS BENEFICIAL ASSOCIATIONS

Pres., William F. Yates, New York, N. Y.; sec., George A. Grubb, 1040 Dakin street, Chicago, Ill. Next meeting at Detroit, Mich., January 15-19, 1912.

INTERNAL COMBUSTION ENGINEERS' ASSOCIATION

Pres., Arthur J. Frith; sec., Charles Kratsch, 416 W. Indiana St., Chicago. Meetings the second Friday in each month at Fraternity Halls, Chicago.

UNIVERSAL CRAFTSMEN COUNCIL OF ENGINEERS

Grand Worthy Chief, John Cope; sec., J. U. Bunce, Hotel Statler, Buffalo, N. Y. Next annual meeting in Philadelphia, Penn., week commencing Monday, August 7, 1911.

OHIO SOCIETY OF MECHANICAL ELECTRICAL AND STEAM ENGINEERS

Pres., O. F. Rabbe; acting sec., Charles P. Crowe, Ohio State University, Columbus, Ohio. Next meeting, Youngstown, Ohio, May 18 and 19, 1911.

INTERNATIONAL MASTER BOILER MAKERS' ASSOCIATION

Pres., A. N. Lucas; sec., Harry D. Vaught, 95 Liberty street, New York. Next meeting at Omaha, Neb., May 23-26, 1911.

INTERNATIONAL UNION OF STEAM ENGINEERS

Pres., Matt. Comerford; sec., J. G. Hannahan, Chicago, Ill. Next meeting at St. Paul, Minn., September, 1911.

NATIONAL DISTRICT HEATING ASSOCIATION

Pres., G. W. Wright, Baltimore, Md.; sec. and treas., D. L. Gaskill, Greenville, O.

POWER

NEW YORK, MARCH 28, 1911

"THERE ain't no chance these days for a fellow to get along" is the sentiment often expressed with the degree of grammatical accuracy quoted. And for the grown man who talks that way, usually there "ain't." But, truth to tell, these are wonderful times, and there are more opportunities than ever just going abegging for lack of men to see and make use of them.

If you cannot readily believe this, we half suspect that you are one of those who sing the refrain quoted in the opening sentence. Figure over the matter for a minute.

What were the engineer's opportunities 50 years ago? Pretty small and few in a hill, weren't they? Ignorance was rife; means for self-education were totally lacking; jobs were small; the engineer had absolutely no standing, and, worst of all, there was no incentive for him to improve himself even if he had the inclination. His life was a dull, dirty, colorless monotony.

Today, there is hardly any limit to the progress that the engineer can make, the field is so broad. There are positions for men of every caliber from the two-dollar to the twenty-dollar-a-day man. There are means easily within the reach of all of fitting oneself for higher grade work; these are the correspondence schools, the engineers' periodicals, the countless good books and the associations—all can be made sure stepping stones by the man who *will*.

No one can "wish" himself well. A man must attain good health, once he has lost it, by careful diet, proper exercise and rest. So also with advancement; "wishing" that you had the other fellow's "cinch" is poor "nourishment." To reap the reward of better pay requires conscientious, hard work in increasing your ability and experience.

In steam engineering today, knowledge means ability. Professor Ennis made this quite clear by his lecture to the proposed Institute of Operating Engineers on March 9. The lecture is reproduced on page 485 herein. Many engineers have already found it to be true, and its truth is dawning on an ever increasing number as time goes on.

The men for the big jobs of the future are the men who are in training for them now. If a man is unprepared when his big chance comes, it is usually too late to start.

Knowledge will not do anyone harm, even if it is never used. But how valuable it is when there is occasion to apply it!

There is great need for educated, capable men in the steam-engineering field, and that need is constantly growing. There are opportunities, open to all, to acquire education of the kind needed. The wise ones are making use of them.

If you are not thoroughly thankful that you are alive and well and kickin' on this day of grace and exceptional opportunity, it probably is because you need to see a doctor and don't know it.

Power Plant at North Carolina College

By Francis J. Thompson

A small central plant containing a De Laval turbine unit and an engine-driven unit, supplying light and power to the various buildings and heating them with the exhaust steam.

The various buildings of the North Carolina College of Agriculture and Mechanic Arts are supplied with heat, light and power from a central service station situated on the campus. The plant, although having a capacity of only 200 kilowatts, contains many interesting features for one of its size.

Steam is furnished by two 200-horsepower Atlas boilers and two 75-horsepower Babcock & Wilcox boilers (see Fig. 1), working under a normal pressure of about 125 pounds, the pressure being controlled by a damper regulator. Natural draft of about 0.5 is furnished by a 100-foot radial brick stack. A spur track from the Seaboard Air Line railroad runs in front of the boiler room and coal is dumped from the cars into concrete pockets having a capacity of 300 tons. These are in front of the boilers and may be shut off from the boiler room by corrugated-iron drop curtains.

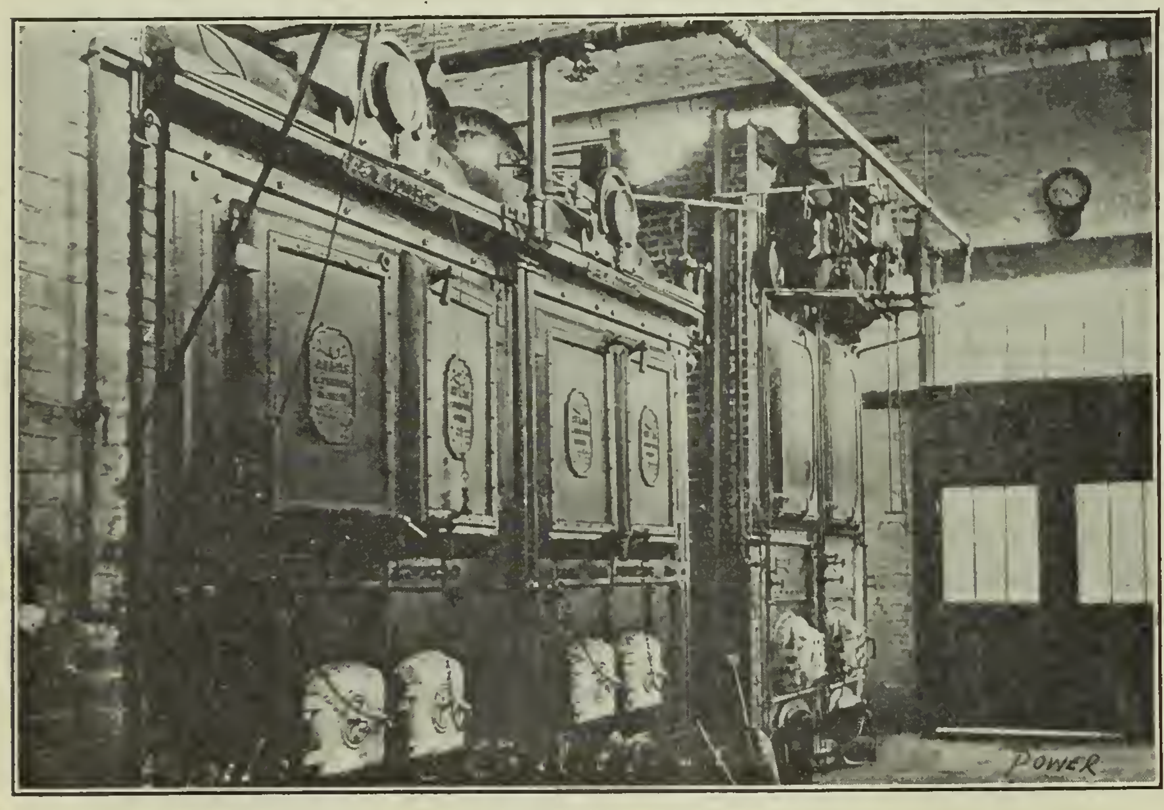

Fig. 1. Boilers

Next to the boiler room, and separated from it by a brick fire wall, is the pump room. This is several feet lower than the engine room and, on one side, is open to the latter, as may be seen from Fig. 2. A 10-inch main leads from the boilers to a header running the length of the pump room and from this header long-radius bends branch off to the steam receivers placed above the throttles of the engines. Van Stone joints are used on all high-pressure lines and a notable feature of the station piping is its accessibility.

There are two main generating units: one consisting of a 13x12-inch Skinner engine direct connected to a three-phase 60-cycle generator of 75 kilovolt-amperes capacity; the other a 150-horsepower single-stage DeLaval turbine running at 12,000 revolutions per minute and geared through 10 to 1 reduction gears, to two three-phase 60-cycle generators. Owing to the high rotative speed of a single-stage turbine the shaft must be made small in diameter, and when transmitting horsepowers of from 50 to 300 it is the practice to supply two generators for the purpose of balancing the side thrust on the turbine shaft. Mounted on the shaft of one of these generators is an exciter. Two other exciter units are provided: one a motor-generator set, and the other a direct-current generator driven by a 5x5-inch vertical engine. Either of these two exciters may be used to supply excitation to the fields of either of the main generators.

A diagram of the switchboard connections is given in Fig. 3. From this it will be seen that common practice has been departed from by supplying an ammeter for each phase. A water rheostat is also furnished for supplying the maximum load when making experimental tests in connection with the courses of instruction. The normal load comprises the motors in the machine shop, forge shop, laboratories and textile mill in addition to about 500 incandescent lamps.

The exhaust steam from the main units and auxiliaries is used to heat the various buildings on the campus through the Warren Webster system, operating at about 5 inches vacuum. This supplies approximately 40,000 square feet of radiation and the condensation is handled by two vacuum pumps delivering into a receiving tank from which the hot water flows by gravity to a Cochrane feed-water heater. Provision is made for supplying live steam to some of the buildings when the supply of exhaust steam is inadequate.

Smoke Abatement in Glasgow and Liverpool

There are many who believe that the wisest and most hopeful method of attacking the black-smoke problem is by the education of those who have produced it, and that the further education of manufacturers and factory owners, of boiler engineers and firemen and, last but not least, of the ordinary householder is required before any real and permanent progress can be made in suppressing the black-smoke evil.

Those of our readers who accept this view will be pleased to learn that Glasgow and Liverpool have this winter followed the lead set by London three years ago, and have instituted courses of lectures for the general public and for boiler engineers and firemen upon smoke abatement.

At Glasgow the lead has been taken by the newly formed local branch of the Glasgow and West of Scotland Smoke Abatement League, and it is interesting to note that the municipality has allied itself with this body in providing two really useful and attractive courses of evening lectures; the one series intended for working boiler engineers and firemen, and the other for the general public.

The series of lectures for firemen consists of five similar courses, each of twelve lectures, delivered by the Glasgow smoke inspectors, in different centers of the working-class portions of the city, a fee of $1.25 being charged for the course. The education authorities have granted the use of suitably situated elementary schools for these lectures, and it is stated that 186 firemen and engineers have registered their names as students at one or other of the various centers, and are now attending the courses. In the majority of cases the employers have paid the fee and have urged the men to attend regularly.

The series of lectures for the general public in Glasgow is free, and is made attractive by the aid of lime-light views and experiments. The lectures are being delivered in the large hall of the technical school by several gentlemen connected with the health and medical departments of the university and city, and cover such subjects as: "The Black Smoke Problem," "The Necessity of Pure Air," "The Chemistry of Combustion," "How to Fire Steam Boilers without Smoke," etc.

In Liverpool, the school of hygiene department of the university, and the sanitary-science instruction committee of the corporation have combined to arrange a course of ten evening lectures at the school of hygiene on "The Smoke Nuisance and Its Abatement."

The course is intended primarily for working engineers and firemen but all interested in the general subject of smoke abatement are invited to attend, and, as at Glasgow, a nominal fee of $1.25 is being charged for the course.

Professor Watkinson, of the Walker Engineering Laboratories, Doctor Hawksley, of the medical offices of the health department, J. B. C. Kershaw, of the West Lancashire Laboratory, Waterloo, and Mr. McKelvy, the city smoke inspector, are delivering the various lectures of the course, which commenced on January 27 and has been continued on Friday evenings through February. It is hoped that the series now started will be the forerunner of similar lecture courses every winter in the leading seaport of the north of England.

The municipalities of Manchester, Sheffield, Birmingham, Leeds and other large inland manufacturing cities, with atmospheres certainly capable of improvement, might note the progressive action of the two northern seaports and might make arrangements for instituting similar courses of lectures in their own cities next winter.

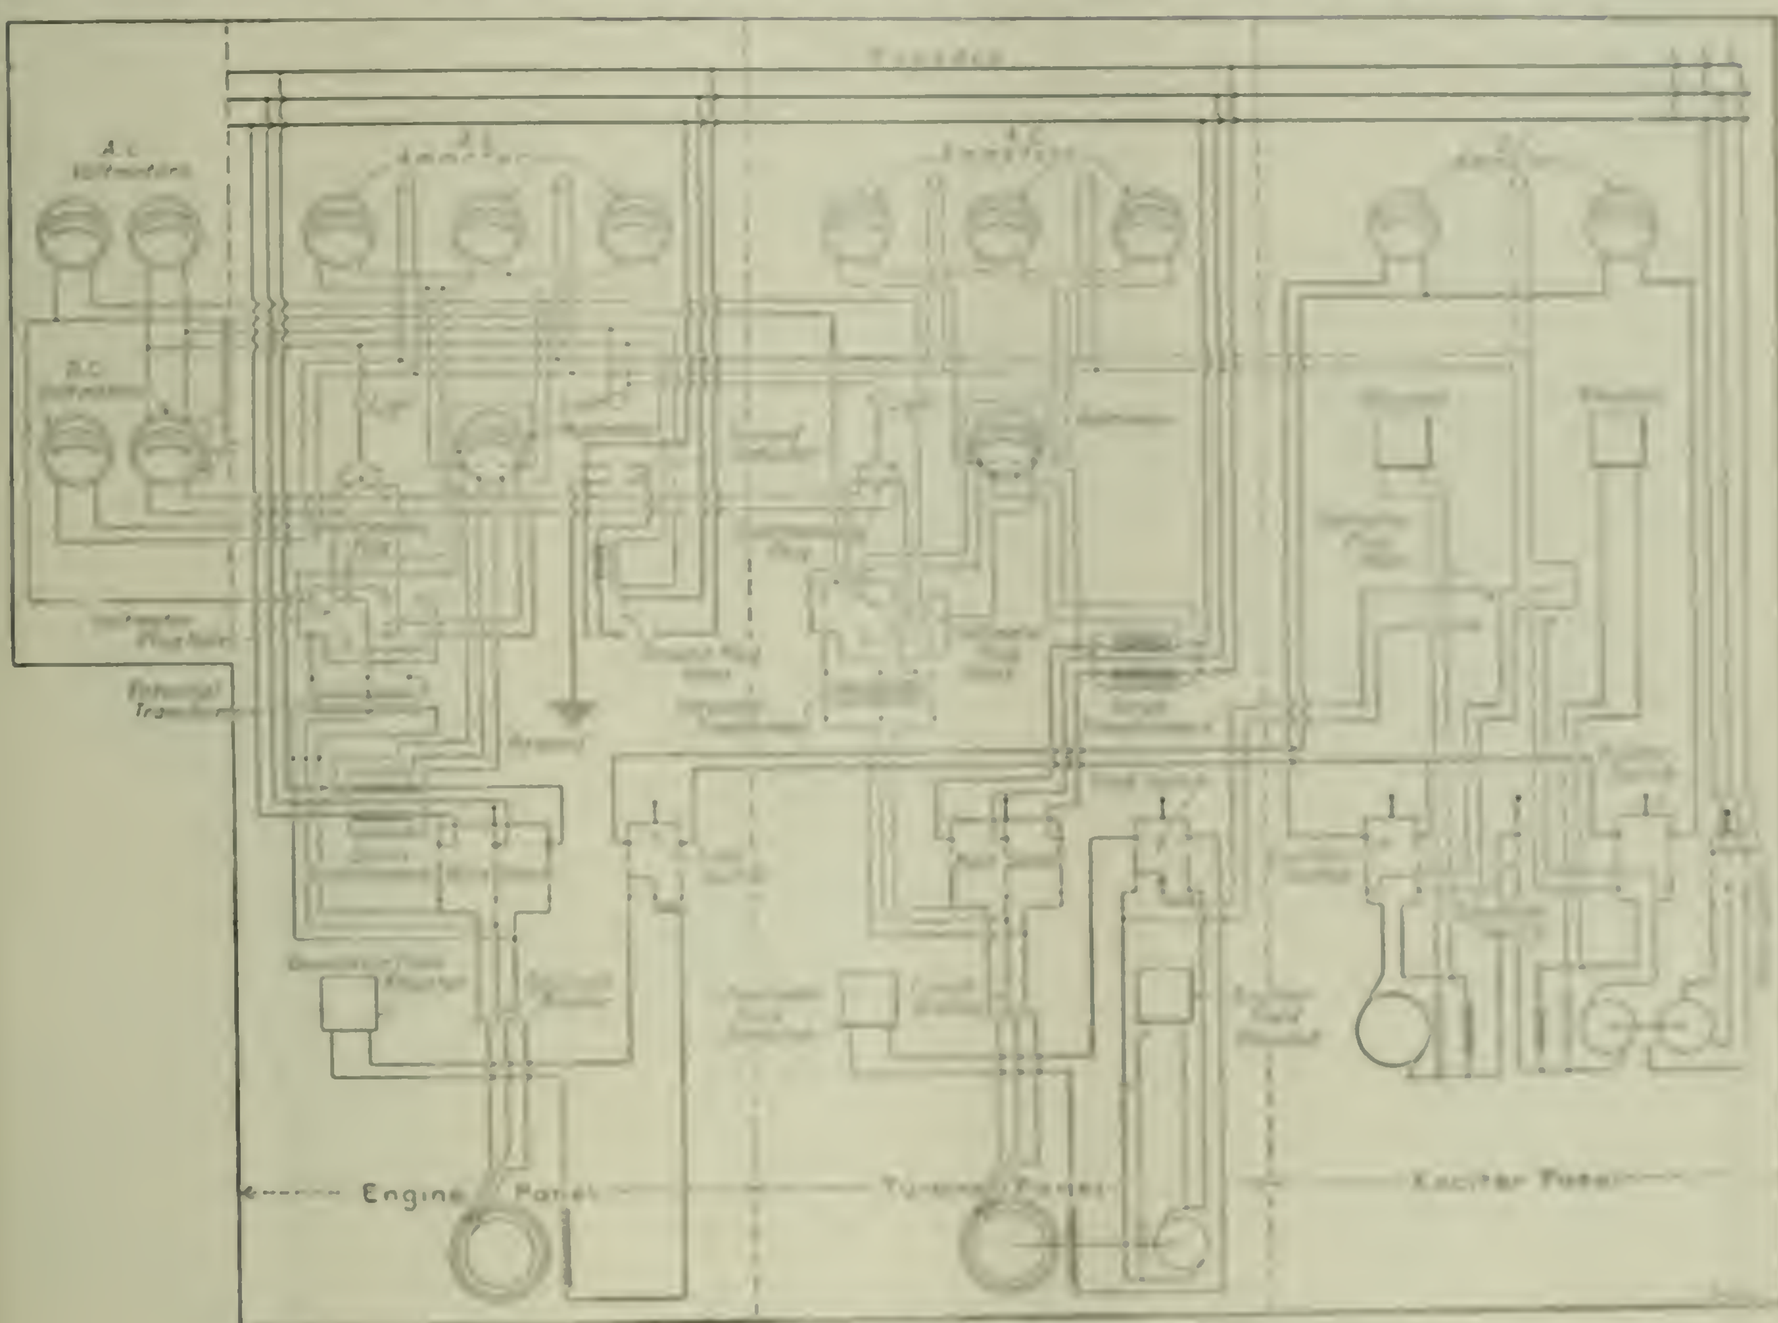

FIG. 3. DIAGRAM OF WIRING CONNECTIONS

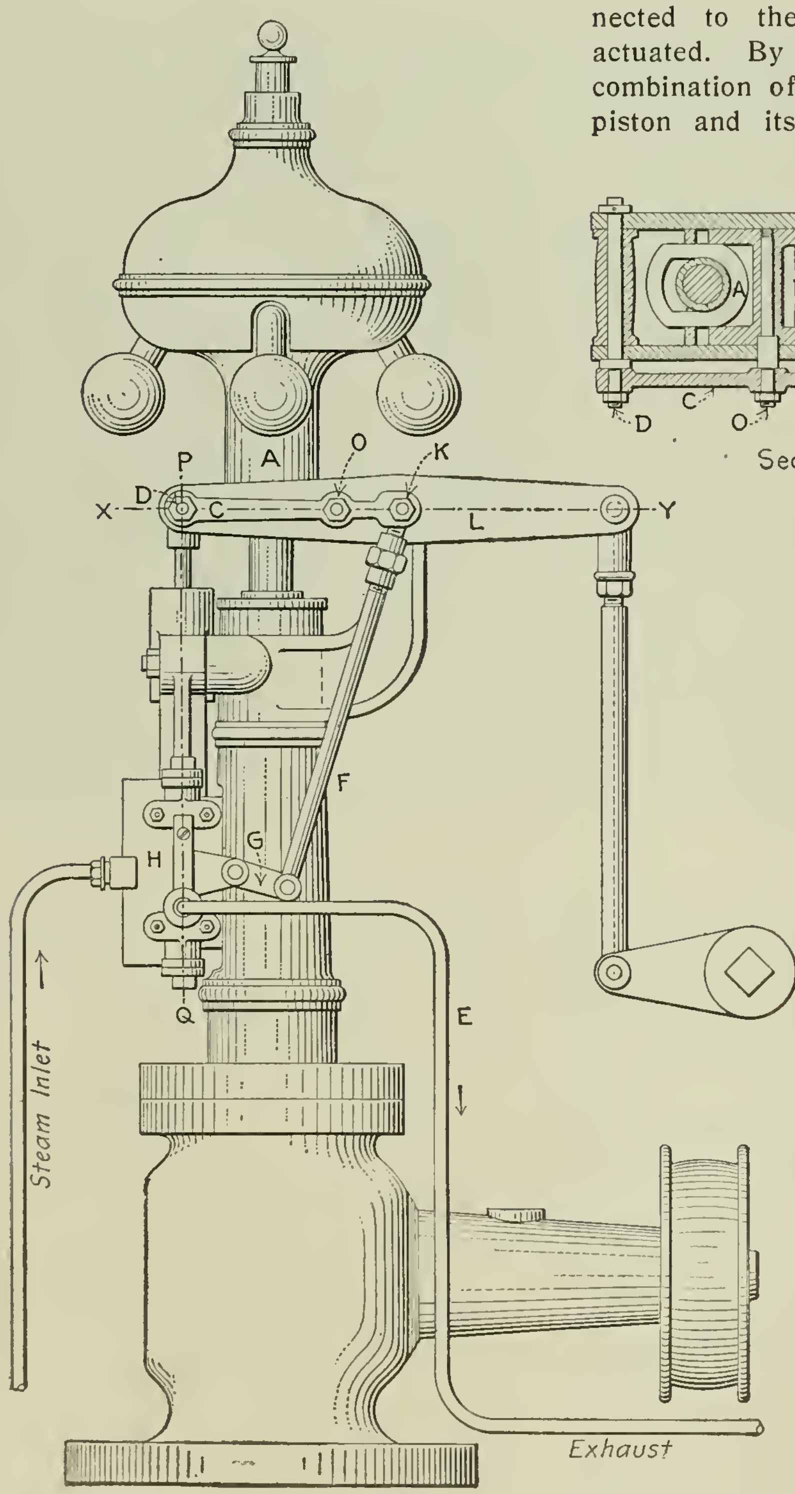
Methods of Governing Steam Engines

By John Davidson

Operation of governors controlled through relay motors, regulators or supplementary governors, safety trip gears, and crank shaft governors, representing standard English makes.

Governors Controlled through Relay Motors

Where the governor of a steam engine is required to actuate a heavy valve gear, it is difficult to obtain sufficient power, combined with sensitiveness in the governor itself, unless it be made of massive proportions; even then the friction and wear of the governor renders it an unsatisfactory piece of mechanism. Such valve gears as the Meyer and Ryder are included in this class. The gears themselves are positive, and are suitable for engines running at all speeds, but considerable force is required to move the gear to suit the variation in load.



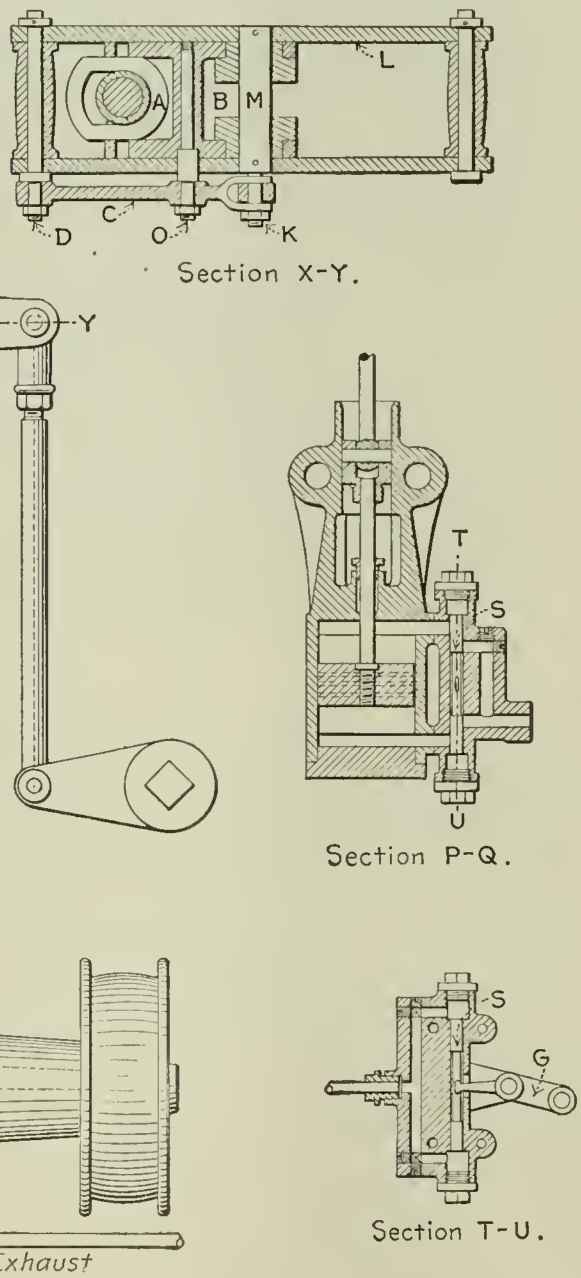


Fig. 30. Lude Relay Gear

Among the many appliances used in connection with governors as a relay gear, that invented by Lude many years ago and illustrated in Fig. 30, is perhaps the simplest in general use. With this arrangement, the only work done by the governor proper consists in controlling the piston valve of a miniature steam engine, the piston rod of which is connected to the expansion gear to be actuated. By the use of an ingenious combination of levers the motion of the piston and its connections is made to correspond with that of the governor, and, even with a very slight variation in load, the piston moves over a corresponding distance under the full steam pressure.

Referring to Fig. 30, the motion of the governor sleeve *A* is transmitted by means of the double lever *B*, to the lever *C* which is pivoted at *D* to the main lever *L*. The short arm of the lever *C* is connected by means of the rod *F* to a small lever *G* which actuates a small piston valve arranged in the casing *H* at one side of the steam cylinder. This valve controls the steam admission and exhaust ports of both ends of the cylinder. The arrangement is such that both sides of the piston are connected with the exhaust pipe when the valve occupies its central position, while a small movement of the valve in either direction will admit steam at one end of the cylinder. The resulting motion of the main piston rod and lever *L*, with its connections, causes the piston valve to return to its central position so as to again open both sides of the piston to the exhaust pipe, when the lever *L* has been turned through an angle corresponding to the movement of the governor sleeve. Normally, the center of the joint *K* corresponds with the turning axis *M* of the lever *L*. When the governor sleeve is moved the lever *C* is caused to turn about the center *D*,

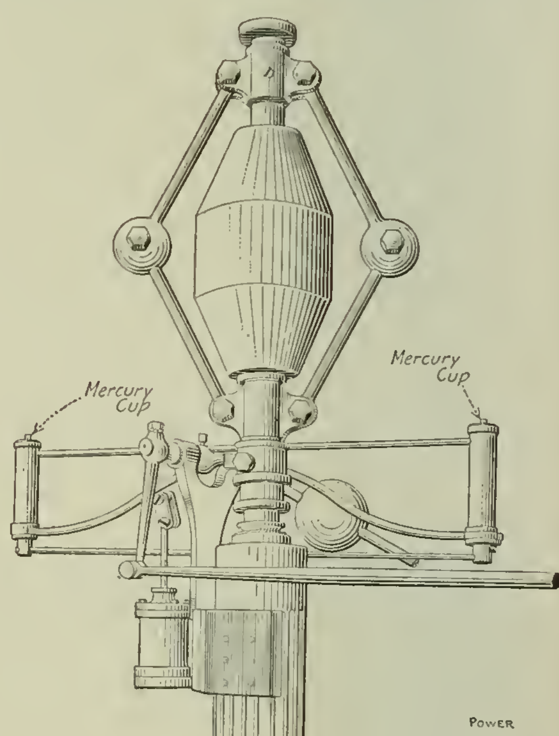

Fig. 31. Higginson Regulator

thereby raising or lowering the center *K*. The resulting movement of the lever *L* causes the lever *C* to turn about the center *O* and the center *K* is consequently returned into line with the axis *M* of the main lever *L*. As the steam flows at a high velocity the movement of the lever *L* is practically simultaneous with the movement of the governor sleeve.

Regulators or Supplementary Governors

With the ordinary type of governor it is impossible to keep the speed of the engine constant if the load or the steam pressure varies, because the governor cannot effect any change in the valve gear or pressure of the steam admitted to the engine until a change in speed has actually taken place. To obviate this defect, supplementary governors or regulators are used.

There are many designs of regulators in general use, more particularly in connection with engines driving cotton mills, etc., where it is necessary to maintain a constant speed. One of the oldest and perhaps most largely used of these is the Higginson regulator, illustrated in Fig. 31, which automatically balances the governor in whatever position it assumes to correspond to a variation in the load or steam pressure. This is effected by altering the level of mercury contained in the two cylinders at the ends of the arms which form the regulator, these being originally attached to the governor rocking ring. The mercury cups are connected by a pipe, and the weight of mercury at each end of the regulator depends upon its angular position, the cylinders being accurately proportioned to the governor. This regulator answers exceedingly well for mills where the

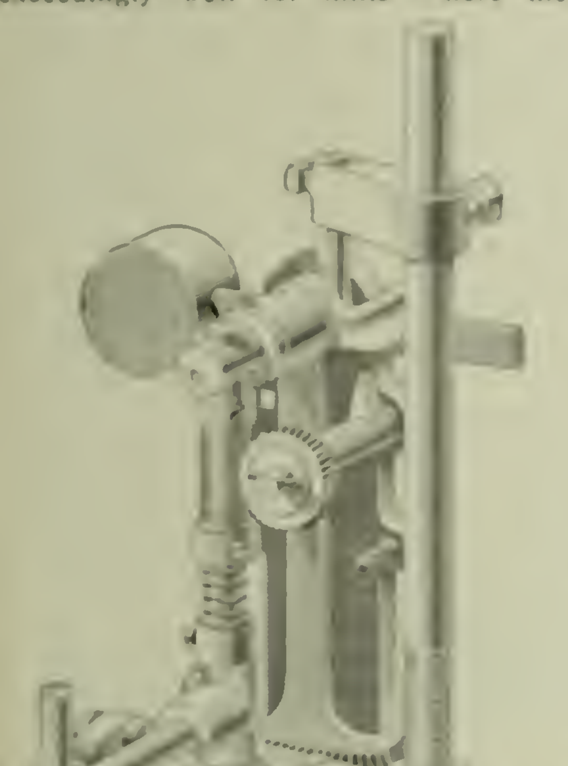

FIG. 32. REGULATOR MADE BY BRITISH METALLIC PACKING COMPANY

variation in load or steam pressure does not take place rapidly.

Another regulator, made by the British Metallic Packing Company, is shown in Fig. 32. The two parts of the governor rod, one with a right-hand thread and the other with a left-hand thread, are joined together by a sleeve. If this sleeve is revolved, the governor rod is lengthened or shortened according to the direction in which it is turned, and alters the valve motion, to give more or less steam to the engine as required. The governor-rod sleeve is rotated by means of a gear wheel, the sleeve sliding through the wheel and rising or falling in the usual manner quite independent of the wheel. The sleeve wheel meshes with another wheel which is mounted on an upright spindle, and on the top of the latter wheel is a plate which has teeth on its upper face. Over this teeth-faced wheel is a movable shield plate which has a portion cut away so as to uncover a number of teeth on the face wheel, and over the shield plate is placed a pawl carrier actuated from some suitable moving part of the engine, the pawls riding on the shield plate. At the top of the bracket is pivoted a three-armed lever,

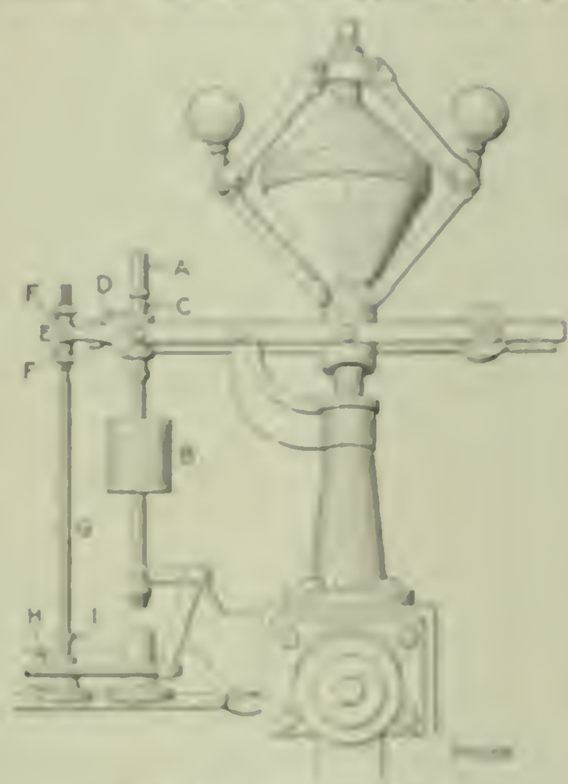

FIG. 33. SPEEDER GEAR

two of the arms being horizontal and the other vertical; the bottom end of the latter is provided with teeth which mesh into teeth formed on the shield plate. The illustration shows the pawls in the center of their travel, which ends when the pawls drop into the teeth of the face wheel.

The governor rod is shown at its normal hight, and one horizontal arm of the lever is held in firm contact with it by means of a weight on the other horizontal arm. It is evident that if the governor rises or falls the T-lever follows it and at the same time moves the shield plate and uncovers one or more teeth to be moved by the pawls. The action of the T-lever is very sensitive, about 1/10 inch rise or fall of the governor uncovering one tooth on the face wheel. The spindle revolves with the face wheel and carries a worm which meshes with a gear, automatically throwing the regulator out of action at any predetermined position.

A special feature of the regulator is that the two gear wheels can be changed, or any other wheels put on so as to obtain the exact speed of regulation suitable for the engine to which it is fixed.

SAFETY TRIP GEARS

Safety trip gears are generally fitted

FIG. 34. TATE'S ELECTRIC STOP

to all engines where the governor is driven through intermediate gearing, such as a belt or ropes. By this means, should the belt or ropes break, or should they be carried away on account of some portion of the engine itself breaking, the steam is immediately cut off. In addition to this, the engine is immediately shut down should the speed exceed any predetermined amount.

A type of speeder gear used in connection with Porter, Proell and similar types of governors controlling trip gears of Corliss and drop-valve engines is illustrated in Fig. 33. Rod A, forming the connection between the governor and the valve gear, is weighted by the pot B so as to slide in the bush C should the catch D be released. This takes place whenever the block between the ends of the pair of hook-shaped levers E comes into contact with the nuts F F on the trip rod G. These nuts are adjusted so as to come into action during about the last ½ inch of movement of the governor at both top and bottom. The tripping rod G rests on the top of the engine frame, and is prevented from lifting by the hinged quadrant H, engaging with a collar on the end of the rod. To prevent the safety trip acting every time the engine stops, it is only necessary, just before shutting off steam, to turn the quadrant H until it catches under the collar I on the trip rod, the weight of the latter preventing the quadrant from falling. This allows the trip rod to lift when the engine stops and the governor falls, instead of releasing D; but in doing this it allows the quadrant H to drop. As soon as the engine starts again and the governor lifts, the trip rod G is lowered, and its bottom collar will again engage with the quadrant, thus automatically resetting the gear to its safe position. It will be seen that the gear, if properly adjusted, will act if the governor reaches its top position through overspeed; also, if the governor falls to the bottom through the failure of its driving gear, before it tentionally prevented from doing so by the attendant propping the trip rod by means of the quadrant as described.

Another well known safety trip gear is the "Tates Electric Stop Motion," shown in Fig. 34. In this trip gear the main stop valve of the engine is closed by a powerful spring should the speed of the engine exceed any predetermined amount. In addition to this, if the engine is condensing, the vacuum is broken. Also, by means of suitable electrical connections the engine stop valve can be instantly closed from any part of the building by simply pressing a push button.

A small governor shown at C is driven by means of a belt from the engine shaft. If the engine runs at an excessive speed the tumbler at the top of the governor makes contact and the stop valve of the engine is immediately closed. If, however, the small belt driving this governor should break while the engine is running, the engine is instantly shut down.

Crank-shaft Governors

Governors of the crank shaft or drum

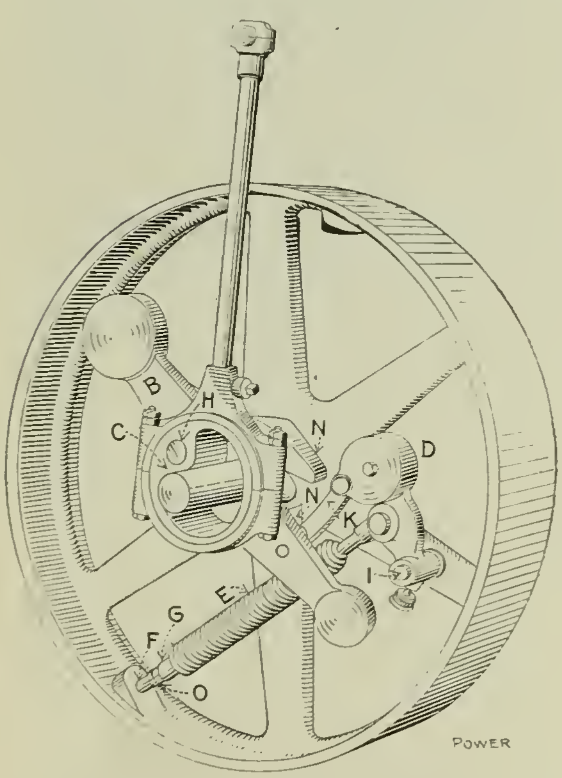

Fig. 35. Tangye Governor

type which control the speed of the engine by altering the travel and angle of the eccentric driving the valve, are not largely used in England. In the early days of high-speed engines, they were largely used and are still used by a few firms, but most makers of this class of engine have abandoned this type of governor and use the throttle type universally. For small engines, crank-shaft governors are very suitable, and a design of governor used by Messrs. Tangyes, of Birmingham, is illustrated in Fig. 35.

This governor consists of an inertia arm B, with which is cast the eccentric C, pivoted on the steel pin H, and free to swing within the limits provided by the stops $N N$. The weight box D, carried upon the pivot I, is connected to the governor arm by link K, and the spring E tends to pull the arm B against the stop N. When the direction of rotation is in a clockwise direction, the action of the governor is as follows: The weight D flies out radially when the wheel is rotated, and moves the governor arm by means of the link K. The inertia arm B lags behind, and assists the weight D

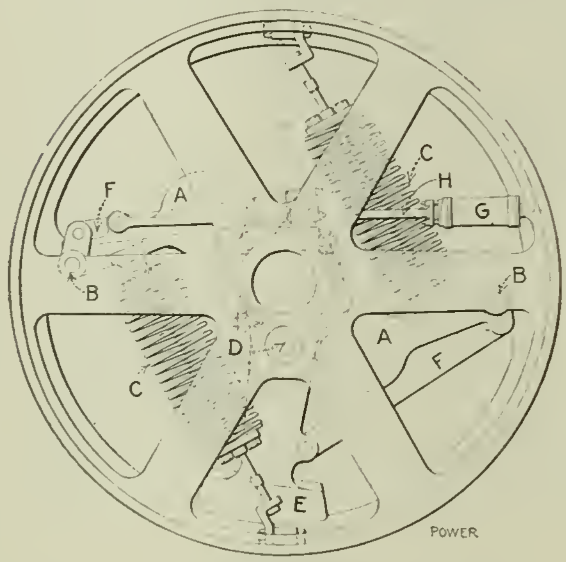

Fig. 36. Wilson-Hartnell Governor

either at an increase or a decrease of speed. This has the effect of either increasing or decreasing the travel of the eccentric and the cutoff of the equilibrium piston valve is adjusted to the required work. The eccentric in the position shown is at the maximum travel, such as when the engine is starting up. Upon the required speed being attained, the center of the eccentric moves toward the center of the shaft, and the travel of the valve is reduced. The weight box D contains loose weights secured by a cover plate and bolt; by removing one of the weights the speed of the engine is increased about five revolutions, and the entire number of weights gives a variation of about fifty revolutions. The required spring strength for best working is obtained by a plug in the spring E, which can be moved by the box spanners G. The position of this plug is secured by locknuts O.

A very powerful and at the same time sensitive type of crank-shaft governor is shown in Fig. 36, which is made by Messrs. Wilson, Hartnell & Co.

The two centrifugal weights $A A$ pivoted at $B B$ are restrained by the springs $C C$. The eccentric is pivoted at D and has a counterbalance weight fitted at E. The movement of the centrifugal weights is transmitted to the eccentric by the links F and the counterbalance for the eccentric at E makes the governor act partly as an inertia governor. A dashpot is fitted at G and is coupled to the centrifugal weight by the rod H. This is found necessary in order to resist the thrust of the eccentric.

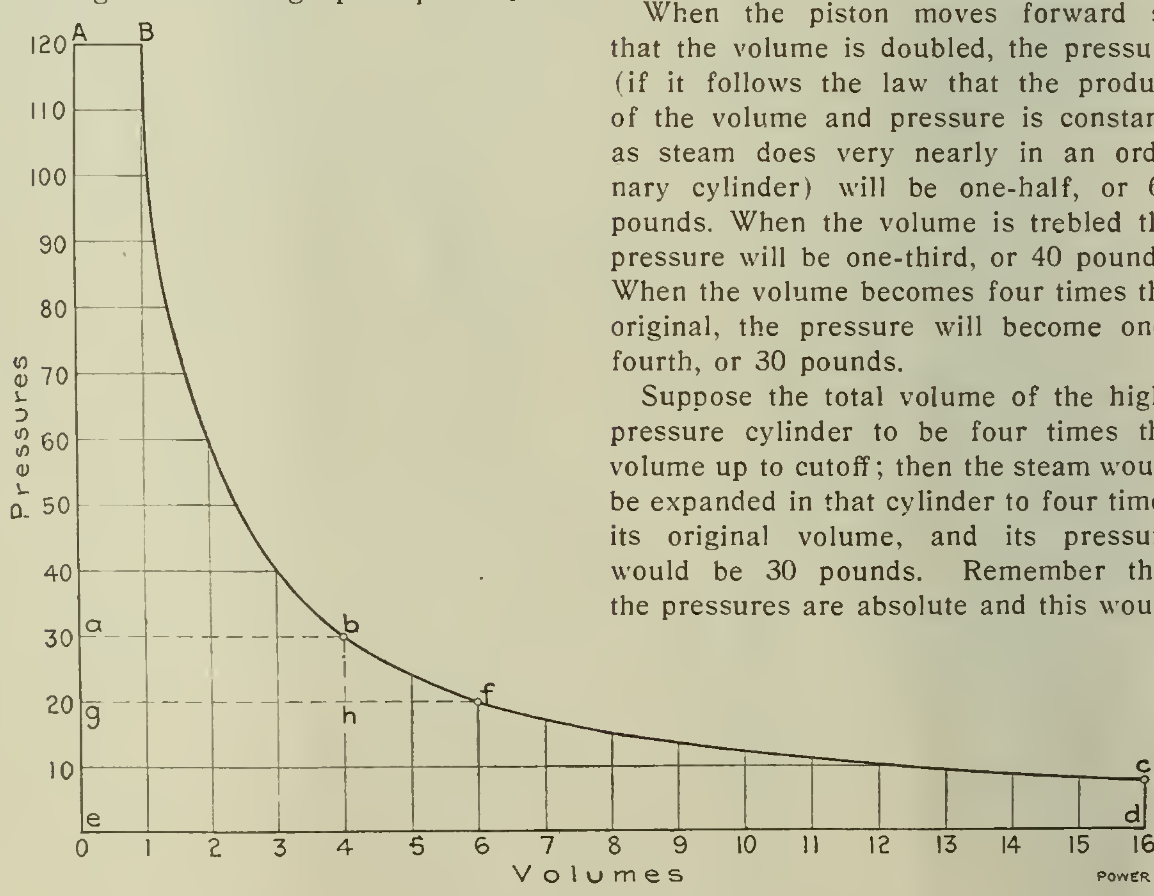
Effect of Low Pressure Cutoff on Compound Engine

A perplexed subscriber cannot understand how shortening the cutoff on the low-pressure cylinder makes that cylinder do more work.

In the diagram herewith, let the line $A B$ represent the volume of steam in the high-pressure cylinder of a compound engine at the point of cutoff and the line $A O$ represent its absolute pressure.

When the piston moves forward so that the volume is doubled, the pressure (if it follows the law that the product of the volume and pressure is constant, as steam does very nearly in an ordinary cylinder) will be one-half, or 60 pounds. When the volume is trebled the pressure will be one-third, or 40 pounds, When the volume becomes four times the original, the pressure will become one-fourth, or 30 pounds.

Suppose the total volume of the high-pressure cylinder to be four times the volume up to cutoff; then the steam would be expanded in that cylinder to four times its original volume, and its pressure would be 30 pounds. Remember that the pressures are absolute and this would be the receiver pressure, about 15 pounds by the gage.



Pressure-volume Diagram

This steam is now discharged into the low-pressure cylinder, and if the volume of the low-pressure cylinder up to cutoff is just as much as the total volume of the high-pressure cylinder, this steam, neglecting resistances, will be simply transferred from one place to the other without change of volume or pressure The line $a b$ will be the back pressure for the high-pressure and the steam line of the low-pressure diagram.

Suppose now the steam to be again expanded four times in the low-pressure cylinder. The pressure would run down the curved expansion line shown, and at the end of the stroke the steam would have 16 times its original volume. It was expanded four times in the high-pressure cylinder and then this already expanded steam is expanded four times in the low-pressure cylinder, so that the total volume of the low-pressure cylinder must be 16 times that of the high up to cutoff. The terminal pressure will then be

$$120 \div 16 = 7.5 \text{ pounds}$$

The low-pressure diagram will be *a b c d e* and the high-pressure diagram will be *A B b a*. Of course, there will be some back pressure above the absolute pressure line even with the condenser, but it is not material to the present argument.

Now suppose that the low-pressure cylinder cuts off at *f* instead of at *b*. It will take six of the original volumes out of the receiver at each stroke instead of four. But the high-pressure cylinder is delivering only four of these volumes, so that there will be a fall of pressure in the receiver to $\frac{2}{3}$ of 30 = 20 pounds.

The high-pressure diagram will now be *A B h k g*, and the low-pressure diagram *k f c d e*.

The lengthening of the low-pressure cutoff has, by reducing its initial pressure, taken the work represented by the area *a h i g* off from that cylinder, and by reducing the back pressure of the high added the work represented by the area *a h k g* to that done by that cylinder. The energy represented by the triangle *h i k* is that of the free expansion in the receiver. It is not wholly lost, as it results in some drying of the receiver steam with a slight increase of its volume or pressure.

Locomotive Boiler Explosion

By C. L. Greer

The explosion, which occurred in Texas, killed nine men and injured twelve. Probable cause was defective gage and pop safety valve screwed down to the last thread.

An awful example of the destructive force of an exploding steam boiler was recently had in the explosion of a Missouri, Kansas & Texas locomotive boiler in the little town of Smithville, on the Colorado river, in Texas.

On February 8 a switch engine was brought from the shop after being thoroughly overhauled. While steaming up preparatory to a run to another town the boiler let go in one of the most disastrous explosions ever known. The wreck was so complete that it could not be ascertained at just what point the rupture first occurred. The whole firebox end of the engine was blown to pieces and the cab to splinters. A portion of the roof sheet of the firebox was hurled a distance of three blocks, landing in the street, while smaller pieces flew twice as far. This portion is shown in Fig. 3. One large piece crashed through the roof of a business house several blocks away. At some places the rivets were sheared completely while at others the sheets, [illegible] inch thick, were torn like paper.

Fig. 1 shows a general view of the wreck. The wrecked engine before the explosion stood between the two engines indicated by the arrows. When the explosion came the tender was thrown back into the turntable pit and the front part of the boiler was shoved forward a distance of about 100 feet with the drivers plowing in the ground. The rear pair of drivers were sheared completely off

Fig. 1. Scene of Locomotive Boiler Explosion, Smithville, Texas, [illegible]

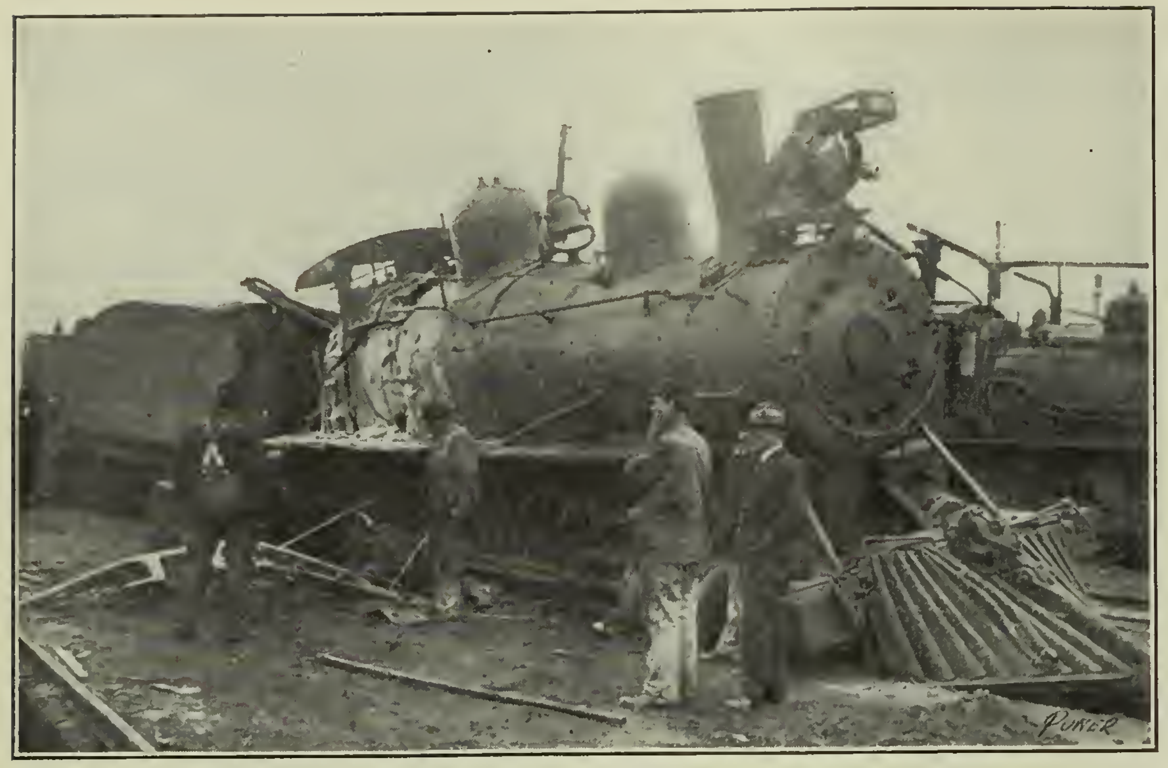


Fig. 4. This Engine Dropped into Pit Below Track

their axle, as shown in Fig. 2, and were dragged along by the connecting rods while the axle was bent to the arc of a circle. These wheels were pressed on their axle under a pressure of 90 tons. The two engines shown in Figs. 3 and 4, which stood on each side, were badly damaged, the cabs being almost entirely blown away. The engine shown in Fig. 4 was shoved off the track and dropped into the pit below while the rail on the far side was broken by the driving-wheel flange.

Fig. 5 shows how the braces and staybolts were broken and torn from the sheets. In Fig. 2 may be seen some of the sheared rivets still in the holes.

Nine men lost their lives and twelve were injured. Two men in the cab and one on top of the boiler were blown to atoms, being identified only by hands, feet and bits of clothing. A man working in the front end of the engine shown in Fig. 3 was unhurt, while one standing on the pilot of the same engine was found in the pit badly injured. Four bodies were taken from under this engine. Parts of human bodies were blown 600 feet away, rising high into the air.

It is the general opinion that the cause of the explosion was a defective steam gage. The man on the engine was setting the pop valve and it is thought the gage stuck when the pressure reached 155 pounds, as the gage stood at that point when found.

It is thought that the man screwed the pop valve down too tight and the gage failed to register the rising pressure. It is common report that when the pop safety valve was found it was screwed almost entirely down and when tested it took a pressure of 600 pounds to make it pop.

Parties who were near stated that before the explosion steam was issuing from under the jacket and apparently came from the seams, which were strained to the leaking point.

Operating Engineer's Opportunities*

By W. D. Ennis †

> *Factors upon which economical power generation depends—the engineer's part in determining them. Education is the instrument which the operating engineer must use to further his interests.*

The wise manager endeavors to stop the big leaks first, to "hit the high spots." What are the "high spots" in power-plant engineering? It will probably be agreed that there are four fundamental considerations to be taken into account in any effort to produce cheap power. These are: first cost of the plant; the load factor; cost of the fuel, and the heat value of the fuel.

No sensible man would install stokers and economizers in a plant to be used as a water-power auxiliary for only a few hours in the year; the fixed charges on such equipment would offset any possible fuel saving. One would not expect to see the so called automatic type of engine in a pumping station running constantly at full load, because the high load factor there justifies making every reasonable effort to secure steam economy. The argument for a gas engine becomes weakened when good coal can be purchased for a dollar a ton, because the saving in fuel will not be sufficient in terms of dollars to offset the higher fixed and maintenance charges of the gas-engine plant. Power costs in western Washington are not greatly different from those in New York for the reason that, although coal there is poor in quality, it is cheap.

European engineers will scarcely build a large engine without jackets, because interest with them costs less, and fuel more than here.

It is said that the most economical rate of evaporation for a steam boiler is from 3 to 3½ pounds per hour, and perhaps it is, from a purely thermal standpoint; but if the plant has a one-hour overload of 100 per cent twice a week, it may pay better occasionally to force up the evaporation rate to 8 or 9 pounds than to install more boilers.

The operating engineer today is a business manager, and he must not be a manager of that extinct type which became fossilized a generation ago. He must not work without tools and expect people to make allowances. Tools are available and people will *not* make allowance. Executive ability is what makes cheap steam. What we need is economics as well as thermodynamics.

You can judge an engineer's work by its results. Some may think that this is a handicap for the engineer. It is a good thing, not a bad thing. You cannot frighten a good man by "keeping tabs" on him. The more "tabs" you keep, the better he likes it.

It is probably safe to say that all the power in the world is obtained from heat, and the stock of heat in the universe is not unlimited. When we burn a ton of coal—in the everyday, ordinary steam plant—we utilize the heat of about 40 pounds of that coal. The rest we throw away. We do not know how long our coal will last—it may be a couple of centuries, it may be a thousand years—but the fuel is surely going. It may be said that in the nature of things we *must* waste the greater part of the coal, and, unfortunately, that is, for the present at least, true. But few ever reduce the waste to its irreducible minimum.

The first point of attack should be perhaps the fuel itself. What is available besides coal? What coals may be used that are now not commercially available? There are wood, fuel oil, natural gas, peat, and in certain places various waste-product fuels which will never concern most of us. A wood-working establishment may produce more refuse than is necessary for the making of all of the steam that the plant can use. One principal difficulty in using slabs, edgings and shavings in such plants is the great labor involved in firing. The products of the planer and saw are also apt to burn with much smoke. In some districts where lumbering is an important industry, the best engineer is the man who burns the most, not the least, fuel. Even when he does his best, there will be a rapid accumulation of refuse which must be incinerated in open burners running night and day, at no small fire hazard. It is not easy to sell this fuel to other steam users; it is too worthless to stand much transportation, and the supply is too irregular. In one Western plant the chips and shavings from a lumber mill were blown some 900 feet through a 14-inch pipe running along the beach to a flour mill, the nearest neighbor, where they were used for boiler fuel.

To burn good wood especially cut for fuel seems like a crime. A mill plant in the West burned 100 cords a day of splendid fir for several months in 1901, paying about $3 a cord. Wood is worth too much in that district now for any such application. California oil has replaced it. Fuel oil in New York costs more than twice as much per heat unit as ordinary coal, and it is impossible to think of using it for steam making. In western Washington, California oil at one cent per 72,000 B.t.u. has driven out both wood and coal at the same price, because the oil can be fired with less labor and greater economy. In San Francisco and other cities nearer the oil-fields the price of oil is much lower. This is fortunate, because in California other fuels are high in cost and the far Western coals are mostly of poor quality.

As to natural gas, the problem is simple. Not long ago there was occasion for the writer to give advice regarding the installation of a gas engine in Pittsburg. The company owned a gas well of its own, but the pressure was irregular and the supply could not be depended upon. It was suggested that an engine be installed for natural gas—the necessary gas to be purchased—and that later on as natural gas became more expensive, the company could make its own producer gas to use in the same engine. But it was found that they could not hope to buy natural gas at a less cost, even at that time, than one cent per 80,000 B.t.u., whereas producer gas could be made at the rate of 100,000 B.t.u. for a cent. Even now, natural gas is a high-priced fuel for power purposes, and it should be. A fuel of that sort should be reserved for domestic consumption.

Engineering is constantly growing. The man who does things precedes the man who theorizes. Both types of man are useful. The steam engines of the eighteenth century were built without the help of thermodynamics, and they ran—some of them ran, some of the time—perhaps some are running yet. That wonderful engineer, James Watt—one of the most remarkable characters in engineering history—added as much theory as he could to much hard-bought experience and made the steam engine a practical machine. By the year 1800, pumping engines very nearly of the original Watt type are said to have developed a horsepower on about [illegible] pounds of coal per hour. There are pumping engines throughout the country at this moment not doing any better. The average steam engine does by no means as well. The very best engines will cheat this figure only about 50 per cent, and few of us have ever seen such engines.

That looks like a small advance to make in three-quarters of a century, but it must be remembered that in the nature of things no large advance is possible. The best engines of 1820 had an efficiency of about 45 per cent of that which

*Lecture to the proposed Institute of Operating Engineers at its second monthly meeting in New York on March 9.

†Professor of mechanical engineering in Polytechnic Institute, Brooklyn, and member of the proposed institute.

could be attained by an ideal engine; in the best engines of today this figure has been brought up to about 70 per cent. Working along present lines, we have made about all the gain that can be made. Not until 16 ounces cease to make a pound or until there are 101 cents in a dollar can more work be obtained from heat than that amount which corresponds with its drop in temperature.

Yet, the progress of the last two decades has not been negligible. There has been progress in overall efficiency rather than in engine economy, and this promises decided betterment in fuel consumption per delivered horsepower. Ideas as to plant arrangement have completely changed. Take the single matter of piping. Engineers have been closely studying power-station piping for about thirteen years. In 1898, we were using extra-heavy cast-iron fittings, screwed-flange joints, duplicate systems, ring mains, etc. The flared-over flange was brand new; cast steel was unheard of: the first special casting I ever saw used in pipe work was a gun-iron header installed in the Concord, Mass., electric-lighting plant in '99. We were just beginning to use pipe bends; there were only three (or, usually, two) places in the country where we could get them. All that has changed. The steamfitter of that day would be a cat in a strange garret if turned loose along the valve gallery of the modern station.

Thirteen years ago we were talking about magnetic clutches to connect engines and generators and the direct-driven unit was a novelty. The economizer was a matter of much interest but scarcely of immediate concern to the average man. Mechanical draft was a dangerously new invention. There were no stokers. We had just begun to talk about coal per kilowatt-hour and we did not have anything very creditable to ourselves to say. Today, we are rapidly improving some hitherto neglected details. We have been forced into the manufacture of better condensing apparatus and we are by no means through with that matter yet. We are faced with the question of superheat. We know that it pays—it increases gross earnings, so to speak—but we do not in all cases clearly know what it means finally in the year's business. Too much superheat has been installed with improper piping, valves, fittings and regulating devices. We are learning the mechanical requirements now.

It is a curious fact that the general type of apparatus adopted for some of the largest power plants has been determined by the insignificant (?) factor, cylinder oil. There is no way of thoroughly removing oil from exhaust steam under vacuum. If turbines are used, the exhaust steam is free from oil and many plants are using turbines partly on that account. If the older type of engine is used, with surface condensers, it is usually considered conservative engineering to throw away the condensed steam (although in a few plants they are filtering out the oil). Since in New York the circulating water is necessarily salt water, we must waste almost every unit of heat leaving the main-engine cylinders. With jet condensers we obtain the same result. Fresh city water might be used for condenser supply in connection with cooling towers; but it is problematical whether the very slight resulting heat economy would represent any commercial gain, and the cooling tower itself is scarcely to be regarded as standardized.

And in any case, we are face to face with the question of type of prime mover. The turbine has already shown a better everyday economy than its predecessor, although it has probably not quite equaled the latter's best record. This is from the technical, heat-unit standpoint. Commercially, the turbine plant costs less and will eventually cost very much less, so that it often has a distinct advantage. Along with this, the gas engine is looming up large, promising an efficiency well along toward double that of the best steam engines, but it is thus far handicapped by greater cost, lack of overload capacity, relatively poor efficiency at light loads and unproved reliability. Which of the three, reciprocating engine, turbine or gas engine, is to survive no one can yet say; final types have not been developed and final data are lacking as to thermal and commercial efficiency; but we may hazard the following surmises:

For direct connection to generators and other revolving machines where condensing water is available, the turbine should displace the reciprocating engine. Should its cost per pound be reduced to anything like that of the older motor, and if it can be made fairly efficient when running noncondensing, it may displace the latter in *all* applications where direct connection is possible. As to the gas engine: assuming the present rapid rate of development to continue, this form of prime mover should replace the steam plant in nearly all cases where, steam coal is high in price; the load factor is reasonably good, and there is no steam required for heating purposes. The gas engine will make more rapid progress as its underload efficiency and overload capacity are increased and its first cost is reduced.

The operating engineer's work is not confined to the engine room. Those who have to do with mill plants well know that large savings are to be made in the economical utilization of exhaust steam for heating and process work. This field is not being exploited as it should be. There are dollars to be found in the vacuum pan or steam kettle as well as in the cylinder and it is usual experience that they are somewhat easier to find in those places. You may have heard of the use of receiver steam from compound engines for process supply where steam at atmospheric pressure would not answer. You may *not* have heard of the proposal to run an engine at 20 pounds back pressure in order to supply a triple-effect evaporator. I see no objection and a certain gain. In the great majority of cases, ordinary exhaust steam is all that is necessary. Many a mill owner is superstitious about it; he thinks that exhaust steam is not hot, does not realize that with good circulation exhaust steam will warm his kettles up to 200 degrees just as quickly and reliably as live steam will. When a somewhat higher temperature is necessary, it may be better to pass the exhaust steam through a small separately fired superheater than to supplement it with a final live-steam boiling through special coils.

These are side issues, if important, to the main work of the engineer which is now more than ever centralized in the boiler room. As always, he must first of all keep things running. In the vast majority of plants this is the all-important consideration compared with which everything else is secondary. He must comply with local laws and ordinances and as far as possible avoid becoming a contributor to the smoke nuisance. A sufficiently difficult task this, with all the fuels of various grades, and it cannot be said that we have yet developed any generally applicable system of smoke prevention. Smokeless combustion is itself a matter of management, based on the coal, the equipment, the men and the load, and there is no infallible prescription for securing it. We can say, generally, that soft coal needs more air than hard coal; that the air and fuel must be thoroughly mixed to produce ignition, and that the flames must not be chilled until after combustion has been completed, that is to say, that about 10 or 12 feet of distance should be traveled by the products of combustion from the grate before they strike the boiler. These simple principles underlie the design of every "smokeless" furnace, dutch oven and soft-coal stoker in existence. We have recently developed another form of power-plant nuisance no less objectionable than smoke, namely, the discharge of fine cinders from plants burning low-grade buckwheat coal at high drafts and rates of combustion. In New York City there have been several criminal proceedings against plant operators who have offended in this way.

When we have mastered these things, in a reasonable degree, we have before us the whole field of plant economy. Here, if anywhere, a campaign of education will pay. It costs perhaps one cent in wages to shovel ten cents' worth of coal onto the grates, and I am afraid that we get good measure, that is, the willing fireman often makes it ten cents' worth of coal when it might be seven cents' worth. We should remember that in no place are brains more needed than in the *expenditures* of life, and we ought to pay enough for fire-room labor to obtain the proper degree of intelligence. The firing of coal should be made more a matter of brain than of brawn.

How is this to be brought about? One of the popular magazines which has been publishing a great deal about scientific factory management suggests that we adopt a sort of piece-work basis, paying the fireman so much per ton of coal fired. I should rather work it the other way, paying him so much for every ton he did not fire. Everyone nowadays is interested in the new "efficiency" systems of wages. These systems are claimed to have nothing in common with piece work, but they resemble piece work at least in that the more a man does the more he earns. There is no reason why such systems cannot be introduced in the fire room, but, of course, what a man "does" there is not the amount of coal he shovels but the amount of steam he gets for each pound of coal.

It is a fortunate engineer who has a poor plant—particularly in a process mill. He has the best opportunity to make great records in economy, if he can only stand the strain of keeping the plant running. Of course, there is always an element of luck that cannot be depended upon; but in the long run, as Napoleon said, the luck is on the side of the best general. Power-plant management must be judged by its results like everything else from advertising to church going. Nobody is interested in our failures and mistakes. To save is our only excuse for existing. The plant which stands still in the matter of costs is the plant that is ready to start on the down grade of efficiency. It is a fight all the time.

A word as to records. It is a fine thing for an engineer to keep statements of fuel consumption, etc., from day to day, or even, if possible, from hour to hour. Generally speaking, the more records the better. One record that should certainly always be kept is a log, recording dates of scaling and washing boilers, packing rods and the like. Data on these points are necessary and easily forgotten. I am afraid that sometimes engineers' records become literature rather than bookkeeping, interesting rather than important. This happens when a man forgets that his daily coal weights, for example, should check with the invoices and inventory month by month. If they do not, they are not worth much; if the invoice weights are wrong, the office is concerned; if the boiler-room weights are wrong, they must be made right.

If we have any cure-all, any universal medicine, in the power plant and in business generally, these days, it is system. I hope that we do not carry it farther than is profitable, but we cannot get along without it.

I sometimes think that it would be a good thing if every engineer were temporarily moved to a new plant for about four months once every two or three years. A new man will always see some new things in a plant—some disregarded opportunities for economy. The change would be good for each plant and it would teach the man some things, and when he went back to his own boiler room he would approach it with a more or less fresh view. I once looked into a mill which had a small closed feed-water heater supplied with exhaust steam from the auxiliaries. It was so overloaded that, although there was an ample supply of steam, the water could not be made hotter than 180 degrees Fahrenheit. When a condensing engine was installed later on, a large heater was placed between the engine and the condenser, and the feed water after passing through the old small auxiliary heater was put through the new large heater. It seems incredible that among all the people concerned there was no one who knew that steam at any vacuum, however poor, is colder than 180 degrees; at any rate, that was the arrangement when I saw it, and we had to buy two thermometers in order to prove to the superintendent that this heater was literally a *feed-water cooler*.

It is unfortunate that in engineering, as in everything else, we are all more or less apt to adopt fads. There was a time when everyone who preached power economy used boiler scale as a text, and we thought that we knew with mathematical accuracy just how much loss would follow the presence of so many sixteenths of an inch of scale. Our methods of treating scale were cure-all methods, and the idea of "making the punishment fit the crime"—of choosing a treatment adapted to the water and type of boiler—was scarcely heard of. I suppose that a critic might say that today the chief fad is air supply and CO_2. Perhaps this subject has become a fad in some places; we "know" a great many things about it that are not so; the facts of the matter are outnumbered by the fancies. Yet, disregarding all questions of measurement methods, recording apparatus and exactness of deductions therefrom, the incontestable facts remain that in the average plant an excess of air is admitted to the furnace; that this, by diluting the products of combustion causes the most serious preventable loss in the whole plant; that improvement in this direction is to be accomplished, not by the installation of expensive new equipment but by intelligent control of the ashpit door and the damper. Between the plant where the air supply is right and that where it is badly wrong the difference may amount to half of the coal that burned. Hard coal needs high draft but not a great amount of air. Until we learn that air pressure is one thing and air quantity another we shall not get very far. We want to get about as intelligent as the engineer I once met in the West who knew no such thing as a pound of steam other than the "pound" registered on the steam gage. Men who have plants close to New York and are not interested in oil fuel, producer gas, or water power—here is a subject which concerns you and demands the best that is in you.

One of the chief needs in power-plant economy today is a better method for the purchase of fuel. When we buy anything else, we intend and aim to get what we pay for. Too many of us, in buying coal, take what we get. Every man who contracts to sell something is supposed to state what and how much he sells. It is very difficult to get sellers of coal to do this. Nobody seems to know less about coal than those who have it to sell. And we who have to buy it take it as it comes—more or less; there are some exceptions—although it is the largest single item of power cost.

Coal should be sold on the basis of its heat value and analysis and a pound paid for should weigh 16 ounces. Perhaps we need a National "pure-coal law" to protect us in this respect.

The value of coal to the user depends on its quality and whenever a contract is made it is based on the supposed analysis of some sample or standard. If the quality descends, the coal is not worth the contract price and should not be paid for at such price. No matter whether the decrease in quality is ascertained by actual experience with the coal in the fire room or by analysis, the fuel should be condemned. It is cheaper and quicker to determine heat value and composition in the laboratory than in the furnace, the results are more accurate and less affected by variable conditions (a 500-horsepower boiler is a poor piece of experimental apparatus) and the only failures of analysis to give the same results as practice have been due to insufficient or improper analysis or an unintelligent interpretation of the results of analysis. This is one of those cases where trouble arises not from "too much theory" but from too little theory.

We should not be called on to accept coal high in sulphur. We should not be handicapped with excessive percentages of moisture and ash; three dollars a ton is too much to pay for these things. If the volatile matter in the coal runs up to 50 per cent. and black smoke is produced, the coal man should be arrested, not the engineer. We are entitled to what we pay for. By purchase regulations or in some way, we pay for coal of defined properties. If we do not get such coal, within a reasonable limit of variation, we are not getting what we pay for. The coal dealer may say he has no control over these details, but somebody has, and we must reach that somebody through the man who gets our money. Take the matter of sizes, I have met men who did not know that No. 1 buckwheat meant a certain range of size. If we buy No. 1 and pay for No. 1, why do we not see that we get No. 1?

And then, there is the commercial problem of delivery. Those of us who operated plants in New York in the winter of 1903-04 know what happened to costs per kilowatt-hour during that time. Why? Because nearly every dealer defaulted on his contracts. We would not tolerate such a thing on the part of anyone else; why should we tolerate it when perpetrated by the coal men?

To city engineers with office-building plants, the prospect of coal shortage is serious enough, but to the mill engineer out in the suburbs it involves some additional troublesome problems. He must store coal at the beginning of the winter if he wishes to keep running in spite of strikes or railroad delays. Storage of coal is one of the most serious items of cost. We say nothing about the money tied up in the coal pile; the expense of handling and rehandling is alone rather staggering in a plant of any size. And then, there is shrinkage, in quality as well as in quantity. The hazard of fire is extremely serious, at least with soft coal, and fires in a coal pile are hard to put out.

These are some of the commercial aspects of a few of the problems entrusted to the operating engineer. This Institute of Operating Engineers is going to help us solve them. I believe the institute will succeed because it recognizes in its foundation two broad principles which accompany all great work and which are always associated with success: the principle of education and the principle of helping the other man—especially the younger man. We all need education, all we can get of it, and we need it before anything else. Our troubles come from too little, not from too much education. Therefore, it was wisdom to make education one of the institute's first aims. Just what kind of education operating engineers need and what shall be the program of getting it, will be gradually determined as time goes on. Let us merely aim high and then let matters shape themselves. It was most wisely said by the editor of POWER that the worth of your certificate of membership will be determined by the first one hundred holders of it. Be sure of your first hundred and you will be bound to grow in the right direction.

We sometimes forget what the word *engineer* means. In its derivation, it has no reference to engines. The engineer means the man who is ingenious, inventive, of wide-awake and active mind and who can meet and master situations with science and skill. If we remember that derivation, we will all agree that the word describes the highest and best type of engineer, the type we ourselves aim to be. Our work does not begin with the throttle and end with the flywheel; it does not even begin with the coal pile and end with a salary check; it is a part of the great work of efficient men all over the world making two blades of grass grow where one grew before.

Flywheel Explosion at Greensburg Ind.

Failure of the governor to shut down the engine after the breaking of the governor belt, was responsible for the wrecking of a flywheel at the works of the Bromwell Brush and Wire Company, Greensburg, Ind., at 7:30 a.m. on March 2.

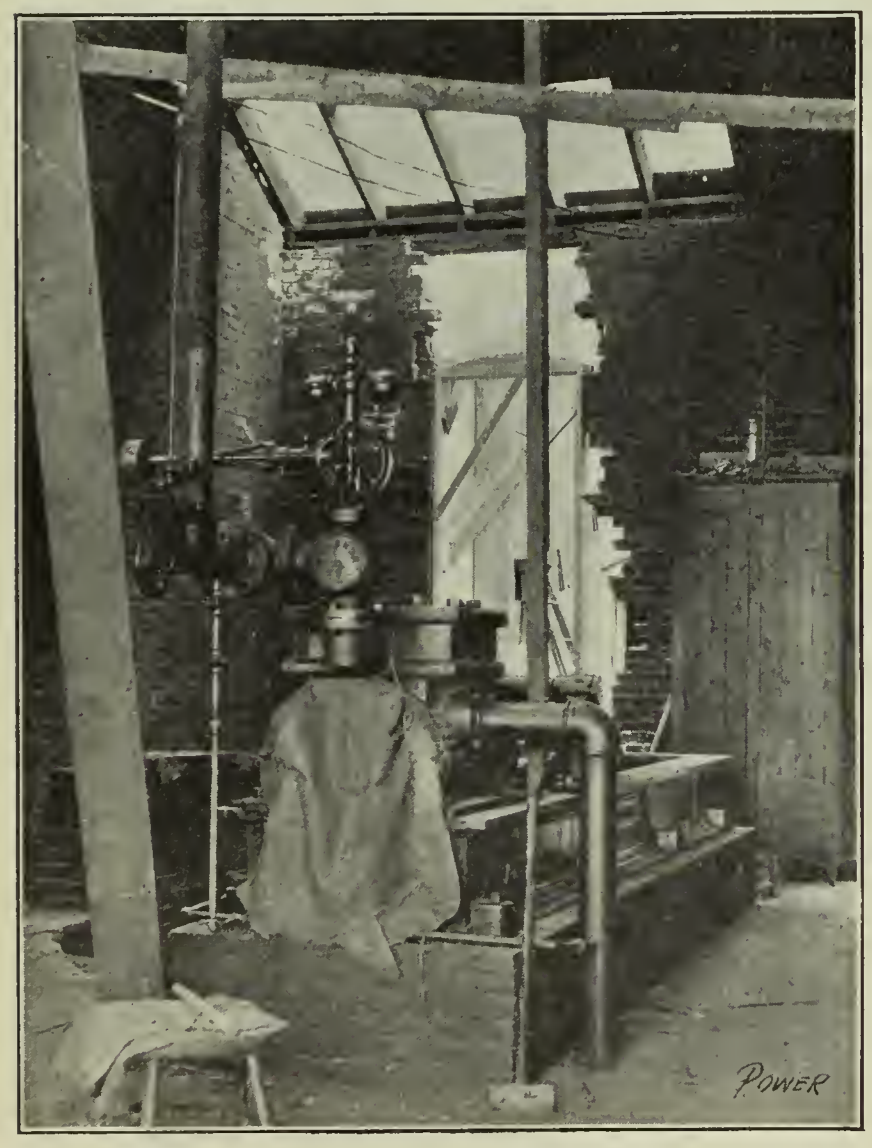

FIG. 1. ENGINE ROOM AFTER THE ACCIDENT

FIG. 2. PART OF RIM OF THE BROKEN FLYWHEEL MID RURAL SURROUNDINGS

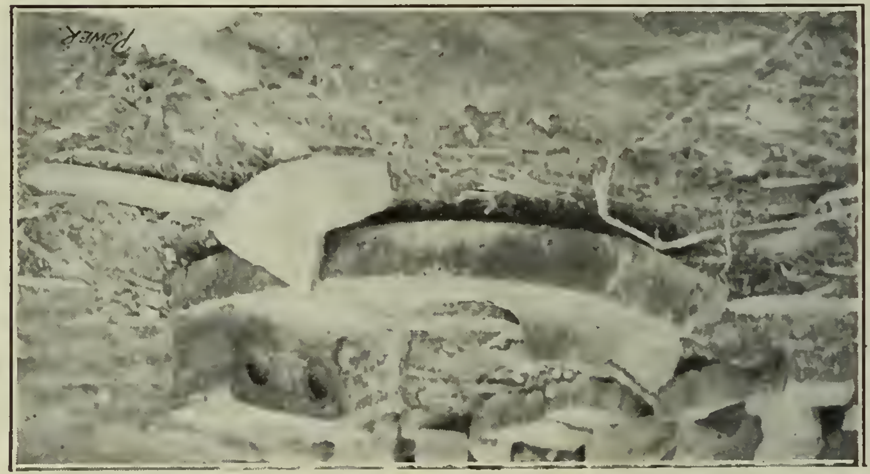

FIG. 3. ANOTHER PIECE OF THE RIM

The engine was of the old slide-valve throttling type, with a 14x24-inch cylinder and a 10-foot cast-iron flywheel made in two pieces. The rim was 10 inches wide and 2½ inches thick and was held together at the circumference by lugs, each containing two 1⅞-inch steel bolts. The normal speed of the engine was 110 revolutions per minute.

The engineer had left the engine room a few minutes before the accident to get a piece of 2-inch pipe from the storeroom. On his way back he noticed that the machinery was speeding up and hastening to the engine-room door he found the engine running at a dangerous rate of speed. As the throttle valve was directly in line with the flywheel and wide open, he saw that it would be impossible to screw the valve to its seat before an explosion would occur, so turned and ran from the room. He had gone but a few feet when the wheel let go, a number of pieces tearing through the roof and side of the building, as shown in the accompanying photographs, wrenching the main shaft from its journals and breaking the frame of the engine. Pieces of the flywheel weighing from one to two hundred pounds were scattered all over the neighborhood, one of them landing in a corn

Fig. 4. Part of Bandwheel with Piece of Flywheel in Background

field several hundred feet away, another crashing up through the floor of the main building and coming to rest in the attic.

No one was injured, owing principally to the fact that when the speed of the machines in the factory began to increase, all the operatives left their stations and made for the exits furthest removed from the power plant.

The flyball governor was equipped with a safety device designed to shut down the engine in such an emergency. This consisted of a ball-weighted lever, held up by the tension of the belt, causing the belt-wheel shaft, which was pivoted to swing loosely, to bear against a lug on the weighted lever, the idea being that should the belt break, the tension would be removed and the weight would close the valve and shut off steam.

After the accident this weighted lever was found in its upper position, and consequently the throttle valve was held wide open.

Fig. 5. Parts of Flywheel and Main Journal

Engineer Bungle Repairs an Engine

"Blank the blackety blank double blank blank luck. Blank * * ! * * * * ! * * * !"

The above is but a faint imitation of the sounds that came out through the open windows of a small country engine room. Waiting until I concluded it was safe, I ventured in where the commotion had occurred.

There I found a small slide-valve engine and a big, fat engineer with about as much expression as a half decayed potato.

The engine had been stopped and the reason was apparent from the broken valve-stem guide lying on the floor. The blacksmith's helper in trying to juggle a sledge hammer while passing through the engine room had accidentally hit the guide with the hammer and broken it. The profanity had come from the proprietor of the sawmill, but he had departed to telegraph for a new part.

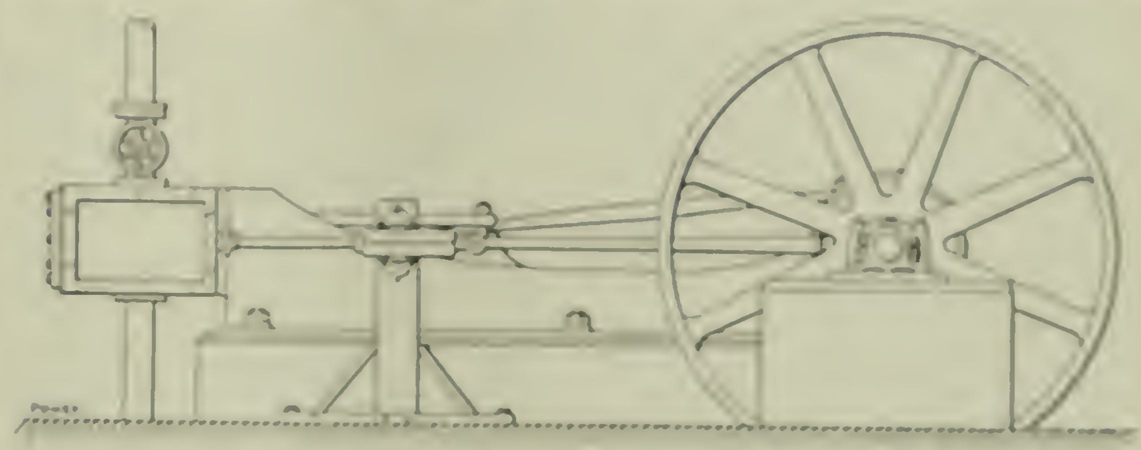
"In trouble?" I asked of the engineer.

"Yep," he replied, which was half a groan.

"Why don't you surprise the boss and fix the engine so it will run?" I asked.

"Dunno how," was the answer.

After some more talk, I decided that the engine could be fixed up temporarily and run until the new part arrived. A stand was made of wood, the upright piece being braced as shown in the illustration. To the upright piece two window-cord pulleys were secured by hook bolts and nuts, after placing the frame back of the valve-stem guide in such a position that the two pulleys, which se-



How the Engine Was Repaired

cured in place, formed a guide for the valve-stem end. The grooved pulleys served to prevent side play of the rod and were sufficiently strong to resist the thrust of the eccentric rod. The illustration shows the makeshift guide.

When all was ready, the engineer started up with fear and trembling, but soon had the engine up to speed.

Just then there was a shout and a clatter of horses' hoofs and wagon wheels, as the boss, on his return, seeing exhaust steam issuing from the exhaust pipe, hurried to find out what it all meant.

Not wishing to have any possible trouble with the proprietor, I stepped into the boiler room and, as I made my way past the engine-room windows, I heard him exclaim:

"Well, I'll be ——. Bungle, I didn't know you had half enough brains to do a job like that!"

"Huh, is that so? Well, you ain't the only man as what knows a steam engine from a cobble stone."

The lignite coals of Texas are excellent fuel for stationary, power and domestic purposes. The coal mining industry in Texas at present is not extensive, but the time is not far distant when the State will rank as an important coal producer. There are thousands of acres of lignite coal in several counties of Texas. The coal veins from 4 to 10 feet in thickness, ranging from 20 to 80 feet under the surface. At different places in the same section coal is found at a depth of 125 feet. The mines have no gas or firedamp, and the lignite is easily mined.

Especially conducted to be of interest and service to the men in charge of the electrical equipment

Hydroelectric Developments in Georgia

By R. C. Turner

On February 8, the 24,000-horsepower plant of the Central Georgia Power Company, located on the Ocmulgee river at Jackson, Ga., was put into commission. The first line connecting out will be the line for Macon, supplying current for operating the street-car system and electric lighting. At present only 6000 horsepower is being used, but as soon as the connections are completed to several large manufacturing concerns near the city the load on this line will be increased to 16,000 horsepower. The lines into Macon will operate at 50,000 volts and are about 25 miles long. The lines leading to Atlanta, 75 miles long, will be operated at 100,000 volts. Branch lines from this feeder will extend to Griffin, Forsyth and Monticello. The current is generated at 6000 volts and stepped up for transmission.

The plant at Jackson is the first of the three which will be developed by the company; when the other two are completed the three will be capable of delivering 100,000 horsepower. The water rights for the other two plants have been secured and will be developed as speedily as possible.

The Georgia Power Company, which controls the rights for 200,000 horsepower in the State, is rushing the work on the development at Tallulah Falls, which will be largest single development south of Niagara Falls. The water from the head level will be conducted through flumes to the power house a mile away, and will have 600 feet fall. It is estimated by the engineers in charge of the development that this plant alone will be able to deliver 100,000 horsepower. Two three-phase lines will be operated at 100,000 volts pressure and will terminate at Atlanta, 90 miles south of the falls.

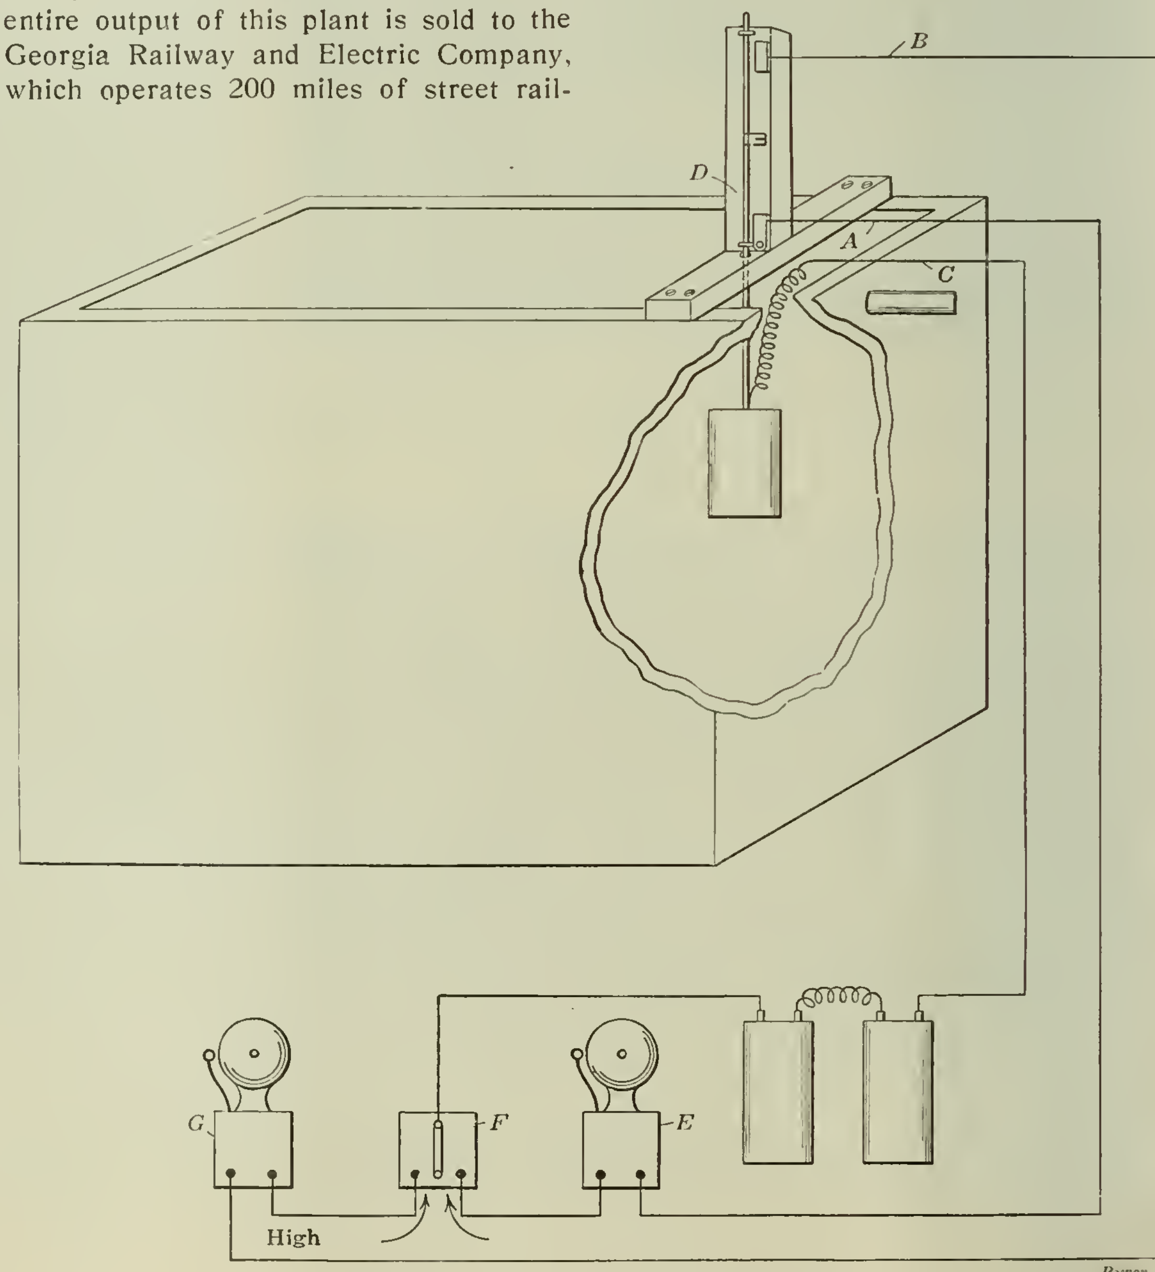
The 15,000-horsepower development of this company at Gainesville, on the Chattahoochee river, known as the Dean plant, has been completed and is supplying current to Gainesville, Buford and Norcross. A 50,000-volt line also is operated from this plant to Atlanta, 55 miles south of Gainesville. At the city limits the current is stepped down to 11,000 volts and delivered at this pressure to manufacturing establishments on the edges of the city. At Morgan's falls, 18 miles north of Atlanta, the company has in operation another plant, which has a capacity of 17,000 horsepower. Two three-phase lines terminating at Atlanta are operated at 22,000 volts pressure. The entire output of this plant is sold to the Georgia Railway and Electric Company, which operates 200 miles of street railway and a 20-mile interurban line to Marietta and also supplies current for electric lighting in Atlanta.

All the plants of the Georgia Power Company will be tied together so that a breakdown at one plant will not cause a dead shutdown. The properties of the company when fully developed will represent an expenditure of ten millions of dollars and will supply to Atlanta and vicinity 200,000 horsepower of electrical energy.

Water Tank Signal System

Most tank-signal alarms are equipped with an electric bell that rings until a switch is thrown, the signal being only for high water; but, in some instances, it is just as important to have a low-water alarm.

An alarm system for both high and low water in a tank is shown in the accompanying illustration. Two bells, a switch



Alarm System for Water Tank

and two primary cells are used. The tank is square and has a cross piece reaching from one side to the other. This piece supports a wooden upright acting as a guide to the float rod, which slides through eye screws turned into the riser. A contact spring is attached to the float rod and comes in contact with the terminal blocks of the wires *A* and *B*. A third wire

C is connected to the float rod at one end and to the batteries at the other end.

The operation is as follows: When the water is low the contact spring *D* engages with the terminal *A*. This closes the circuit through the bell *E* and the battery when the lever of the switch *F* is thrown to the right contact head.

When the water is high the contact spring *D* engages with the terminal block *B*, closes the circuit through the bell *G* and the battery when the switch *F* is thrown to the left-hand contact head.

This arrangement permits the contact spring *D* to be engaged with either *A* or *B* for any length of time, as the switch *F* can be thrown on the central contact head. This arrangement is desirable in cases where the water level remains practically stationary for several days at a time, the switch allowing the engineer to test for the hight of the water at intervals.

Brush Setting for Interpole Motors

By R. W. Wilbraham

It is a well known fact that the good performance of an interpole motor is dependent upon exactness of brush setting far more than the common shunt-wound or compound-wound motor. Some trouble lately encountered with a number of small interpole motors brings this out remarkably well. The motors were all of the same type, rated at 1 horsepower, and designed for variable speed; they were compound-wound machines direct connected to the headstocks of wood-turning lathes. The speed range was from 800 to 2800 revolutions per minute, the first part of the range being controlled by armature resistance and the latter part by field resistance.

The motors were started up by a starting box which left them running at 800 revolutions per minute. As they were speeded up, some of them upon reaching 1600 revolutions per minute would stop and reverse, running at approximately the same speed in the other direction; others would do the same thing when passing from 2000 to 2800 revolutions per minute. It was then found that the motors that reversed at the 1600 point would not reverse until they reached 2000 revolutions per minute if they were speeded up very slowly. These particular motors, it was discovered, had no oil in the bearings. Upon being oiled, they could be rapidly speeded up to the 2000 point where, like all the rest, they would reverse. After making a number of tests, the conclusion was reached that the brush position was wrong. This proved to be the case and after setting the brushes backward (opposite to rotation) about one bar the trouble was entirely remedied.

The internal magnetic actions that take place are very interesting and are as follows:

In any motor when the brushes are ahead of the neutral point, as they were at first on the motors just mentioned, the armature reactions are less than normal and, consequently, the resultant magnetic field is stronger than usual. The result is that at each successive point in the speed range the armature falls more and more below the designed speed. As the counter e.m.f. of an armature is directly proportional to the speed, there is a proportional decrease in counter e.m.f. and a proportional increase in armature current, which results in a very strong armature field the strength of which is relatively greater than the proportional increase of armature current.

In the case described, the higher speeds being obtained by field control, at the last point the field due to the field-magnet winding was very weak and the armature field very strong. The consequence was that the magnet poles were first demagnetized and then magnetized with opposite polarity, causing the motor to reverse. This reversing, as would be expected, was accompanied by sparking at the brushes due to the interpole polarity being wrong for the reversed rotation.

CORRESPONDENCE

Mr. Blue's Induction Motor Trouble

I have had the same experience with induction motors that Mr. Blue described in the issue of February 14, and I believe that his trouble can be cured by removing all the rotor conductors, thoroughly cleaning the ends of the bars and the short-circuiting rings and reassembling the structure carefully with a view to making the joints as nearly perfect as possible. The ends of the bars should be bolted to the short-circuiting rings for mechanical security and then thoroughly soldered to them to get good electrical joints. It might be well also to reinsulate the rotor bars with heavy manila paper wherever the original insulation has become worn. This will improve the torque.

J. E. Danforth.

Harrison, N. J.

In response to Mr. Blue's request in the issue of February 14 for suggestions regarding a "cranky" induction motor, I offer the following:

The facts that the motor starts in one direction on the second controller point and in the other direction only on full-line voltage indicate clearly that the trouble is in the starter. Wrong connections or, more likely, imperfect contacts should be looked for. On the day that the motor started all right but refused to take its load the starter probably failed to make contact on one phase in the running position. If it got current on both phases in the starting position it would have started and run near enough up to speed for one phase to keep it going when the lever was thrown into the running position. One phase being out and the airgap not uniform would account for its refusing to carry the load.

If the stator windings had been open-circuited it would have refused to start at all, and if they had been short-circuited the fuses would have blown.

In some instances the rotor bars become loosened from their connecting rings; in such a case the motor will refuse to carry full load. This may have been a contributing cause in this case but cannot have been the whole trouble as it does not account for the motor's behavior in starting; moreover, this trouble usually comes on gradually.

Salida, Colo.

Melville-Macalpine Gear for Direct Current Generators

The letter of Mr. Malcolm, in the February 14 issue, pertaining to Mr. MacMurchie's discussion of large gear-coupled direct-current turbo-generator sets, is unfortunately not well founded. Mysteriously the salient fact has been overlooked that the use of the Melville gear permits the most efficient turbine and generator, respectively, to be employed, obviating the compromise necessary with the two different elements on a common shaft. The deductions in the second table are manifestly illogical. Turbine kinetic efficiencies were arbitrarily assumed by Mr. Malcolm. Had a value of 50 per cent. been taken also, for illustration, it could have been shown that the geared generator would have had to possess an efficiency exceeding 100 per cent. On the other hand, a higher turbine efficiency, say 70 per cent., which is feasible, would prove the direct-driven generator to be unreasonably low in efficiency.

I infer from the conclusion reached by Mr. Malcolm that he understands that the benefit resulting from the use of the gear would indicate an improvement chiefly in the generator, while, in fact, the greatest gain in economy occurs in the turbine, and very much so in small sizes. From a commercial standpoint, however, the geared generator has the advantage of more desirable commutation speeds.

On determining the Rankine-cycle efficiency, Mr. Malcolm applied an actual water rate for saturated steam against the ideal steam consumption for 100 degrees of superheat and identical pressure conditions. The efficiencies derived are, therefore, lower than they should be, accordingly affecting the values in the second table. Furthermore, the comparison with a turbo-alternator and rotary combination has, in the estimate, several omissions, which is immediately refuted by the fact that such combinations have been installed for the express purpose of obtaining direct current immediately at the point of generation, before the large gear had been completely developed and which system was given preference over the large direct-coupled continuous-current turbo-generating unit. To my knowledge four such plants have been installed.

In looking at the first cost of the geared set disparagingly, Mr. Malcolm loses sight of the facts that standard turbines and generators may be used while for direct coupling the designs must be special.

Mr. MacMurchie's presentation of the comparison, in my mind, is entirely equitable, and is in conformity with the actual performance of the different elements.

EDWIN D. DREYFUS.

East Pittsburg, Penn.

Mr. Dreyfus' comment on my article relating to Mr. MacMurchie's paper is in error in at least one point: I did not assume any turbine efficiency in preparing the table accompanying my article; I simply took Mr. MacMurchie's figures for steam economy and worked back from them to see what would be the probable distribution of the overall efficiency between the turbine and the generator on the basis of 97 per cent. efficiency for the gear.

My assumption of 100 degrees of superheat for the turbine was based on the fact that this is commonly assumed in discussing turbine plants. If Mr. Dreyfus prefers a comparison based on saturated steam at the turbine throttle he will find it in the accompanying tables. The theoretically available energy in a pound of steam expanded adiabatically from 150 pounds pressure to the condenser pressure corresponding to 28 inches of vacuum is 319½ heat units. According to Mr. MacMurchie's figures the direct-connected unit would require 20.6 pounds and the gear-driven unit 19.3 pounds of steam per kilowatt-hour, showing overall heat efficiencies of 51.85 and 55.34 per cent. respectively. If the Melville-Macalpine gear has 97 per cent. efficiency, the geared turbine and generator must have a combined efficiency of

$$\frac{55.34}{0.97} = 57.05$$

per cent., as compared with 51.85 per cent. for the direct-connected turbine and generator.

Not knowing what Mr. MacMurchie allowed for turbine and generator efficiencies separately under the two sets of conditions I have simply presented in Table 1 a list of possible turbine efficiencies and given opposite each the generator efficiencies necessary to fit the stated overall efficiencies; in Table 2, the generator efficiency is the starting point.

Mr. Dreyfus seems surprised that I should construe Mr. MacMurchie's paper to mean that the use of the gear would permit the use of electric generators of higher efficiency. As Mr. MacMurchie's paper contained that specific statement I do not see how I could "construe" it otherwise. However, assuming that facility of commutation is the only generator advantage and that the turbine gets all of the increase in efficiency, Table 2 gives the direct comparison.

TABLE 1.

Turbine Efficiency.	Corresponding Generator Efficiencies.	
	Direct Driven.	Gear Driven.*
54	96.02	.....
56	92.59	.....
58	89.40	98.37
60	86.42	95.09
62	.....	95.02
64	.....	89.15

TABLE 2.

Generator Efficiency.	Corresponding Turbine Efficiencies.	
	Direct Drive.	Gear Drive.*
86	60.3	64.4
88	58.9	62.9
90	57.6	61.5
92	56.4	60.2
94	55.2	58.9
96	54.0	57.7

*Assuming 97 per cent. efficiency for the gear.

It is conceivable that a large turbine running at a favorable speed will show an increase of 3½ to 4 per cent. in efficiency, as indicated by the table, when compared with its performance at a lower speed. But it is also quite reasonable to suppose that the generator efficiency would suffer somewhat by a reduction in speed. I cannot imagine a turbine (other than the De Laval) of 1500 horsepower that would require such a high rate of speed for maximum efficiency as to carry the generator beyond its maximum-efficiency rate of speed.

However, that phase of the question is scarcely worth haggling over; it is within the reach of imagination that in relatively small units the use of the gear might effect some improvement in overall efficiency and an appreciable reduction in the cost of the turbine, but I believe the cost of the gear would more than eat up the gains.

The bald truth is that increased facility of commutation is the only real excuse for using anything except a direct coupling between a turbine and a direct-current generator. Whether or not that justifies the expense I am not sure; only a practical demonstration would convince me.

GEO. W. MALCOLM.

Brooklyn, N. Y.

Would It Have Been Serious?

Under the title "The Light That Failed," in POWER for January 31, Howard H. Bliss tells of a retiring operator who, through spite, filed a brass connection thin, with the idea that it would melt as a fuse when the synchronizing lamps were at full candlepower and thus extinguish them and cause the new operator to close the switch and throw two machines together when they were farthest out of phase.

I believe, however, that the probabilities of success for the scheme are very remote. In the first place it would have required very fine calculation to have enabled the man to file the brass so it would melt just when the lamps were at full candlepower. The chances are that it would either have melted too soon or not at all. In the second place it is not likely that anyone would have thrown the machines together the first time that the lamps went dark, and the fact that they stayed dark would or should have aroused suspicion and led to investigation. In the third place, had the brass melted just when the lamps were at full candlepower, they would have gone out suddenly and not gradually, as is the case when machines are near enough the same speed to be thrown together. This would or should have caused the operator to hesitate. He would have expected the lamps to light up again just as suddenly and would not have risked closing the switch. Their failing to light again would have started him looking for trouble.

I do not mean to say that it *could* not have happened as planned, but I hope that if ever anyone tries to make synchronizing trouble for me he will choose as uncertain a way as the one described; I believe that in the majority of cases, cold snap or no cold snap, that plan will result in nothing more serious than the trouble of running down an open circuit.

Salida, Colo. G. E. MILES.

John T. Nicholson, of high-speed boiler fame, in a letter to *The Engineer*, of London, upon the comparative merits of the cut-and-try method and mathematical investigation, says: "Mechanical engineering is not only an art or a craft, but it largely consists also in the application of mathematical and physical principles. Men who do not possess a good knowledge of these principles are incapable of foreseeing in what way a new apparatus will behave. They can in fact only repeat with slight and timid modifications what other engineers have done before, and as Professor Perry has said, 'By dint of expensive trial and failure they sometimes arrive at results which they might have arrived at very inexpensively if they had been better educated.'"

Gas Power Department

Everything worth while in the gas engine and producer industry will be treated here in a way that can be of use to practical men

Notes from the Gas Power Plant at Gary

Some of the engines in the mammoth power house of the Indiana Steel Company at Gary, Ind., have now been in operation over three years and it is interesting to note the experiences encountered. During the first few months there were slight difficulties, due mainly to the inexperience of the operators. One or two cylinders were cracked (but are still in operation) and some troubles from back firing and preignition occurred. It did not take long, however, for the operating engineers to become familiar with the engines and now everything is said to be running as smoothly as could be desired. The alternating-current generators have a nominal rating of 2000 kilowatts each at 80 per cent. power factor but regularly carry from 2500 to 2800 kilowatts. Units are cut in or out so as to maintain this high unit load as nearly constant as possible.

As the power is largely used in the rolling mills the load is subject to frequent variations and it may happen that an engine will be started and stopped a dozen times during the day. This is done with much facility now; it is not usually over one minute from the time an engine is ordered into service until it is on the line in parallel with the other machines. The shortest time in which this has been done is 37 seconds.

The engines operate on the waste gases from the blast furnaces and as there is available more power than is needed at the plant electricity is regularly supplied for lighting the city of Gary, for operating the water works and for private uses. In addition to this, some power is delivered to the plant of the Universal Portland Cement Company at Buffington, Ind.

The Gary power house operates in parallel with the power house of the Illinois Steel Company at South Chicago, where gas engines, steam engines and steam turbines are in operation. The junction point of the lines is at Buffington. This arrangement enables either plant to supply power to the other in case of necessity, or both can supply the cement plant.

The Boott mills, Lowell, Mass., are gradually going over to electric power, which is being bought from the Lowell Electric Light Company. The company, however, soon expects to furnish its own power.

LETTERS

Mr. Rushmore's Freak Diagrams

In the February 28 issue, Mr. Rushmore shows two "freak" indicator diagrams taken from a single-cylinder producer-gas engine. If the diagram illus-

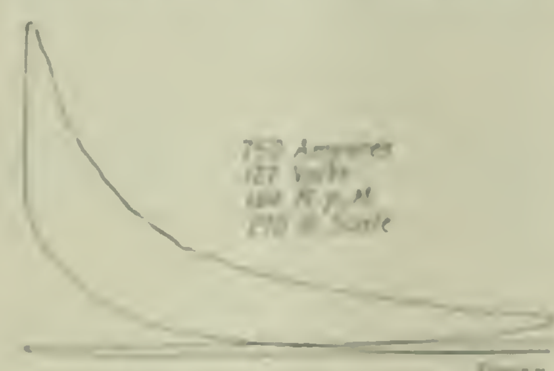

FIG. 1. NORMAL DIAGRAM

trated as "first freak" had been properly taken, the work diagram outline would have extended farther to the left, as it did in the "second freak." It is impossible for an indicator to produce a card of that kind if the external connections, springs, etc., are in good working order, unless the direction of rotation

FIG. 2. FIRST FREAK

of the flywheel is reversed, and it appears that this did not occur in Mr. Rushmore's test. I attribute the first freak to a faulty external connection, catching of the indicator cord, or sticking of the drum spring. I cannot understand why compression did not begin sooner, because by laying a tracing of Mr. Rushmore's normal diagram over the expansion curve of the first freak diagram I find they coincide almost exactly,

FIG. 3. SECOND FREAK

which means that practically the same quantity of gas and the same number of heat units were taken into the cylinder and ignited. Fig. 4 shows Mr. Rushmore's first and second diagrams superimposed; from this it can be seen how nearly the curves coincide, the dotted curve being taken from Fig. 1, his normal diagram.

I would call his second freak a case

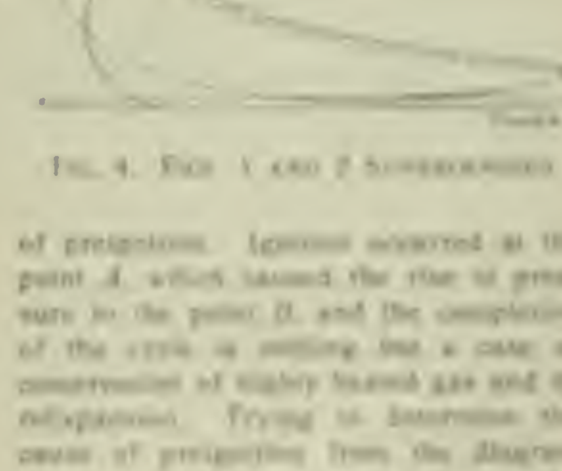

FIG. 4. FIGS. 1 AND 2 SUPERIMPOSED

of preignition. Ignition occurred at the point A, which caused the rise of pressure to the point B, and the completion of the cycle is nothing but a case of compression of highly heated gas and its reëxpansion. Trying to determine the cause of preignition from the diagram alone would be mere speculation on the part of anyone not acquainted with the engine.

W. F. SCHAPHORST.

Agricultural College, N. M.

There is no mystery about Mr. Rushmore's diagrams. Compare the length of the diagram labeled "first freak" with that of the normal diagram. It is considerably shorter, indicating that a knot or joint in the indicator cord slipped near the head end of the stroke. The diagram is not complete; the compression line is not indicated until near the end of the compression stroke and at this point the indicator cock was thrown open.

The second freak was caused by preignition due to overload. The high peak is a sign of full or overload in using a throttling governor. Ignition took place slightly before the piston reached the middle of the compression stroke and the momentum of the flywheel carried the piston against the explosive pressure, as indicated by the rising compression line. The expansion line falls below the compression line because of the loss of heat through the cylinder walls.

HAROLD DOOLITTLE.

Birmingham, Ala.

The Diesel Engine and Engineers

I read in the February 21 issue the article by Edward B. Pollister on "The Diesel Engine in Service," and I share Mr. Pollister's good opinion of the Diesel engine.

About five years ago I took charge of a large power plant in central Europe containing a 1000-horsepower horizontal cross-compound steam engine and a four-cylinder Mirrlees-Diesel engine of 225 brake horsepower direct-coupled to a 150-kilowatt generator. The Diesel engine was five years old, but it carried its load successfully with great economy, running only at night for lighting service. During my two years of service the biggest repair was a new piston for the air compressor, but I spent about ten hours every two weeks in inspecting and taking up connections and various other parts, and had the men blow out all piping and wash out all other parts with kerosene. I did not take the pistons out every time, but turned the crank over and cleaned out deposits in the cylinders with sponges and kerosene, working through the suction and exhaust-valve ports. The engine ran satisfactorily and never scored the cylinders.

I presume that Mr. Pollister understands that the Diesel engine is successful only when operated by skilled engineers who have had proper training; an internal-combustion engine, whether using gasolene, gas or crude oil, will not run with the exhaust valves opening 4 inches late or with the eccentric set 5½ inches of the stroke late, as will some Corliss engines.

I do not say that there are not skilled men in plenty; there are well trained, capable men in the United States and Canada, but plant owners cannot expect to get a well educated and skilled engineer for $70 to $75 a month to work 66 and more hours a week and be ready to respond cheerfully whenever the night engineer calls him out of bed to clear up trouble in the water or steam line, or to fix up a balky ignition system or a cranky mixing valve. Under such conditions there need be no wonder that 90 per cent. of the capable men are working at manufacturing trades instead of running power plants.

In the hands of the right sort of engineers, the Diesel engine is the most economical prime mover known.

J. G. KOPPEL.

Montreal, Can.

Generator Linings

The method of lining a gas generator described by C. R. McGahey in the February 7 issue is interesting, but I think it would be unnecessarily expensive. We set the firebrick in 8 inches from the shell and fill in behind the lining with sand. As we have no trouble, we believe the method is all right. I think, also, that this is the way it is generally done in this part of the country.

J. O. BENEFIEL.

Anderson, Ind.

Mr. Barker's Engine Speed

In the issue of February 28, Mr. Barker asks if a speed of 300 revolutions per minute is practical for a vertical gas engine of 9½ inches bore and 12 inches stroke with a connecting rod 30 inches long.

In my opinion this speed is practical. I have one 11x12-inch gas engine running at 300 revolutions per minute with connecting rods 36 inches long; also, a 12x12-inch engine running at 275 revolutions per minute with connecting rods 36 inches long. Both engines are three-cylinder verticals with long trunk pistons lubricated by splash from the crank case, and both run 12 hours per day, under about the same conditions. The crank-pin and piston-pin brasses of the 12x12-inch engine need adjusting every two days but the brasses of the 11x12-inch engine need adjusting only about once a month. The pistons and cylinders show very little wear and have been in service over eighteen months.

M. W. UTZ.

Minster, O.

The piston speed of a 9½x12-inch engine at 300 revolutions per minute is not too high, but the flywheels should not be more than four feet in diameter because at 300 revolutions per minute the rim speed of a 4-foot flywheel would be 3600 feet per minute. The safe working speed being about a mile a minute, this would leave enough margin for safety in case the engine should run away.

It is very seldom that the flywheel of a gas engine breaks from excessive speed; more often the connecting rod breaks, due to the piston being heavy and being cushioned only at one end of the stroke every other revolution.

Petroleum in Turkey

According to Consul George Horton, the importation of Russian petroleum into the Saloniki district is increasing despite Hungarian competition, which is handicapped by higher freights. As nearly as can be ascertained the imports of petroleum into this district in 1909 were as follows, in cases: Russian, 370,000; Hungarian, 50,000. The figures for 1910 will show a decided increase.

American petroleum is imported in small quantities, but on account of the higher price the demand is not important, despite its acknowledged better qualities, viz., less odor and clearer light. Before the opening of the Batum wells petroleum was exclusively imported from the United States, and the market was lost through the inactivity of the American producers; but it can be regained, and steps to this end have been taken by the purchase by an American company of a site here for tanks and a factory. This real-estate transaction has caused considerable interest here as the company was forced to pay an exorbitant price for the land. A Hungarian company had already purchased a site, but it is now rumored that it is ready to sell it and retire from the contest.

Constant Receiver Pressure

Recently I visited a power station in which there were one 24 and 48 by 48-inch and one 26 and 50 by 60-inch cross-compound condensing engine. The large engine was running with a receiver pressure of 12 pounds; in a short time they shut down this engine and started the small one and carried a receiver pressure of but 6½ pounds.

I asked the engineer why he carried 12 pounds receiver pressure on one engine and but 6½ pounds on the other. He replied that the engine with the low receiver pressure had just been repaired and that it did not require any more, but that the engine carrying 12 pounds receiver pressure was old and required repairs, so he had to carry a higher receiver pressure to make it do its work.

The engineer said that the engines had not been indicated since he had been there, some nine years, and that he guessed the engine cylinders balanced.

I told him that he ought to indicate his engines, adjust the valves, equalize the cutoffs and then work out his cards to see which cylinder was doing the most work, and, if the low-pressure side was not doing the same amount as the high-presuere side was, to shorten the cutoff on the low-pressure side and raise the receiver pressure until both cylinders were doing the same amount of work.

I have also noted that the receiver pressure of many cross-compound engines varies as much as 20 pounds. With some engines the pressure goes up when the load goes off; with others it goes up when the load comes on. I contend that if an engine is properly constructed, valves properly set and the load balanced between the two cylinders, it should maintain the same receiver pressure at no load that it does at full load, providing that the governor controls the cutoff on the low-pressure cylinder as well as on the high-pressure cylinder. If the governor controls the high-pressure side only, this is not possible, as the low-pressure side has a fixed cutoff.

When a large engine is running with a variable load and the receiver pressure varies from low pressure at no load to a high pressure at full load, the high-pressure cylinder will do most of the work until the receiver pressure is built up. With a constant receiver pressure, the instant the load is thrown on, the low-pressure cylinder is ready to do its share of the work without waiting for the pressure to be built up in the receiver.

When the load is suddenly thrown off, steam to the high-pressure cylinder is cut off shorter, less steam is taken, and the low-pressure cylinder likewise cuts off steam shorter at the same instant, keeping a constant receiver pressure. The low-pressure cylinder is ready when the load is again suddenly thrown on to do its share of work at the same instant the high-pressure cylinder takes its load.

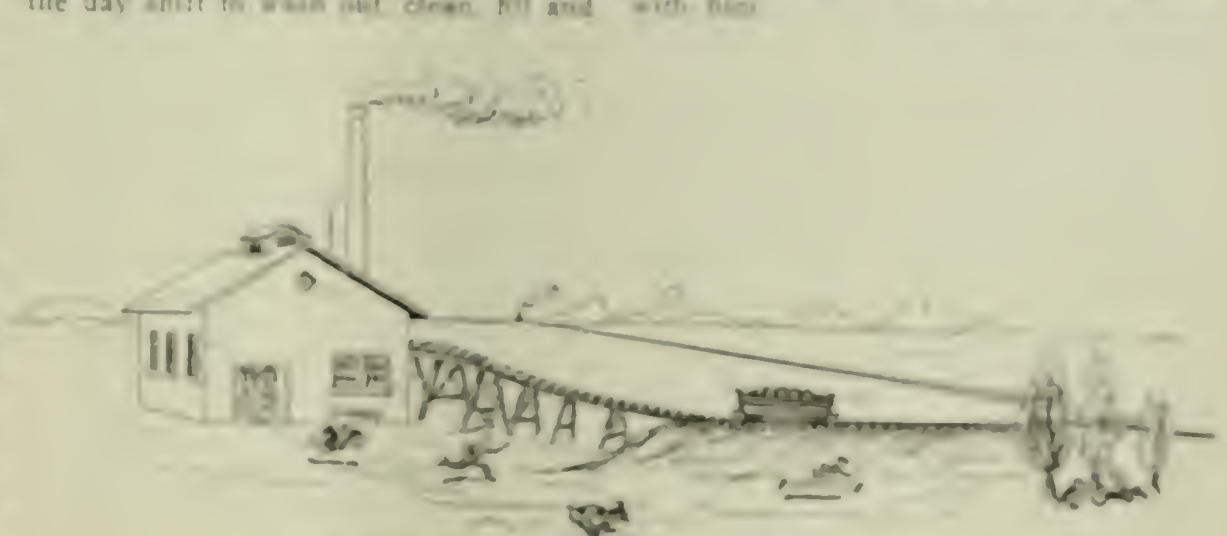
White Hot Boiler Stampeded the Firemen

In a steam plant containing 12 return-tubular boilers it is the custom for the day shift to wash out, clean, fill and prime six of the battery every Sunday; the night shift fires them up and has steam ready by six o'clock Monday morning.

Not long ago this same routine was gone through with as usual. The night shift fired up and everything went along smoothly until about 5 a.m.

These boilers are fed by mechanical stokers and each fireman feeds four stokers and attends to the feed water. The fireman at No. 7 boiler had an empty stoker and was about to refill it when he thought he would have a look at his fire. He opened the little door on the side of the stoker through which a slice bar is usually thrust and what he saw almost threw him into a fit; but he did not take time to indulge in one. With white face and standing hair he raced down the boiler room, shouting as he ran "Biler g'wine bust." The other firemen, coal and ash wheelers, seeing his white face and wild actions, surmised something was wrong, and without stopping for orders started after the leader until seven men were doing a "marathon" up the coal trestle and down the railroad track. About 1000 feet from the plant they came to a stop behind piles of railroad ties, trees and other objects and then asked the panic maker for an explanation.

What that fireman saw in that momentary glance into the peek hole was enough to "frazzle" the nerves of the most reckless shovel mechanic who ever held a scoop. The first fire sheet was hanging down to the grate bars and was white hot all over. While the fireman was informing his fellow workers of how the boiler looked, he ducked at every second word as if the expected crash was coming, and the rest would duck in unison with him.



THE FIREMEN DID NOT STOP TO ASK QUESTIONS

After about half an hour's breathless waiting for the blast that did not come, one of the firemen, braver than the rest, started back. He got to the boiler house and found the master mechanic on the job.

The boiler that had caused the scare had cooled off, for, as there was no more coal in the hopper, the grate had gradually burned bare. The boiler was at once cut out from the others and an investigation disclosed the trouble. There were two gages of water in the glass, but both gage cocks were closed. The try-pairs consisted of a new sheet and a full set of tubes.

The firemen and coal and ash wheelers came back, but the fireman who caused the stampede did not even return for his hat and coat.

What Is Wrong with the Valve?

The automatic cutoff engine, from which the diagrams shown in Fig. 1 were taken, was apparently running satisfac-

Fig. 1

torily at a speed of 215 revolutions per minute. The governor was keyed to the shaft and there was no way to shorten the valve rod except to heat it. After taking the diagram shown in Fig. 1, I

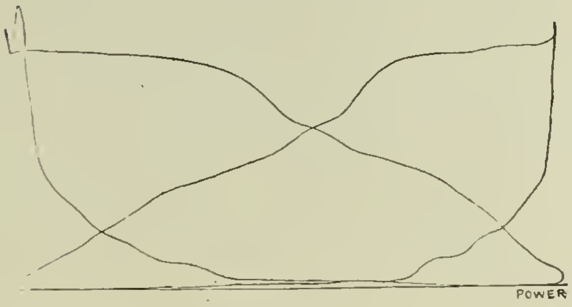

Fig. 2

shortened the rod ¼ inch and took those shown in Fig. 2.

Upon removing the valve-chest cover all that could be seen was a square piece of cast iron. I came to the conclusion

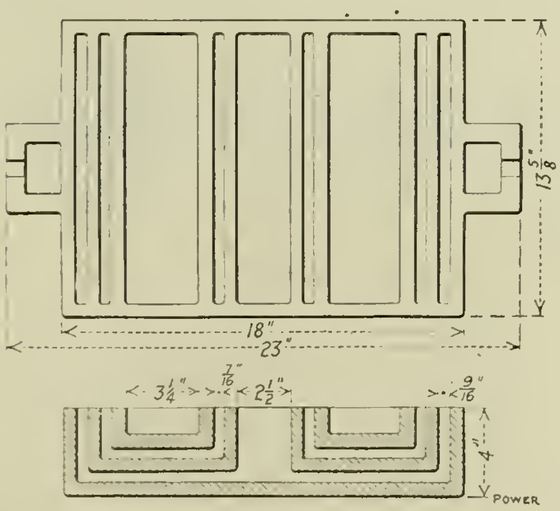

Fig. 3

that the man who invented the proposition never intended to run it. Fig. 3 shows the face of the valve. Who ever saw one like it?

Allen J. Stocks.

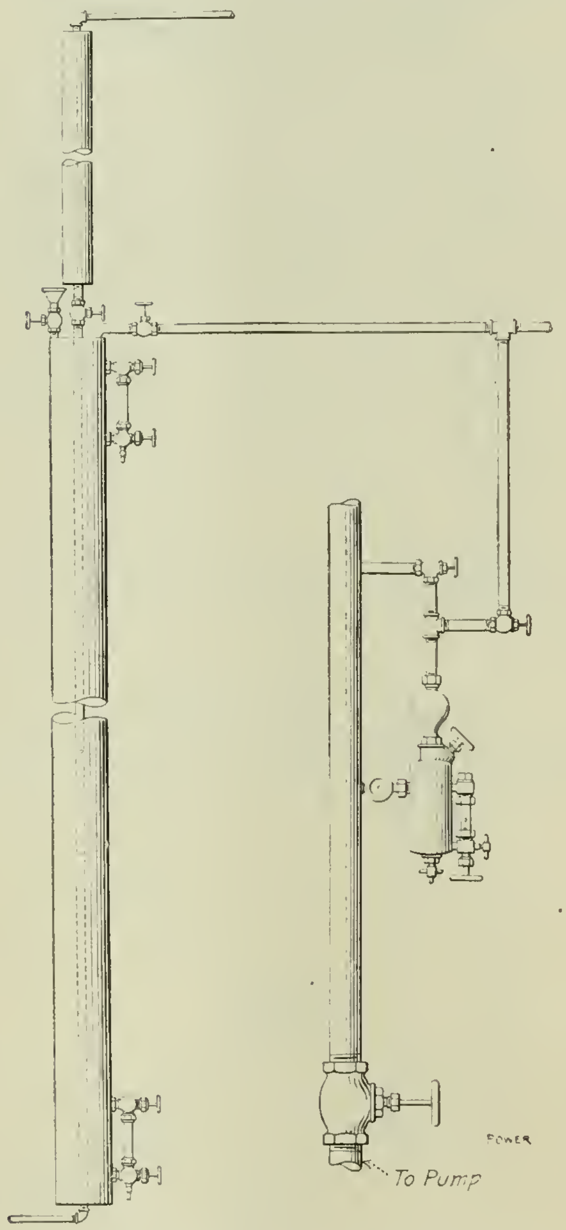
Lubricator Connections

Some time ago I took charge of a water, light and power plant in which there were ten sight-feed lubricators. The oilers always filled them to overflowing, which caused a waste of oil at each filling, amounting to about ½ pint per day. Then there were the time and waste necessary to use in cleaning up the lubricator and floor.

This loss and annoyance were overcome by using a piece of 4-inch gas pipe, 10 feet long and capped at each end to form an oil chamber. A ¼-inch hole was tapped in the lower cap for a drain pipe and a ½-inch hole drilled in the center of the upper cap. A ½-inch pipe, 9 feet



Oil Reservoir and Lubricator Connections

10 inches long, was screwed inside of the 4-inch pipe, through the upper cap. A valve was put on the upper end of the ½-inch pipe just outside of the 4-inch cap. Then 3 feet of 2-inch pipe was placed above the ½-inch valve to serve as a condensing chamber and was connected at the top to a steam header.

I also connected a ½-inch pipe in the 4-inch cap and extended it to the individual lubricators. A gage glass was placed near the top and bottom of the oil chamber to indicate the hight of oil. The main feed line is attached to each individual lubricator just above the condenser bulb by means of a tee and valve as shown.

A Makeshift Gin Pole

I was recently sent to erect a boiler and engine on a rice farm. Work went along smoothly until I was ready for the 40-foot gin pole, but none was to be found. Two 20-foot sections of 3-inch gas pipe were finally obtained and coupled together. A piece of wood was driven into one end of the pipe, to which a short crossarm was nailed to support the guy lines and hoisting ropes. As there was a derrick over a well the raising of the gin pole and stack was an easy matter.

Ernest Beck.

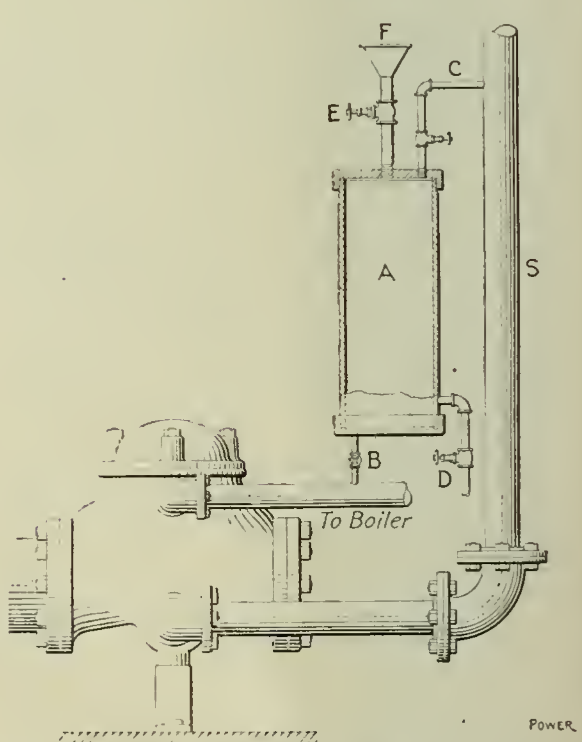
Compound Feeder

In the accompanying sketch is shown a convenient method of feeding boiler compound, where the pump receives water under pressure, as from an overhead tank.

A cylinder, which may be made from



Compound Feeder

a piece of 12-inch pipe, capped on each end, is shown at *A*. A ¼-inch pipe *B* and valve runs from the discharge of the pump to the bottom of the cylinder. *C* is a ¼-inch pipe leading from the top of the cylinder to the suction pipe *S*.

A ½-inch drain pipe *D* leads from a point near the bottom of the cylinder. *E* is a 1½-inch pipe and gate valve through which the cylinder is supplied with boiler compound.

To refill the cylinder with compound, close the valves *B* and *C* and open the valves *D* and *E*. The cylinder will drain through the valve *D*, which is then closed and the cylinder fills through the valve *E*, which is then closed and the valves *B* and *C* opened, when the apparatus is at work.

This is a particularly good arrangement for feeding soda ash as there is no possible chance for the pipe to become clogged and the force of the entering water is a great aid in dissolving the soda ash.

J. D. Chambers.

Tacoma, Wash.

Engine Needed Indicating

The accompanying diagrams are from a 16x42-inch Corliss engine running at 100 revolutions per minute. The diagrams

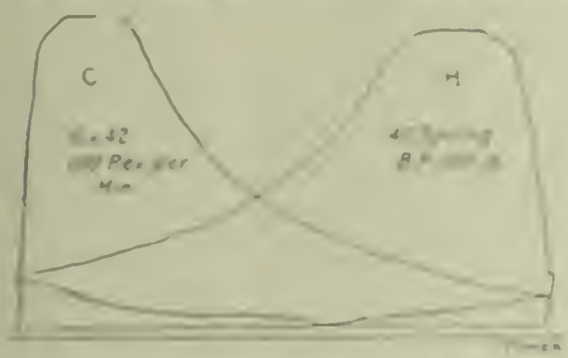


Fig. 1. Before Setting the Valves

shown in Fig. 1 were taken from the engine as I found it, and those in Fig. 2 as I left it.

I would like to have some of the indicator men figure the saving made. They

Fig. 2. After Setting the Valves

had two boilers in operation before the change and could run with one afterward. It required but 20 minutes to make the adjustments.

Pressure on Pump Plunger

If, in a single-acting triplex power pump, with the cranks set at an angle of 120 degrees, and the space below each plunger be connected with a suitable pipe, and, if this space is filled with water, can the crank shaft be turned around one complete revolution without the pressure on the water being raised, and indicated by a gage attached to the pipe? Or, in other words, will there be a constant volume during all parts of the revolution?

This problem came to me while trying to locate the cause of a breakdown on a triplex pump, which was of the piston type, but was single acting, and discharging only when the plungers were descending. The top ends of the plunger cylinders were all connected beneath the stuffing boxes, with a suitable sized port. This port was supposed to connect with the suction also, but had become stopped up.

Now the question is, if the plungers did not leak, would there be excessive pressure on top of the plunger when the pump was in operation?

B. U. Potter.

Holyoke, Mass.

A Governor Problem

Recently a governor problem came up, a discussion of which may be of interest. It is as follows:

A diagrammatic sketch of an inertia shaft governor is shown herewith, in which *A* is the engine shaft, *B* the eccentric, *C* the point of suspension of the weight arm, *D* one of the two weights attached to one end of a weight arm, the weight having a pocket so that shot may be added. *E* is the other weight, which is made up of removable plates, and *F* is the weight connected to the weight arm. The hollow part of the weight *D* was filled with shot, all of the plates were removed from the weight *E*, and 20 pounds of lead were added to the weight *F*, as shown at *G*. Why were these changes made, and what effect did they have on the speed of the engine?

After carefully analyzing the sketch it seems to me that the aim in making the change was to change the center of gravity of the weight arm so as to increase the centrifugal force and at the same time keep the inertia effect practically the same. By removing the plates from *E* and adding shot to the weight *D*, the center of gravity of the weight arm is shifted toward the weight *D*. Since the weight *E* is made lighter and the weight *D* is made heavier there is less tendency for these weights to balance each other and, consequently, the inertia effect of the weight arm is decreased and the centrifugal force is increased because the weight *D* is increased and its distance from the center *C* remains the same. Since the weight *E* was lightened the inertia effect of the weight arm was decreased and in order to make up for this inertia 20 pounds of lead were added to the weight *F*, as shown at *G*. Now the weight *F* has practically no effect on the centrifugal force of the governor because the center of the shaft, the center of the pivot *C* of the weight arm and the center of gravity of the weight *F* are very nearly in a straight line. The effect of the weights *F* and *G* is almost entirely that due to inertia; therefore, by adding the weight *G* to the weight *F* the inertia of the governor was maintained and, consequently, the sensitiveness of the governor was not lost, but by increasing the centrifugal force by shifting the center of gravity of the weight arm the power of the governor was increased.

The centrifugal force of the governor being increased, the speed of the engine

Showing Weights on Governor Arm

will be decreased because the governor will respond at a lower speed.

Scranton, Penn.

Operating a Dangerous Boiler

An old boiler, located in the oilfield of Ohio, is used to steam and pump oil about two hours in four weeks. It remains idle the rest of the time, but a small flame from a gas jet keeps the water from freezing.

One morning the boiler was fired up to steam a tank of oil preparatory to pumping it into the line. When the steam gage registered 100 pounds pressure the front head sprung a leak around the handhole plate, which promised to drain the boiler in short order.

The fireman started the injector, but seeing that the water was dropping about an inch a minute he drew the fire and, after the boiler had cooled down, an examination showed that the front head was so wasted away around the handhole that two holes were visible and the head could be punctured with a light tap with a hammer. The rivet heads of the rivets joining the head to the shell had entirely wasted away. The front head was originally [illegible] inch thick, but up to the third row of tubes showed a thickness of [illegible] inch.

This boiler is of the firebox type and of about 25 horsepower. It does not come under the license law of the State, and is fitted with an old ball and lever valve set to operate at 100 pounds pressure. It is 15 years old and has been almost continually exposed to the weather. That the boiler did not explode is a mystery, but it will have another chance, for it was patched up again and put in service at 100 pounds pressure and is doing business at the old stand.

Questions Before the House

Comment, criticism, suggestions and debate upon various articles, letters and editorials which have appeared in previous issues

Indicator Cord Hook

A hook for connecting the cord from a reducing wheel to the rod on an engine crosshead was described in the February 7 issue. I have used this form of hook and, although it serves the purpose admirably, have found that the one shown in Fig. 1 is more convenient to connect. The distance between points *A* and *B* is a trifle larger than the diameter of the rod on the crosshead. The hook is held at the head end of the engine stroke and tilted as shown so that the rod will pass between *A* and *B*, whereupon it will readily connect.

This hook cannot be used satisfactorily with high-speed engines when the reducing motion is obtained by link work. For this purpose I have used the connector shown in Fig. 2, which is made of moderately stiff wire, a little longer than the stroke of the pin prepared for cord attachment, that is, about 3 or 4 inches. To use this connector, the indicator drum is drawn to the end of its stroke by pulling on the cord *C*. The wire is then slipped over the end of the reciprocating pin so as to take the position shown in Fig. 2—the dotted circles representing the end-stroke positions of the pin. Now, by allowing the indicator-drum spring to draw the wire to the right until the pin strikes it at the end of its stroke to the left, the "hooking up" is very easily accomplished. The end of the cord *C* should then be attached to some convenient point so that it will not swing around the link motion. When disengaging the indicator, this cord *C* is used, the wire connector being pulled with it until free of the pin.

FIG. 1. CONVENIENT CONNECTOR FOR ENGINES OF MODERATE SPEEDS

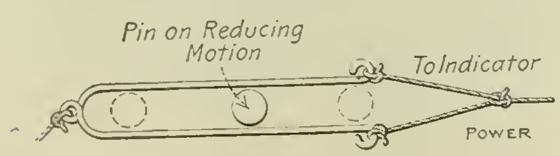

FIG. 2. CONNECTOR FOR HIGH-SPEED ENGINES

If it is found at all difficult to slip the wire in place on account of its ends being drawn together, the form shown in Fig. 3 may be used. In this case the wire is bent so that its legs have a slight spring outward which is taken up as soon as the indicator cord becomes taut. The right hand is used only to slip the wire over the pin; after this is done, the hooking up is as before.

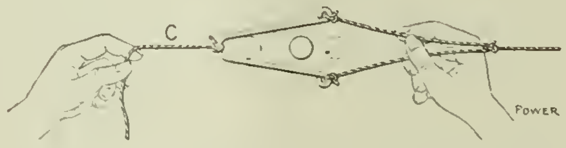

FIG. 3. ANOTHER FORM OF CONNECTOR FOR HIGH-SPEED ENGINES

JULIAN C. SMALLWOOD.

Syracuse, N. Y.

See Your Plant as Others See It

Referring to the first-page editorial in the March 7 issue, it is a good plan for a chief engineer to get away from his plant occasionally and do some visiting around among the other plants. It tends to broaden him and gives him a better knowledge of engineering matters in general. It also enables him to get many valuable ideas which he can apply in his own plant to his own and his firm's advantage. Ideas gained in this way make a lasting impression and cannot be obtained in any other manner.

Most engineers are confined so much to their own plants that they are more than likely to get into a rut and overlook many things about it which might easily be changed in a way to give better economy. As long as they do not have an opportunity to see how the engineers of other similar plants are handling them and overcoming their troubles, they are likely to continue in the same old rut to the detriment of both themselves and their employers.

When an engineer visits other plants he frequently notices things which he knows could be changed in a way to produce better results and when he returns to his own plant he is likely to find that he has the same set of conditions or a worse set. The reason why he had not noticed it before was that he had became so accustomed to it that it escaped his attention until he had traveled around visiting the other plants and got jarred out of his rut.

I believe that the best investment that a firm can make is to give its chief engineer a couple of weeks off each year with full pay and expenses and have him spend the time visiting other plants in order that he may keep uptodate.

If the engineers who are unable to get away from their plants would make it a point to ask questions of all of the traveling men who call on them, they would probably be surprised by the amount of information that they can gain in this way. A great many of the traveling men today are well posted on engineering practice, many of them having had years of practical experience in the engine room and, as they are constantly visiting plants of various kinds, they are always able to give an engineer much valuable information. In addition to getting all of the information possible by discussions with others an engineer should read as many journals and books on the subject as possible.

S. KIRLIN.

New York City.

Slipping Latch Blocks

In the February 28 issue, I read C. L. Greer's reference to slipping latch blocks of Corliss engines. Of course, the steel plates should not be allowed to become so worn that slipping off is liable to occur. It is to prevent this that daily inspection of the plates is a regular rule in some power plants, particularly in large power and lighting stations. Whenever the edges begin to get "rounded," as they call it, the plate is to be turned so that a new and square edge is presented for wear. Sometimes, though, an engineer thinks that a certain plate will last through just one more run and he allows it to remain. After running for, perhaps, three-quarters of the watch, slipping begins, much to the annoyance and disgust of those concerned. It is not desirable to shut down to effect a repair, especially as the watch is almost up, and so various things are tried to keep the engine going until it is cut out of service at the proper time.

It is better to prevent the possibility of such slipping off, but if caught during a run, try the following: Squirt kerosene oil on the plates, and the slipping will stop, or the slips will not be so frequent. Turpentine is better still and seems to have the same effect as roughening the surfaces with a smooth file. Still another expedient that I have tried is to wipe off all the oil or grease and chalk the edges of the contact plates.

CHARLES J. MASON.

Scranton, Penn.

The Pabst Verdict

In regard to the damage suit growing out of the recent boiler explosion at the Pabst brewery, I am unable to agree with the opinion of B. J. Morrison, as reported in the February 21 issue, that the initial rupture came in the main steam line and that, as a result, the water in the boiler flashed into steam, causing an overpressure and the resultant explosion. I should expect a sudden escape of steam to produce a reduction of pressure in the boiler.

Professor Breckenridge's belief that the reinforcing plates prevented the drums from conforming to a true circle seems far fetched, as his belief must be equally applicable to the reinforcing strip at the butt joint.

The lack of information regarding the general layout of the plant and the position of the points of supposed initial rupture in relation to surrounding objects precludes any reasonable judgment being formed regarding the primary cause of the disaster. The appearance and location of the several parts subsequent to the explosion tell very little of value in founding just judgment regarding the cause or source.

JOHN W. PAYLER.

Detroit, Mich.

I have just read the report in the February 21 issue of the verdict in the Pabst boiler-explosion damage suit. I was at the scene of the explosion on the morning after it occurred and examined the wrecked boilers as best I could.

If the boiler tubes had been connected into the sides of the drums instead of into the bottoms, the disaster might not have occurred. The expansion and contraction of the straight tubes caused the excessive "breathing" action and the weakening of the plates.

The theory that the steam line let go first has no substantiation in my opinion. An accident occurred to a tug-boat boiler here recently and I had a chance to observe the effects. A bridge swung around and broke off the main stop valve. The boiler did not explode, although it was rather badly distorted, and the staybolts were pulled away from the sheets.

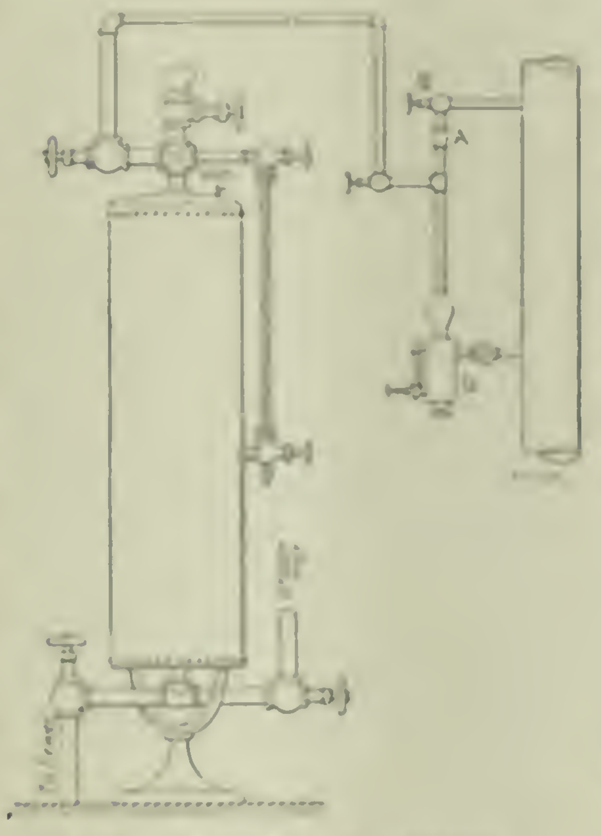
JOHN DOE.

Milwaukee, Wis.

Oil Reservoir Layout

In response to Mr. Pierce in the February 21 issue, I submit the following on a "central-station" lubricating system which I installed in a hotel. A 30-gallon tank was procured and set up as shown in the accompanying figure. The figure is self-explanatory.

Some engineers might prefer a simple sight feed instead of a complete lubricator at *G*, but I prefer using the lubricator as then the outfit is "hooked up" double. If for any reason the "central station" is out of commission, the lubri-



ARRANGEMENT OF OIL RESERVOIR

cator can be filled in the old way from "Grannie's" teapot and used as originally intended until such time as the system is in commission again. I would advise anyone who installs a system of this kind not to forget the vertical check *A*, as I have found by actual experience that valve *B* can be opened mysteriously.

CHARLES P. WEAVER.

Buffalo, N. Y.

Size of Air Chamber

In the issue of February 21, F. A. Dew wants to know about the air chamber on a power pump. I think all of the trouble is in the suction pipe and the knock or pound of which he speaks is a water ram or hammer in the suction pipe. If he will tap the top of the suction pipe for a ½-inch pipe and use either a valve or a pet cock to admit a little air, the pound will stop. The cock should be closed when shutting down the pump so as to prevent the water from going back to the well. I have tried this scheme and know that it will work.

C. E. TALLMAN.

Cripple Creek, Colo.

I have read of Mr. Dew's trouble in the February 21 issue and I would like to offer a few suggestions.

In the first place, is there a foot valve on the lower end of the suction line?

When a volume of water in a suction pipe of a pump is once set in motion it is quite important, especially when dealing with high speeds, to stop it gradually. For this purpose a vacuum chamber is often placed on the suction side of the pump. Perhaps a vacuum chamber would eliminate some of Mr. Dew's trouble.

WILLIAM A. VINSON.

Fort Logan, Colo.

In the issue of February 21, F. A. Dew requests information regarding air chambers.

As a rule for diameters I have taken three times the diameter of the discharge pipe for the diameter of the air chamber and sixteen times the diameter for the length.

Water hammering of check valves is easily overcome, if the operator will study the conditions that cause the hammering. The size of the air chamber used to overcome the hammering depends upon the amount of air that the water absorbs and the means at hand to

POSITION OF AIR CHAMBER AND METHOD OF REPLENISHING IT

refill the chamber with air. The proper point at which to install the air chamber is at some elbow near the pump, preferably on a tee in a vertical pipe in direct line with the flow of water as shown at *A* in the accompanying figure. With this arrangement the air chamber takes the direct blow of the water from the pump and then transmits it gradually to the line. The aim is to keep the water flowing as uniformly as possible.

With no pressure on the line the chamber would be full of air; with 15 pounds pressure the chamber would be one-half full of water; at 45 pounds it would be three-fourths full and at 105 pounds the air would occupy only one-eighth of the space that it did at atmospheric pressure. At high pressures the water absorbs the air very rapidly.

To refill the air chamber with air, close the suction valve and open a valve between this valve and the pump and place a hose in the short section of pipe, as shown in the figure. As nearly all pumps have two suction connections, one on either side, the one not in use can be used. By the means just described air will collect in the air chamber because the water, being heavier, will force the air to the top. The air chamber can thus be refilled whenever the check valves give the slightest indication of hammering.

C. A. Davies.

Cincinnati, O.

Advice on Giving Advice

In answer to E. L. Morris' appeal for aid in solving his radiator trouble there were several suggestions printed in the February 21 issue, each of which is adjudged by its author to remedy the difficulty and warm the cold radiator. What surprises me is to see that no two correspondents come to the same conclusion. If I were in Mr. Morris' position I believe I would be in as much of a quandary to decide which bit of advice to follow as to solve the heating problem itself.

This multiplicity of advice (often conflicting) I believe to be one reason why so few interesting problems of this kind are sent in for the consideration of the practical readers of Power; and it has been the reason, in past instances which can be pointed out, why some smart (?) writers have sent in perplexing and often ridiculous conundrums, the correct answers to which were immaterial to them, and beneficial to neither art, craft nor science. I do not wish it to be understood that the editors should restrict the number of published answers to the two or three which may agree—for, often, replies bearing little on the subject under consideration contain some instructive matter applicable to other cases—but that the editors should review the replies sent in, and at the end of a discussion issue their own advice or give some one correspondent's answer such a conspicuous position in the paper as to denote that they favor it.

If Mr. Morris should write directly to the Power editors, I do not doubt that he would receive a satisfactory solution or, at least, some kindly suggestion that would aid him to reach a conclusion which would lead to the elimination of the trouble. Now, why cannot Power make public such answers? Do the editors suppose that their own opinions would be uninteresting to the readers or do they fear criticism of their answers? Possibly they refrain because they were not asked for their own advice. Surely that is a poor extenuation, but it is more charitable to surmise this than that they forbear because of the humor derived from the diversity of opinions which are sent in.

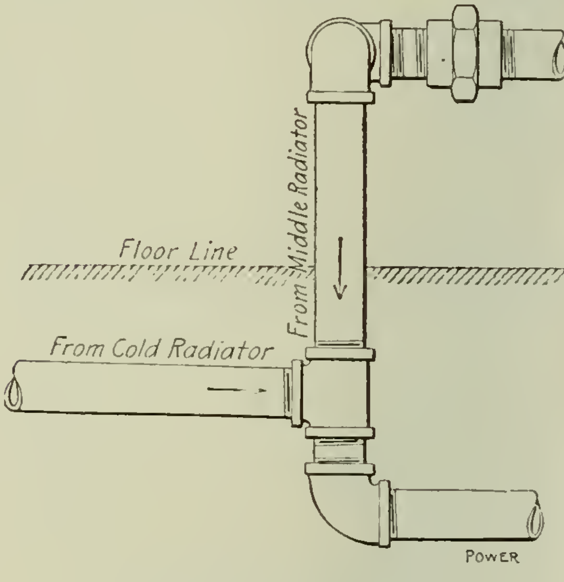
It may be considered somewhat imperious of me in giving advice as to the lines along which answers should be given to such an inquiry as the one under consideration, but it may benefit some writers who are willing to state their opinions, to learn how their advice could be made more valuable. Also, the inquirer may benefit by my endeavor to show how to glean and adopt what is valuable in the replies given. I do not proffer an opinion of my own but merely point out the facts already given by my fellow correspondents.

It is essential that the adviser place himself in the position of the inquirer and remember that the trouble must be eliminated at as little expense and with as little inconvenience to the tenants as possible; therefore, it is unreasonable to expect expensive changes to be made unless it is certain that such changes will improve matters materially. It is, then, the recipient's first duty to discover whether any of the remedies suggested are applicable to his case. Applying this principle to the case under consideration, one may infer from Mr. Noble's communication that the trouble is due to the water of condensation in the supply pipe. To test the correctness of this assumption Mr. Morris should "break" the union between the valve and the radiator and let out all of the water until steam issues freely. If now the coil heats up after reclamping the union, he would at least have found the cause but the remedy suggested—supplying an extra line of piping—may be inconvenient.

If the water of condensation flows out slowly when the union is apart, a lack of pressure may be inferred and Mr. Dixon's theory that all of the steam condenses before reaching the radiator is correct. The remedy would be either to lessen the percentage of friction by supplying larger sizes of piping, as he suggests, or to carry a higher boiler pressure. It would be well, however, first to make sure that there is no obstruction in the pipe itself. This can be ascertained by closing the valves on the other two radiators and maintaining a good head of steam on the line.

Mr. Plowman's suggestion that air-vent valves be placed on the outlet end of the radiators is good advice, but this is so well understood by the veriest novices that it is here taken for granted that Mr. Morris' radiators are equipped with them.

From Mr. McCoffin's letter it might be inferred that the water of condensation chokes the riser tee when steam emanates horizontally from two outlets. If this is the case, closing the valve of the right-hand radiator should cause the left-hand radiator to heat up. If this fails, Mr. Morris could try Mr. McCoffin's idea on the return tee of the middle radiator as shown in the accompanying figure. The condensate from the middle radiator will now have a tendency to siphon the air in any pocket that might exist in the left-hand return pipe. In any case, the arrangement is an effectual check to the backing up of the water of condensation and should be beneficial if its advantages are not offset by a too great reduction of the general angle or dip of the return pipe. To test this suggestion Mr. Morris should close the valve on the middle



Rearrangement of Tee

radiator, when, the cause of the choking at the return tee having been eliminated, the entrained water should flow freely from the cold radiator.

These are but a few suggestions whereby Mr. Morris can aid himself to detect the trouble without tearing things apart. If it be possible, answers to inquiries should contain a statement of some method whereby the suggestions which they contain may be tested without undue expense.

Low Pressure Turbines

I read with interest Mr. Fenno's letter published in the January 30 issue in which he took exception to the statements made in the catalog published by one of the turbine manufacturers. I also noted in the February 28 issue, Mr. DeGroot's attempt to disprove Mr. Fenno's analysis.

While all of the statements that Mr. DeGroot made are true and really do occur in practice, I believe that they have no application in the present instance, as the original assumptions were all made on theoretical grounds alone, that is, the comparison of the number of B.t.u. rendered available by a pound of steam expanding adiabatically from 150 pounds gage pressure to atmosphere, and the same pound expanding adiabatically from atmospheric pressure to a 28-inch vacuum, was made on theoretical grounds alone. If it was made on theoretical grounds, Mr. DeGroot's criticism is not warranted. If it was not made on theoretical grounds, the original figures, giving the amount of energy available in the two ranges of expansion, are not correct.

If a pound of steam expands adiabatically from 150 pounds gage to atmospheric pressure, it must of necessity have a quality at the end of expansion of about 86 per cent., as pointed out by Mr. Fenno. If it does not have this quality, the pamphlet referred to had no right to assume that 160 B.t.u. were rendered available for useful work. Furthermore, I do not believe that Mr. DeGroot has any right to introduce the subject of reevaporation, because if this is present then the expansion is not adiabatic, which would be contrary to the original assumption.

I also believe that Mr. DeGroot errs in introducing the subject of a drop in pressure at release, which would evaporate the wetness fraction in the steam. The original assumption being that the reciprocating engine expanded the steam adiabatically down to atmosphere, and that the turbine started with steam at atmospheric pressure, of course precludes the supposition of any drop in pressure.

As mentioned above, I believe that all of Mr. DeGroot's statements are correct, but the original assumptions do not allow the application of his argument to the case in hand. I, therefore, believe that as we are arguing solely on theoretical grounds, Mr. Fenno's criticism is perfectly just and warranted.

Organization

The first-page editorial in Power for February 21 should cause engineers to "sit up and take notice." Comment is made on the fact that economic engineers, lubricating experts and specialists of other types are used by owners of steam plants more frequently than ever before. The opinion is given that the operating engineer, who is constantly about the plant, should, and generally does, know more about the plant than any expert that can be called in.

The writer of the editorial sees no reason why a chief operating engineer should not be able to install a new plant, if called upon to do so; and, further, advises all engineers to break away from routine once in a while and view the plant as an outsider through a binocular. Such articles in theory and on paper look fine and tend to raise the pride of the "knights of the throttle," but an essential thing to determine is why the operating engineer is usually consulted at the last moment.

In the first place, the engineer in a one-man plant is usually regarded as a necessary evil. The mill cannot run without him and as his energy has disappeared in the products of the other employees there is nothing visible that he leaves behind him after the day's work that can be sold for a profit. Such being the case, the object is to get as much work out of him as possible and give him as little in return both in money and credit as he will consent to accept. The chief of a one-man plant has to use more ingenuity on and do more scheming over a two-cent job than does the average business man over the problems with which he meets in the business world.

The owner of the one-man plant demands first-class results from all the old junk that has been collected in the course of time. When these results do not materialize the engineer is immediately dubbed no good. He is asked to buy and use second-hand pumps, belting, pulleys, hangers, shafting, engines and boilers; in fact, he runs up against the second-hand proposition so often that when he begins to think of dying he more than half expects to go to a second-hand hereafter. If the second-hand goods do not look as well and give as good results as first-class new goods, the engineer is unceremoniously told that he has done a poor job and the "main guy" audibly wonders why he cannot have things looking as well and giving as good service as in some places where only first-class machinery is purchased, and he comes to the sage conclusion that it is because his engineer is no good.

There is not much doubt that the average engineer could install a new plant and is perfectly able to replace an old one without the aid of a specialist, expert or consulting engineer. But he is seldom given the same latitude that the so called expert is given. For instance, the engineer says to the boss, "We must have a separator on the steam line."

"Nonsense," is the reply, "we have gotten along for years without one and they cost money."

The boss listens to all of the engineer's arguments, gives bored attention to his data and does no more about the matter until an "expert" comes along and gives one-half the reason already advanced by the engineer and the boss "falls" for the separator.

The engineer in a plant of under 150 horsepower capacity has no routine. His work is all over the shop. He is the engineer, fireman, machinist, electrician, wireman, dynamo repairer and tender, carpenter, plumber, steam- and gasfitter, beltmaker, etc.; he must be able, ready and willing to jump in and repair any machine that may go on a strike. If he cannot or will not do any or all of these things, he is either no good or lazy or both. Now, why are things thus? There is one very good reason: the average engineer does too much and, because he does so much, he loses the respect of his employer who comes to look at him as a little higher grade man-of-all-work than the general run of "lumpers."

The carpenter, machinist and other skilled laborers in a factory do what they are hired to do and no more; and they are not asked to do more. Why? Because they have an organization back of them that defines their hours of labor, kind of labor and the wages they shall receive and the employer, if he can help it, does not care to clash with the trades union, recognizing that it is an unprofitable argument. But as the engineer has no organization back of him, the employer gives it to him for all that he will stand.

All the engineers realize their need for more and better knowledge. But, in my opinion, there is something else they need to acquire as well, and that is, "organization" knowledge. "To earn more, learn more," is a mighty fine motto, but when we find mechanics who master their trade in three or four years getting a shorter day and higher wage than the engineers, who may not hope to ever master theirs, we know that they have learned something that the engineers have not. They have learned that collective bargaining for hours and wages "knocks the spots" out of individual bargaining and, having learned, they have put their knowledge to use.

It seems to me that the engineer should take a night course in some good school that teaches organization and when he has learned a little, get together with his fellows. If he applies his knowledge of organization one quarter as well as he has his knowledge of mechanics, he will put his trade in the lead of all trades.

A Practical Compression Test

I have read with some interest the article by Charles J. Mason under the above caption in the February 28 issue. I cannot see wherein it was a "compression test" at all. He says that the engines had "considerable compression" in both high- and low-pressure cylinders and were operated under a boiler pressure of 150 pounds and a receiver pressure of 15 pounds. Now, instead of changing both compression and receiver pressures, why did not the engineer change only the compression? Then there would have been a test. But I should think that any engineer would know that 15 pounds receiver pressure with full-load conditions, the usual ratios for cylinder volumes and a boiler pressure of 150 pounds, was not a proper amount. Had the engineer simply increased the receiver pressure and left the compression just as it was, he would have made a great improvement in the efficiency of the engines.

It is unfortunate that diagrams were not shown in connection with the report of this test. The term "considerable compression" is rather vague. If the compression was excessive in both cylinders, then there was an unnatural condition, under which any amateur ought to be able to effect an improvement. This matter of compression is one on which engineers are in better agreement than they really know themselves to be. I do not know of any engineer worth mentioning by that name who defends compression as a *brake on the engine.*

Mr. Mason states that positively, the changes having been made—that is, the receiver pressure raised and the compression reduced—the engines used less steam with the same load. This may be readily conceded without even admitting that it was the result of reducing compression, although I am willing to concede that it probably helped. But how could we expect that a heavily loaded engine, with properly proportioned steam cylinders, high- and low-pressure, 150 pounds boiler pressure and only 15 pounds receiver pressure, would give satisfactory performance? How could we expect compound results from so nearly simple conditions? I think that the vast majority of engineers will agree that the increase in receiver pressure from 15 to 25 pounds caused most of the improvement.

It is quite clear that if the cylinders were properly proportioned, the high-pressure cylinders were doing most of the work during the moderate- to heavy-load periods. Naturally, one would not expect economical operation under such conditions.

To claim that this test demonstrates that the compression was or was not economical is hardly warranted. Had the receiver pressure been left as it was, that is, at 15 pounds, and the changes of valve setting made, and the test made under this condition, then we would have had something that could really be called a compression test.

William Westerfield.
Concordia, Kan.

Sizes of Turbine Steam and Exhaust Pipes

With reference to W. J. A. London's charts for selecting the size of steam-turbine steam and exhaust pipes, which appeared in Power for February 21, I agree that the curves are convenient and will save much calculation; but they are not, I consider, based on correct principles. I will confine my remarks to the size of exhaust pipes.

Mr. London has fixed on a constant velocity for all vacua down to 24 inches. This is not, I think, scientific, neither will it work well in practice. The lower the pressure of the exhaust steam, the greater is the velocity which can be employed with a given loss of head; and, moreover, the cost of reducing the velocity by increasing the section of the pipe is, with low exhaust pressures, and consequently large volumes, much greater than with higher pressures. It therefore follows that with high vacua a greater velocity should be allowed than with low vacua, other conditions being the same. Mr. London has, to a certain extent, acknowledged this by allowing a velocity of only 100 feet per second for steam exhausting at atmospheric pressure, while for vacua above 24 inches he allows 400 feet per second.

Another point should, in my opinion, be considered. The friction in a small pipe is greater than in a large pipe for the same fluid at the same pressure and the same velocity. The curves should, therefore, I believe, be based on the allowing of higher velocities with large pipes than with small ones.

I would be pleased to have Mr. London consider and criticize the following formula for the area of exhaust pipes and ducts:

$$A = \frac{W^{0.8} V^{0.5} f^{0.4}}{C}$$

where

A = Area of exhaust-steam pipe or duct in square feet;
W = Pounds of steam per hour passing through the pipe or duct;
V = Volume in cubic feet of one pound of this steam;
f = Periphery in feet of a figure of the shape of the cross-section of the exhaust pipe or duct and of an area of one square foot, and
C is a constant which for condensers for land turbines may be taken at 16,000. Where weight is of greater import or back pressure of less consequence, C may be given a higher value.

The formula was given in my paper on "The Design of Surface Condensers," which was read before the Institution of Engineers and Shipbuilders in Scotland in February of last year. It will be seen that it applies whatever be the section of the exhaust ducts. The ducts sometimes have a rectangular section. It does not matter whether W represents the weight of steam only or the combined weight of steam and water of condensation, so long as the corresponding value is taken for V.

Homemade Tube Cleaner

In the February 14 issue, E. H. Marzolf describes his homemade tube cleaner. He does not state what size of tubes he can clean with it. If he uses it for 3- or 4-inch tubes, 16 to 18 feet long, he will learn that the greater portion of the soot will accumulate near the back end of the tubes. The perforated cap at the end does scatter the steam in a number of currents and impedes the velocity, which should be as great as possible. Volume and high velocity of steam are essential to a good tube cleaner and I fail to see why he uses the perforated cap.

Emergency Pipe Repairs

I was much interested in Mr. Taylor's description of two kinds of pipe clamp in the February 14 issue.

On two occasions I stopped a leak in a pipe where it was not convenient to apply a clamp.

Fig. 1 illustrates the arrangement used in the first case. The leak was in a 2-inch feed-water pipe. Some 1¼-inch fittings and nipples were put together as shown. A 2x2-inch piece of No. 10 gage iron and some packing were placed over the leak. Then, a 1-inch nipple was placed between the valve disk and the sheet iron and the disk screwed down

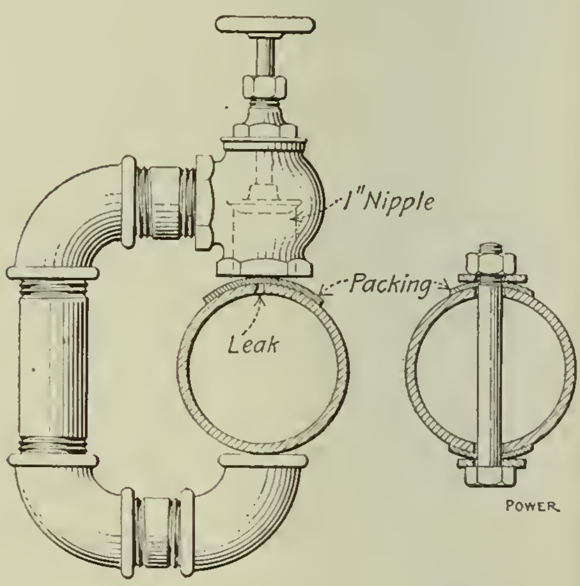

Fig. 1 Fig. 2

Two Methods of Stopping a Leak Temporarily

hard. The job lasted until a more workmanlike repair could be made.

In the second case, a leaking 2-inch feed pipe was repaired as shown in Fig. 2. I bored a hole clear through the pipe and inserted a bolt with washers and packing under the head and nut as shown. This makeshift did the trick until the pipe could be replaced.

Harry E. McArthur.
Port Blakeley, Wash.

An engineer who is envious of his neighbor's lot, because the latter has a more uptodate plant, is assuming an attitude which will hinder him in reaching the top of the ladder. As a matter of fact, in opportunity to gain experience and show his worth, he possesses a distinct advantage over his neighbor. Good equipment and ideal operating conditions never contributed toward the making of a good engineer; it is the experience gained in making the best of a poor equipment and devising means to overcome operating troubles that increases an engineer's worth.

Will an Isolated Plant Pay?

What with depreciation and amortization and obsolescence and apportionment of charges and all the other intricacies with which the modern exponent of power-plant economics cumbers up the process, the plain business man may be excused for not knowing how much his output costs per horsepower-hour or per kilowatt-year. The central-station solicitor, whose salary or commission depends upon landing contracts, will naturally try to convince him that it is costing him a great deal, and will try to charge the electrical equipment with "its share of the burden." He will want it to pay rent and part of the manager's salary, subject it to quick depreciation, make it put aside from one-tenth to one-twentieth of its cost each year for renewal and go on charging interest on the full investment, and in every way try to enhance the apparent cost.

He is not to blame. This is what he is paid for, and he may call attention to some items that might otherwise be overlooked.

But the way for a manager to look at the question is this. It is not a matter of equitable charge between departments. He does not care whether the power is the main product and the heating the byproduct or whether it is the other way around. He should say to himself, if these are the facts, "Here I have a steam plant which I must have anyhow for heating, hot-water service, etc. How much extra will I have to pay out or lose in other ways if I tack some engines and generators on to it?" If he has to rent additional room for them, if they crowd out a department which might make money, the investment should be charged with rent to that extent; otherwise not. If he has to hire more help to take care of them or has to pay the present help more, the investment should be charged with labor, otherwise not. If the manager gets more salary because there is a generating set or two in the basement or if his efficiency in other departments is seriously impaired by reason of the executive ability which he will have to bestow upon this, then the expense of management should be considered; otherwise not. There should be charged, in addition to the fuel and supplies and ordinary upkeep and repairs, the amount of engine, generator, etc., which will be used up annually. That is to say, if the machines will cost twenty thousand dollars and will be used up in twenty years, he will be using up a thousand dollars worth of machinery a year and must charge the investment with it; but he must also credit it with the compound interest on that thousand dollars which is earned every year even if it is not invested at the assumed rate but is used in the business where it earns more. He may consider the chances of obsolescence, i.e., of the machinery becoming so out of date, of something so much more efficient being produced within the assumed lifetime, that he could not afford to run it; but he must also take into account his ability to profit by that increased efficiency. If the investment figures out to pay with machinery now procurable it will certainly pay with machinery so much better as to make it advisable to scrap the old to put it in. He should charge insurance and taxes if he will have to pay any extra; otherwise not. He should charge interest at the rate at which he can get the money and not at what he could make with that amount of money in another department of the business, or on the stock market, for he can get money at the same rate for these purposes. And if with all these charges the investment promises a profit over and above what the cost from the central station would be, and the permanency of the business warrants tying up the amount of money involved for the ordinary lifetime of a plant, he is justified in making the investment; otherwise not.

The Marginal Principle

If a business were making a profit of thirty per cent. per annum on all the money which its owner could raise, he would be foolish to invest a part of such money in a steam plant which would pay a profit of less than thirty per cent. upon the investment.

This is the "marginal principle," the latest bookkeeping device of the central-station solicitor to convince the power user that he can make money by paying the central station more for current than he can make it for himself.

The marginal principle is all right, but it has been proved that a manager should sell his steam engine and electric generator to get money to put into his business than that the owner of a department store should rent instead of own his building if he can rent at any percentage of the cost of building less than the percentage of profit made by his most profitable department. If the most profitable department is capable of extension and he cannot get money at less than the profit which his electrical plant is paying, then by selling it he can make the difference between the profit made by the electrical plant and that made by his most profitable department. But a man so circumstanced can usually command capital at a less rate than that of the profit which the electrical generating machinery pays when tacked onto a steam plant which he must have anyway and operated in connection therewith.

Improve the Personnel

Myriads of articles have been written and orations delivered at great length on almost every phase of power-plant operation. Automatic devices without number and with more or less worth have been invented, patented and put on the market, with the intention of eliminating in so far as possible the reliance that would ordinarily have to be reposed in the human element. This literature has accumulated and automatics good and bad have been scrapped, while but fragmentary articles appear and desultory attempts are made to improve the efficiency of the plant through the medium of the personnel.

A code of rules, drawn up with the intention of making them fit all conditions and adaptable to all classes of humans, would be worthless and impossible to apply. Different conditions call for different treatment, and man is too complex, with moods too varied, to bring within the application of any such method; but a set of rules intended for the maintenance of discipline—and with proper discipline minor troubles will right themselves—is not only possible to enforce but absolutely necessary to the harmonious operation of the power plant.

A ship without a rudder can be managed and brought into port with a jury rudder, but a plant without discipline is a derelict.

When it is considered that no machine is so intricate as to call for the same delicacy of handling demanded by human beings and that subordinates very often kindle a feeling of resentment toward the "old man," traceable in a large number of cases to ignorance and its handmaid stubborness, it is difficult to blame the chief engineer for any continuity of a disagreeable condition. Still there are very few instances where matters could not be remedied by the application of that valuable reagent common sense reinforced with the higher degree of intelligence accredited to the chief engineer, but which is sometimes sadly lacking.

Consideration of the feelings and working conditions of the help should not be overlooked by the man in charge. Attention and care must be given to any machine if it is to work at its highest efficiency; this is applicable with double force to the human machine. It is unwise, and a dead loss to the plant, for a chief engineer to belittle the ideas of those working under him. Many a successful man owes a major portion of his success to the proper discrimination and application of such suggestions. Some engineers when they graduate from the overall class assume such an air of superiority that they consider a suggestion from a subordinate with scorn. It is such men as these that constantly prate and seem to lament the fact that they are placed in any other category than that of a profession. If those that are so particular about the cognomen of their calling would devote more time to education through the medium of engineering journals and societies, and live up to the same standard of ethics demanded of other professions, they would soon find that, according to their standard of worth, the public would put them in the class to which they rightfully belong.

It would be unjust to the chief engineer to infer that all trouble with employees could be avoided. There are men who in their mental arrangement or derangement are so constituted that no one could work amicably with them. They will malign a chief from pure cussedness, and they cannot accept a consideration of any kind from the boss with the same grace that the courtesy was extended. If any chief is so unfortunate as to secure one of this breed he will soon find that tact and diplomacy will eventually have to give way to harsher means. The man must go. Sometimes it will be noticed that two otherwise good workmen cannot work together in harmony. If the chief cannot reconcile one to the other, the wider he makes their paths of duty the more efficiency will he secure from the individual unit.

There is a class of men, and these are generally found among the ranks of assistant engineers, who resent any show of authority toward them, but who are constantly on the alert for some order from the chief that will give them the appearance of superiority. Such men as these provoke trouble in any plant, as they work on the theory of Milton's devil who preferred to rule in hell than serve in heaven.

A congenial feeling must exist between a chief and his crew if the best work is to be derived from all. This feeling on the part of the chief should not be carried to the extent of making any particular man a favorite or pet, but should be applied impartially; nor should it be interpreted by the help as meaning that they can take privileges that would not otherwise be accorded them. A medium founded on respect, courtesy and consideration can be found that will work to the advantage of the station.

Cleanliness in Power Plants

It is said that a man may be judged by his appearance, meaning by this not necessarily fine clothes but neatness. This rule applies not alone to the human element but to the machine as well. Visible cleanliness about a plant is generally an indication that the internal parts of the machines are also well cared for. This is due not only to the fact that an engineer or fireman who keeps his engine room or boiler room spick-and-span is very apt to pay due attention to the invisible parts, but also if there is no accumulation of dust, oily waste, oil leaks, etc., there is less chance of grit getting into bearings, oil getting into generator windings, or dirty commutators. Attention to such matters requires very little additional time and has a marked effect upon the life of a machine, not to mention the saving in repair bills and increased plant efficiency.

"Never use electricity to do anything that can be done equally well some other way." This was one of the maxims of the late Lord Kelvin, and it illustrates the "horse sense" that made him one of the foremost engineers of the world in addition to being one of the foremost scientists. But the "equally well" mustn't be overlooked.

Misleading or over enthusiastic statements are not restricted to American manufacturers. An English builder of suction gas producers advertises "20 horsepower-hours for 1 penny" of fuel cost, using coke; in other words, one-tenth of a cent per horsepower-hour for fuel. The claim is a trifle over 100 per cent. above the fact.

A jack operated by compressed air and capable of a ten-ton thrust was recently used by the police of New York City to break into a gambling house, forcing open a steel door. And yet it is said there is nothing new under the sun.

The business manager of a certain central station always rammed both hands deep into his trousers' pockets when he went into the generating room of the power house. He wanted to guard against unconscious contact with the teeth of a 2300-volt circuit.

A woman's club out in Nebraska has discovered that bald-headed men are "trusting and confiding by nature." Now it is plain why some engineers are buncoed with imitation goods.

Rowdyism is none the less obnoxious when it is practised by a gang of well dressed ruffians from a technical school.

Inquiries of General Interest

Questions are not answered unless accompanied by the name and address of the inquirer. This page is for you when stuck—use it

Mean Effective Pressure

What is meant by the term mean effective pressure, and how is it found?

T. L. R.

Mean effective pressure is the average unbalanced pressure urging the piston forward. There is always some back pressure tending to hold it back and the effective pressure is the difference between the forward and the back pressure. It can be determined accurately only from an indicator diagram, but when the cutoff is known, it may be approximately estimated by the use of the formula

$$M.e.p. = \left(p_1 \frac{1 + hyp\ log\ R}{R}\right) - p_b$$

in which

$m.e.p.$ = Mean effective pressure;
p_1 = Absolute initial pressure;
p_b = Absolute back pressure;
R = Ratio of expansion.

Factor of Evaporation

What is the factor of evaporation, and how is it found?

F. O. E.

It is the number by which the evaporation at any given pressure from feed water at the temperature it enters the boiler must be multiplied in order to reduce it to evaporation equivalent to that from and at 212 degrees. It is found by subtracting the number of heat units in a pound of feed water from the number of heat units in a pound of steam at the given pressure, and dividing the remainder by 970.4.

Blowing Out Boilers

Under what pressure is it best to blow all the water out of a boiler?

B. B. D.

It is best to allow the boiler and setting to cool off entirely and allow the water to run out. In this way all of the loose sediment settles in the form of mud and may be washed out by a stream of water from a hose; while if the boiler is blown out while the brickwork is hot the mud is dried, and sometimes baked into a hard mass which is difficult to remove.

Adjusting Corliss Engine Cutoff

When there is but one reach rod from the governor of a Corliss engine to the valves, how are the knockoffs adjusted?

C. I. C.

The rod extending from the governor to the first valve is made right first and then the rod connecting the knockoff of the second valve to the first is adjusted.

Movement of Valve

The shaft of an engine is 15 inches in diameter and the throw of the sheave 5 inches; then if I move the eccentric 1/4 of an inch, how much will that move the valve, providing there is no lost motion?

J. B.

Some authors use the term "throw of

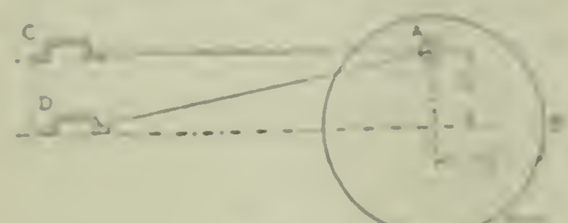

FIG. 1

the eccentric" to signify the total movement, that is, the diameter of the circle described by the center of the eccentric; others, the "throw or movement of the valve to each side of its central position"; in other words, the radius of eccentricity or the radius of the circle described by the center of the eccentric. The latter use is the more usual and it is assumed that is what is meant by the "throw of the sheave."

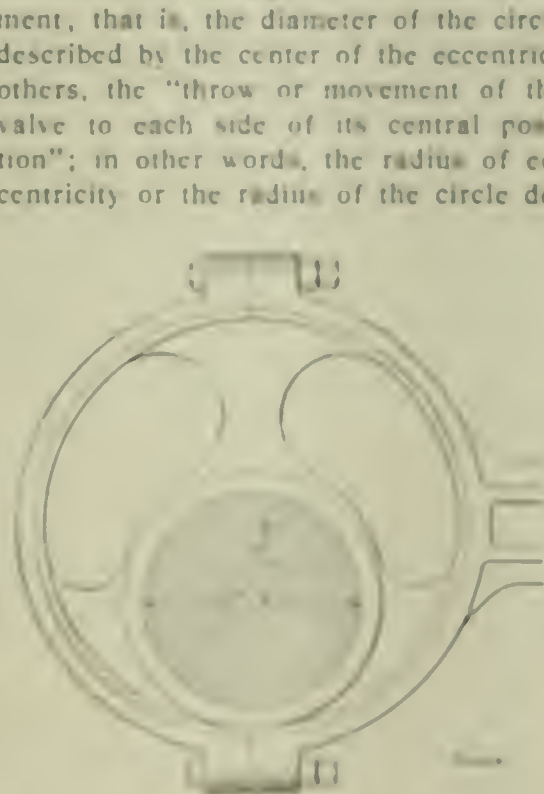

FIG. 2

Suppose a crank pin as at A, Fig. 1, in the end of the shaft, and with its center 5 inches from the shaft center. Then it is evident that the center of the crank pin A would move $\frac{5}{7.5}$ times as far as a point B on the surface of the shaft, and if the shaft were moved forward 1/4 inch the crank pin would move forward

$$\frac{5}{7.5} \times \frac{1}{4} = \frac{1}{6} \text{ inch.}$$

If this were connected off to the valve in a line square with the line connecting the centers of the crank pin and the shaft, the valve would move as far as the pin; but as soon as the angle of the crank and valve stem departs from a right angle the movement becomes less.

It is easily seen that for a given movement of the crank pin the movement of the valve would be less in the position C than in the position D, and when the crank pin gets around on the center so that the center line of the crank is in line with the valve stem, it will take a good deal of movement of the pin to make any appreciable movement of the valve.

If the diameter of the crank pin is increased until it embraces the shaft as in Fig. 2 it is seen that it is also true of an eccentric, the eccentric being but a crank with a pin surrounding the shaft.

Temporary Tube Repair

If one of the tubes in a horizontal return-tubular boiler splits or starts to leak at or near the middle of its length, how may the leak be stopped temporarily?

T. T. R.

A soft-wood plug about six inches longer than the split in the tube may be driven into the tube until the middle of the plug covers the leak. The water will cause the plug to swell and the leak will stop.

Spring Loaded Safety Valve

It is desired to change the blowing point of a spring-loaded safety valve from [illegible] pounds to [illegible]. How can it be done?

S. L. S.

By changing the spring. The springs of safety valves are not intended to operate at a variation of more than 20 per cent. from the calculated load.

Protecting Handhole Crabs

How may the nuts and crabs on the rear handhole plate be protected from the fire?

H. H. C.

By covering with asbestos or a mixture of asbestos and fire clay.

Notes on the Cost of Industrial Power

Abstract of written discussions upon the papers of Messrs. Parker and Hibner delivered at a joint meeting of the A. S. M. E. and A. I. E. E.

Mr. Peck (Rochester Railway and Lighting Company): Referring to Mr. Parker's paper, other methods of providing for amortization might be mentioned, as, for instance:

1. A yearly sum, equal to the investment divided by the number of years of expected life, should be set aside annually, allowing the variable earnings of this fund to be added to the other earnings of the company.

2. A variable yearly sum, equal to a fixed percentage of the decreasing value of the plant, may be set aside; for example, 10 per cent. of the full value at the end of the first year, 10 per cent. of the remaining value at the end of the second year, and so on. This method would never completely amortize the plant, but would more nearly represent its actual depreciation in value, and leave a relatively small amount to be charged off in one sum at the end of its natural life.

"Inadequacy" should properly be mentioned with obsolescence, as, in general, the same considerations hold good for both conditions. Similarly, "business risk" is an element of fair profit, although not always so associated in one's mind.

The depreciation rate, as fixed by Mr. Parker, on certain details, considered by themselves, is not correct when they are considered as part of a plant; for example, a building which might be in excellent condition after fifty years, probably would not be useful that length of time, nor for a period any longer than the life of the equipment in it.

I emphatically disagree with Mr. Parker's statement that obsolescence has essentially no existence in private power plants, even under stress of competition. If I purchase a plant to furnish power to operate a factory, finance it on a 20-year basis, and in five years' time improved equipment can be purchased with double the efficiency of the original apparatus, a new competitor would be able to undersell me by an annual amount equal to one-half the power cost. It would then be necessary to choose between the loss of one-half the power cost annually, or the unamortized part of the plant, less its sale value.

Considering the subject "fair profit," it should be noted that items of necessity do not have to carry their own burden of profit; for example, an ordinary business cannot be carried on without artificial heat in the winter. The total cost of heating must be carried by the profit-making parts of the business, assuming that heat cannot be purchased from a heating company. Thus the various elements making up the cost of heating must be deducted from the corresponding elements making up the cost of combined heat and power before figuring the actual cost of the power alone.

I have observed that if 100 tons of coal per month are required for heating a building, and if 100 tons are required for power alone, it is often assumed that 110 tons will be sufficient for both heat and power. Where the requirements so nearly balance, this is manifestly not the case, for the heating requirements are distributed throughout the twenty-four hours of the day with a marked peak early in the morning before the power part of the plant begins operation. The power requirements, however, are limited to from eight to ten hours a day, with the peak occurring usually during the warmer parts of the day, or during the late afternoon, when it is permissible to allow the temperature to drop slightly. This means that the coal for combined heat and power may easily amount to from 150 to 175 per cent. of the coal required for either purpose alone.

Mr. Tillman (Consolidated Gas, Electric Light and Power Company, Baltimore): Licensed isolated-plant engineers who are responsible for the entire care and improvements of the power portion of an industrial plant; consulting engineers who are to decide, plan and recommend the type and class of equipment for any given problem of their client; and the central-station industrial engineers who recommend and plan the best and most efficient layout of equipment for their customers or prospective customers, should all work together for one great and important purpose: that of giving to the man who is spending the capital a plant which will produce the greatest return upon the necessary investment.

The return on the investment cannot be estimated offhand, because it includes numerous items which must be taken under careful consideration in each and every proposition. The engineering profession demands an honest decision on all points connected therewith.

The advancement of engineering has been so rapid within the past few years that it is difficult for any one man to be thoroughly posted in all lines of engineering practice which come in the industrial-power work. It, therefore, becomes necessary to weigh all conditions from different viewpoints rather than to recommend past practices. Each and every problem has a right solution, but it requires more than guesswork to solve them and obtain efficient results.

Mr. Norris (National Meter Company): The following figures of gas-engine installation costs are presented to show the economy that can be obtained even down to small sizes when using the gas engine for power purposes. I have selected a few typical plants running on various fuels:

Plant No. 1 contains a 50-horsepower three-cylinder gas engine direct connected to a generator and running on natural gas. An 11-hour service of 300 days per year is furnished at an average load of 15 kilowatts.

Cost of plant installed	$3500	
Interest and depreciation at 10 per cent.		350
Repairs and supplies		175
Labor per year		900
Operating cost, exclusive of fuel		$1,425
Gas bill for year		$315.56
Total yearly charge		$1,740.56
Total kilowatt-hour for year		49,500
Cost per kilowatt-hour		3½ cents

Plant No. 2 contains a 25-horsepower engine belted to a 15-kilowatt generator and one 20-horsepower engine belted to a 12-kilowatt generator, both running on natural gas and furnishing light and power at approximately full load for 365 days per year at 16 hours per day.

Cost of plant installed	$4200	
Interest and depreciation at 10 per cent.		420
Repairs and supplies		210
Labor per year		700
Operating cost, exclusive of fuel		$1,330
Gas bill for year		$1,270.18
Total yearly charge		$2,600.18
Total kilowatt-hours for year		128,480
Cost per kilowatt-hour		2.02 cents

Plant No. 3 consists of one 65- and one 30-horsepower gas engine furnishing power for a manufacturing establishment and running on illuminating gas at 80 cents per thousand cubic feet.

Cost installed	$4375	
Interest and depreciation at 10 per cent.		437.50
Repairs and supplies		220
Labor per year		360
Operating cost, exclusive of fuel		$1,017.50
Gas bill for year		3,279
Total yearly charge		$4,296.50
Total horsepower-hours for year		228,000
Cost per horsepower-hour		1.89 cents

Plant No. 4 consists of one 300-horsepower anthracite producer of the suction type, furnishing gas for two vertical gas engines connected to 100-kilowatt generators; 24-hour service.

Cost installed	$22,000	
Interest and depreciation		$2200
Supplies and repairs		1100
Labor per year		2400
		$5700
Cost of fuel per kilowatt-hour		0.3 cent
Operating charges		0.4 cent
Total per kilowatt-hour		0.7 cent

Plant No. 5 consists of a 300-horsepower anthracite suction producer supplying a four-cylinder vertical gas engine connected to a 200-kilowatt generator. Fuel used: No. 1 buckwheat at $4 per ton.

Cost installed	$18,000	
Interest and depreciation		$1800
Supplies and repairs		900
Labor per year		1500
		$4200
Cost of fuel per kilowatt-hour		0.3 cent
Operating charges		0.65 cent
Total per kilowatt hour		0.95 cent

I have a record of a three weeks' run on this plant, in which the following figures may be of interest:

Total kilowatt hours furnished	19,368
Elapsed time, hours	480
Running time, per cent	36
Shutdown time, per cent	64
Average kilowatts	113.85
Percentage of full load	56.9
Coal per kilowatt hour, including all standby losses, pounds	2.36

In this run no attempt was made to meet test conditions; it represented simply the readings of the instruments and the actual amount of coal supplied to the producer during the time specified.

Plant No. 6 consists of three 200-horsepower producers, supplying one 600-horsepower double-acting tandem gas engine driving a 400-kilowatt generator. The fuel used was Texas lignite, containing 8000 B.t.u. per pound and costing $1.50 per ton delivered; 24-hour service.

Cost installed	$40,000	
Interest and depreciation		$4000
Supplies and repairs		2000
Labor per year		3200
		$9200
Cost of fuel per kilowatt-hour		0.160 cent
Operating charges		0.32 cent
Total per kilowatt hour		0.480 cent

Mr. Timmis (consulting engineer): The equipment of a certain power plant consists of three 250-horsepower water-tube boilers, two 150-kilowatt generators driven by compound engines, one 100-kilowatt generator direct connected to a compound engine, and one 50-kilowatt generator direct connected to a simple engine. Also, two 7½-kilowatt balancer sets. The cost of this outfit was as follows:

Boilers, including settings	$11,190
Engines	12,190
Generators	6,100
Balanced draft	2,325
Steam fitting, including all auxiliaries	6,378
Total cost of plant	$38,182
Cost per kilowatt	$84.85

This plant has been in operation for over three years. It was installed to accommodate a much larger load than it has been called upon to carry; with a capacity of 450 kilowatts, the average load, considering a period of one year, has been 127 kilowatts.

The following table gives the actual cost of running the plant for a period of one year from January 1, 1910, to January 1, 1911:

Wages	$5,233.84
Coal	4,417.00
Water	700
Ashes (removed)	227.21
Oil and waste	164.10
Supplies	139.77
Repairs	258.26
Interest and depreciation on cost of plant, $38,183 at 12 per cent	4,581.96
Total	$15,[illegible]

Kilowatts metered, 581,500.

Cost per kilowatt, $0.0[illegible], without interest and depreciation.

Cost per kilowatt, $0.0[illegible]12, including interest and depreciation.

During the year there were 722 hours overtime at time-and-a-half which amounted to $1024.32. This was included in the total amount under wages.

The foregoing figures include the cost of heating the building, the value of which is estimated as follows:

Coal, 785 tons	$1940.75
Two firemen, 30 weeks, at $15 each	900
Part time of chief engineer	300
Water	30
Removal of ashes	50
Interest and depreciation on boilers of 250 horsepower and disinfecting plant, $1700 at 12 per cent	208
Total	$3[illegible].75
Deducting from the total cost of running the power plant for one year the amount for heating, the cost of running the power plant is	$11,765.94
Actual cost per kilowatt-hour	$0.0[illegible]
The cost of Edison service at wholesale rates for the amount of current generated would have been	$17,000.16
As against the cost to operate plant, including all charges	11,765.94
Balance in favor of plant	$5,[illegible]

Mr. Tompkins, of the Brooklyn & Coney Island Railroad, submitted figures showing that, at the power house of this company, power is delivered at the switchboard for $0.007715 per kilowatt-hour. However, as this did not include interest upon the investment, depreciation, taxes, insurance nor *pro rata* expenses of any of the officials of the company, it is of little value in the present discussion.

Mr. Gasche (Illinois Steel Company): The element of depreciation is unquestionably subject to variant views, but the evidence of past experience of many engineers would indicate that depreciation rates are generally too low. I refer particularly to the rapid changes in the method or process which characterize an industry, thus making a power plant obsolete so far as its primary functions are concerned. To illustrate this: Twenty years ago the simple vertical, long crosshead type of blowing engine was installed at a group of four blast furnaces. About eight years after, half the group of engines was replaced by larger machines with large steam cylinders, so as to operate them as disconnected compound units. In fifteen years' time from the start they were superseded by improved forms of compound engines. About two years ago the new engines were assisted by gas-driven blowing engines using blast-furnace gas, with the implied intention of displacing all steam blowing engines. Now arises the specter of the turbine-driven blower. The point I wish to emphasize is that fundamental changes in the iron and steel business imposed these changes and not the mere "obsolescence" of the elements of the power plant. Nevertheless, they had a short life. Other lines of industry, not excepting the business of furnishing electric current, have exhibited similar crises in their development.

There is another element of growing importance in power-plant investments which may, for the want of a better name, be called "insurance on reliability." This consists of an annual charge that should be set against the gross earnings by the provision of spare units to insure uninterrupted service of the plant for any trade that may be assumed. In some cases a full examination of this "reliability" charge indicates that a mistake has been made in the installation of prime movers of excessive capacity to handle the load.

Mr. Edgerton: For the last year I have been paying particular attention to the cost of electric current as generated in private plants. I have here the data as to costs in one case that may be considered fairly typical in regard to equipment and results for equal output. The plant is of 400 kilowatts generator capacity.

Total engine and boiler-room expenses, 1909 [illegible]	$[illegible]
Total expenses for electric service	12,[illegible]
Credit for exhaust steam used for heating	5,137.2[illegible]
Net cost of 403,000 kilowatt-hours	$[illegible]
Net cost per kilowatt-hour	[illegible] cents
Interest and depreciation	0.[illegible] cent
Total cost per kilowatt-hour	[illegible] cents

The electric service includes lighting, motors driving ventilating fans and vacuum-cleaning service; also, 28.4 per cent of the heating and hot-water service. The elevator service (six elevators), pumping service, ice machine, sewage ejector and the remainder of the heating and hot-water services is from other than electric-power sources.

The cost of fuel (pea coal), was $4.20 per ton. The division of the fuel and labor accounts was based upon a series of engine indicator cards, taken over the period of a year.

I notice in Mr. Parker's paper that the selling price of central-plant current is estimated at about three cents per kilowatt-hour. In this locality that figure would not cover interest and depreciation, let alone production and distribution costs.

The rapidly revolving flywheel of a smooth running engine gives no evidence of the tremendous amount of energy stored in it, and few who have never experienced a flywheel accident give the matter a thought. Suppose, instead of a flywheel, the normal operation of your engine required a counterweight of 25 tons or more constantly suspended about 120 feet above your plant and office. Also assume that this weight, by the derangement of the machinery, might be suddenly raised to a hight of 550 feet or even a half mile and then separate in pieces of a ton or more each and fall on your plant. Do you think damage would result? The conditions assumed above are true illustrations of the destructive possibilities of a flywheel when disrupted at normal speed, or when speeded to the bursting point.—*H. E. B. [illegible] Gas Engine.*

Governing Waterwheels

The importance of refinement in waterwheel regulation has appeared only in recent years, since electrical accomplishments have made commercially practicable the development of powers previously unregarded and have imposed new and more exacting service upon those which are in use.

For years cotton mills have been driven by water powers with crude governing apparatus, often with none at all; and a cotton mill is regarded as requiring a high degree of uniformity in speed. But a cotton-mill load is also one of the most constant. If the load does not change, a wheel under constant head and gate opening will run at a uniform speed any way, and the small fluctuations made by throwing individual machines on and off are readily taken care of by comparatively simple apparatus.

When, however, a waterwheel is set to driving an electric generator, subject to abrupt and excessive load variations, the degree of regulation required by the most exacting service upon the line can be effected only by a study of conditions to which little attention has previously been paid, and by the use of refined apparatus adapted to control those conditions. A very important factor is the mass of the water already in the penstock; and when, as in many of the large Western installations, this penstock is miles in length and contains tons and tons of water in motion, a partial closing of the gate results in a conversion of velocity into pressure, a pressure generated by the momentum of the column the flow of which it is attempted to restrict, which interferes seriously with the effort of the governor to control the speed. All that the governor can do is to regulate the amount of water flowing to the wheel; but, if its movement to restrain the flow results in a virtual increase in head, its effect is minimized and a complication introduced which may set up all sorts of hunting and racing. The last meeting of the American Society of Mechanical Engineers at Boston was devoted to the presentation by William F. Uhl of his paper upon "Speed Regulation in Hydroelectric Plants," and its discussion. Although the subject is an abstruse one and the paper (which, by the way, had been previously presented at the general meeting of the society and is to be found in the February number of *The Journal*) is forbiddingly mathematical, the hall of the Edison company's building was filled and all of the time available occupied by pertinent and interesting discussion.

The governor is very materially aided by the flywheel effect of the turbine, generator and attached masses and it is often desirable to put on additional weight in flywheel form. The water will drive the shaft only at a certain maximum speed even if its flow is unrestrained. Above that speed the wheel would be running away from the water, so that a flywheel designed with an ample factor of safety for this "runaway speed" is safe from centrifugal force and not subject to practically unlimited acceleration as is the wheel of a steam engine.

Mr. Uhl explains the derivation of the simple formula for the regulation due to any given flywheel effect, and modifies it for the effect of the friction load, change of efficiency, pressure variations, etc. The time factor is of extreme importance. It takes a certain amount of energy to move a gate a given amount. If this is done in half the time, it takes twice the power. The "mechanical" governor, usually belt driven, has only a limited amount of power to expend and must therefore exert that power for a longer time to exert the energy required; and unless the governor is made inordinately massive this time is too long for close regulation with considerable gate movement. With the hydraulic governor of the type in which Mr. Uhl is interested, gates are moved by pistons actuated by fluid pressure under the control of the governor through a pilot valve, and the regulating time for all gate openings, according to the author, is nearly constant.

It is a well known fact that if penstock conditions are disturbed by moving a gate anywhere in the line, a wave will be produced which will proceed along the flume with a certain velocity. In closed penstocks these waves take the form of pressure variations. Vibrations in water travel with the velocity of sound, 4650 feet per second. The penstock walls are flexible, however, and under the influence of pressure variations expand and contract in a rather remarkable degree, producing what is called the "breathing" of penstocks. This has a dampening effect upon the vibrations, and 4650 feet per second may be regarded as the maximum velocity with which any vibrations of pressure in the contents of the penstock will proceed. The time required for a vibration to pass from the gate through the penstock and back to the gate is twice the length of the penstock divided by the rate of travel of the vibration. It is better then not to reduce the time required to operate the gate below this amount, so that the effect of the waves produced may be minimized by the countereffect of the returning waves which will then have time to get back.

A change of velocity of one foot per second will have a very considerable effect upon pressure variation; hence large penstocks and slow normal velocities, which will require small velocity changes for change of load are desirable. They also avoid loss from friction.

Efforts have been made to avoid the difficulties introduced by this impact of the moving body of water when partially arrested, by the use of pressure regulators, in which the pressure is made a factor in controlling the position of the gate. If the gates are closed suddenly and a sufficient amount to disturb the regulation on account of pressure rise, the regulator will be opened by the governor and allow water to be bypassed around the turbine sufficiently to keep the pressure rise within limits.

The pressure drop when the gates are suddenly opened is always less than the pressure rise when they are closed. It may be corrected by the use of standpipes or equalizing reservoirs, the effect of which is to reduce the effective length of the penstock. The minimum hight of such a standpipe must be such that in no case will the water level in it drop to such a point as will admit air into the penstock. Formulas are given for their design. In a plant with long penstocks where it is impossible to install a standpipe, out of the question to increase the size of the penstocks and impracticable to provide sufficient flywheel effect, recourse must be had to a synchronous bypass which discharges that part of the full-load flow of the water which is not necessary to run the turbine with the given load. The full flow is maintained in the penstock, but that not needed by the turbine is switched to the tail race. The same effect is produced in impulse turbines with deflecting nozzles. With a reduced load the flow of water continues uninterruptedly but one or more of the nozzles is deflected so that its jet is discharged into the casing without hitting the wheel.

In discussing the paper, Mr. Warren, of the Lombard Governor Company, said that they found in the tests to which they had subjected it that the formula upon which the paper was based gave results which were too high for load changes of less than 50 per cent. He called attention to the danger of whirlpools with wheels not sufficiently submerged.

The author was asked about the possibilities of electric generators, operating upon changes of voltage rather than of speed, and replied that they had been tried but never with any degree of success. In one case at least the failure was due to the use of liquid contacts and the production of depressions and elevations in the level by quickly repeated movements.

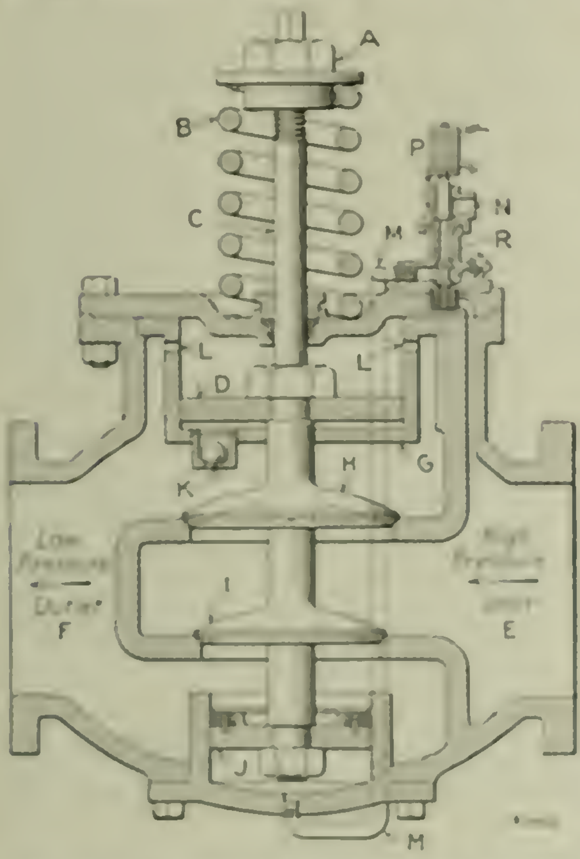
The author had referred to trouble in the draft tube produced by the persistence in its downward movement of the column after the gates had been closed, producing a vacuum behind it into which it returned when its momentum had been spent with a blow which was often productive of disastrous results. One of the auditors told of trouble experienced in the West where the water coming down from the mountain snows often had 1.5 per cent. of entrained air which, under the reduced pressure of the draft tube, assumed a greatly increased volume, and went out in gulps with closings up of the water column, which produced serious shocks. Draft tubes frequently have to be shortened on this account.

New Power House Equipment

What the inventor and the manufacturer are doing to save time and money in the engine room and power house. Engine room news

Anderson Automatic Regulating Valve

This valve, illustrated herewith in section, is shown in a closed position. When the spring *B* is adjusted by the nut *A* to the required pressure, the valve disks



Sectional View of the Anderson Automatic Regulating Valve

H and *I* are forced open. The high pressure side, or inlet, is at *E*. The outlet is at *F*. When the pressure on the low-pressure side has reached the pressure at which the valve, or spring, *B* is set, the pressure, still increasing, is exerted on top of the piston *J* (the valve *H* and piston *D* being balanced), causing the valves *H* and *I* to close.

In order to have the valve open freely and at the same time close very slowly, there is placed a ball check *K* in the bottom of the dashpot *G*. The ports *L*, placed in the upper rim of the dashpot *G*, prevent any accumulation of air while the valve is in service. The water above and below the piston *D* and the air beneath the piston *J* prevent any water hammer and cushion the valve in opening and closing.

The solenoid *P*, which controls the auxiliary valve *R*, is wired to a switch at the pumping station or any other convenient point and, in case of fire, the switch is thrown into contact, which causes the solenoid *P* to open the auxiliary valve *R*, allowing the high pressure from the inlet side of the main valve to pass up through the auxiliary valve and down through the small pipe M to the under side of the piston *J*, which causes the main valves *H* and *I* to open to the full area. When the full pressure is no longer required the switch is thrown out of contact. This allows the auxiliary valve to close and the pressure from the under side of the piston *J* returns through the auxiliary valve, exhausting through the port *N*. The pressure being released from under the piston *J*, the main valves *H* and *I* will automatically return to the regulating position without the necessity of readjusting the reducing feature.

This valve is made by the Golden-Anderson Valve Specialty Company, Fulton building, Pittsburg, Penn.

Best High Pressure Pump

This high-pressure double-acting duplex steam pump is shown in Fig. 1 and in a sectional view in Fig. 2. It is manufactured by M. W. Jamison & Co., Warren, Penn.

Fig. 1. Exterior View of Pump

Both the steam and fluid cylinders are made more than double their necessary strength. Each set of cylinders are separate castings, and are each divided into two compartments, making four distinct and separate pumping heads. The cylinders are tied together by steel rods,

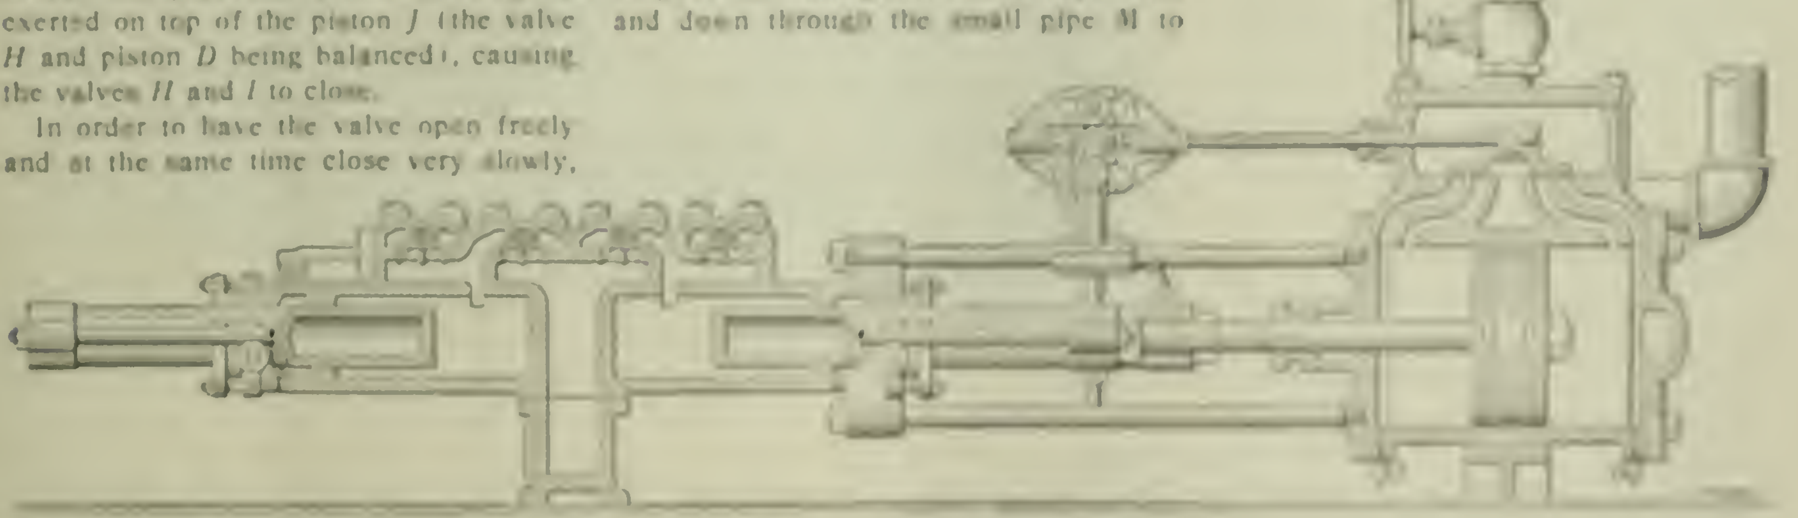


Fig. 2. Sectional View of Pump

made extra heavy, to act also as a support to the valve-motion stand. This forms a rigid construction, and yet makes it possible to replace any cylinder if such a necessity should arise.

The arrangement of the steam valves is shown in Fig. 2. The valve plate is machined to receive a valve-stem block, which is finished to allow no play or lost motion. The stem instead of being run through the valve plate and held by a nut is grooved at the end and held in the block by two set screws, the groove making slipping impossible. This arrangement permits the taking out of a valve with the least possible delay. All adjustment is effected outside at the valve yoke by means of set screws held firmly by jam nuts. The motion levers and rocker shafts are situated between the valve stems, thus placing all moving parts out of the way of the operator as well as making it more compact and neat in appearance.

The distribution of the steam, owing to the proper location of the steam ports and to the valve motion, causes the pump to cushion at the end of each stroke regardless of the speed, steam pressure or pressure against which the pump is working. No cushion valve is used, and the pump has a uniform stroke regardless of the pressure.

All water valves are of the self-adjusting, hardened-bronze type, and seat on an absolutely flat hardened-bronze seat. The valve is guided and held in position by a stem situated on the top of the disk. This stem is bored out to receive the spring and operates in a guide cast in the valve cover and projecting down over it. This arrangement completely incloses the spring and makes it impossible for a broken spring to get free and cause trouble. In addition to this, four lugs or wings project down from the bottom of the disk to assist in guiding the valve. The wings are turned off to allow the valve sufficient play to allow a free passage of any foreign matter without breaking the valve. This arrangement for guiding the flat valve with the valve seat allows it to adjust itself perfectly to all wear and makes troublesome grinding unnecessary. Each valve has a separate cover, making it easy to get at each valve independently.

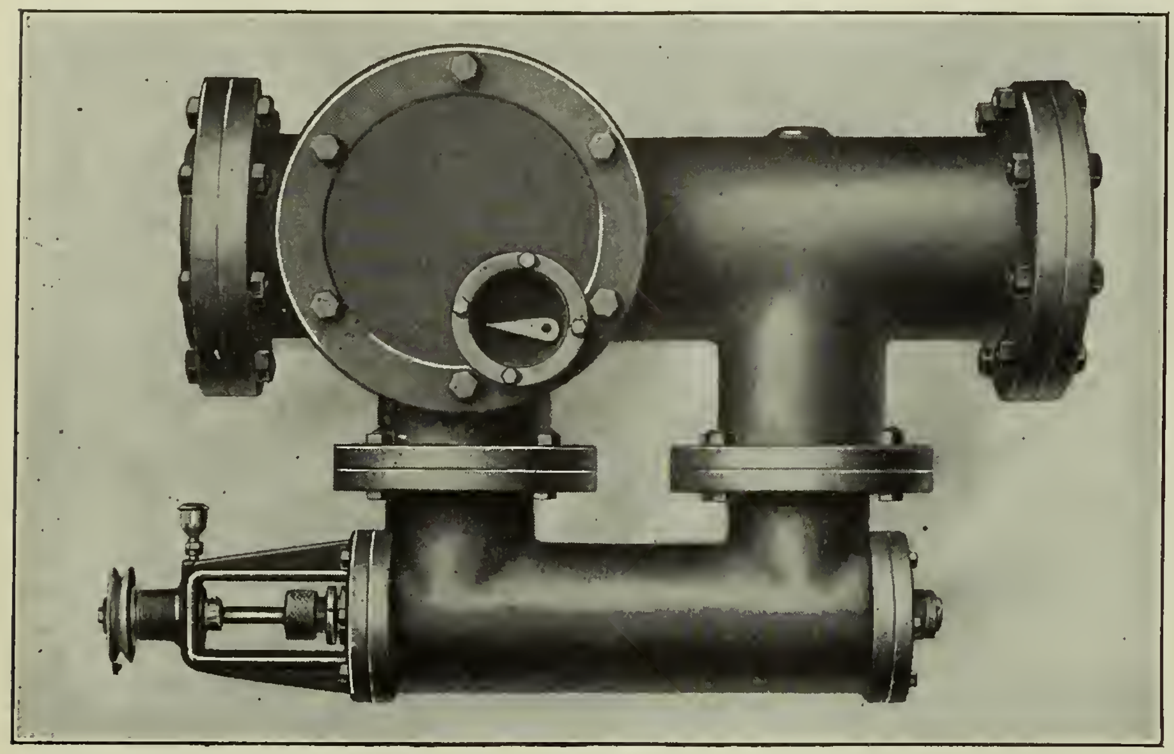

Fig. 1. Belt-driven Water Circulator

The plungers, four in number, are of the outside-end packed type. They are cast in one piece, with extra-heavy flange on the back ends to receive the steel trombone rods which operate the rear plungers. The rods are supported by rollers to secure a perfectly straight and rigid pull and thrust. The power pistons are screwed directly into flanges on the power end so that that end of the pump may be operated independently of the rear end. The plungers are turned and ground perfectly smooth, insuring long life to the packing and preventing loss in fuel by leakage. Plungers may be made brass covered, if desired.

This pump is built to withstand a pressure of from 800 to 1000 pounds.

The Castle Automatic Water Regulator

Recently, hot-water heating systems have been improved by means of a circulating device known as the Castle automatic circulator. It is built in two types, belt driven and with the motor direct coupled to the shaft of the circulator, as shown in Figs. 1 and 2.

This device consists of a small propeller set in the branch pipe that is bypassed from the main return to the boiler and operated by a small electric motor. When ordinary gravity circulation suffices, the circulator is not operated, and it is only necessary to switch off the motor to cut out the circulator. As soon as the propeller ceases revolving an automatic valve cuts off the branch pipe and the water, in returning to the boiler, travels along the main return pipe exactly as though the circulator were not attached to the system. As soon as it becomes necessary to hasten the circulation the motor is switched on, the propeller revolves and the automatic valve takes up a new position, cutting off the main return pipe so that all the returns must necessarily go through the branch pipe and past the propeller.

There are no valves to be set and no attendance is necessary beyond the mere starting and stopping of the motor. In many installations the motor switch is placed at some distance from the circulator. Under ordinary conditions of hot-water heating the circulation depends upon the difference in temperature between the supply and the return lines, and opposed to the difference in head between the two sides of the system is the friction in long lines of pipes, fit-

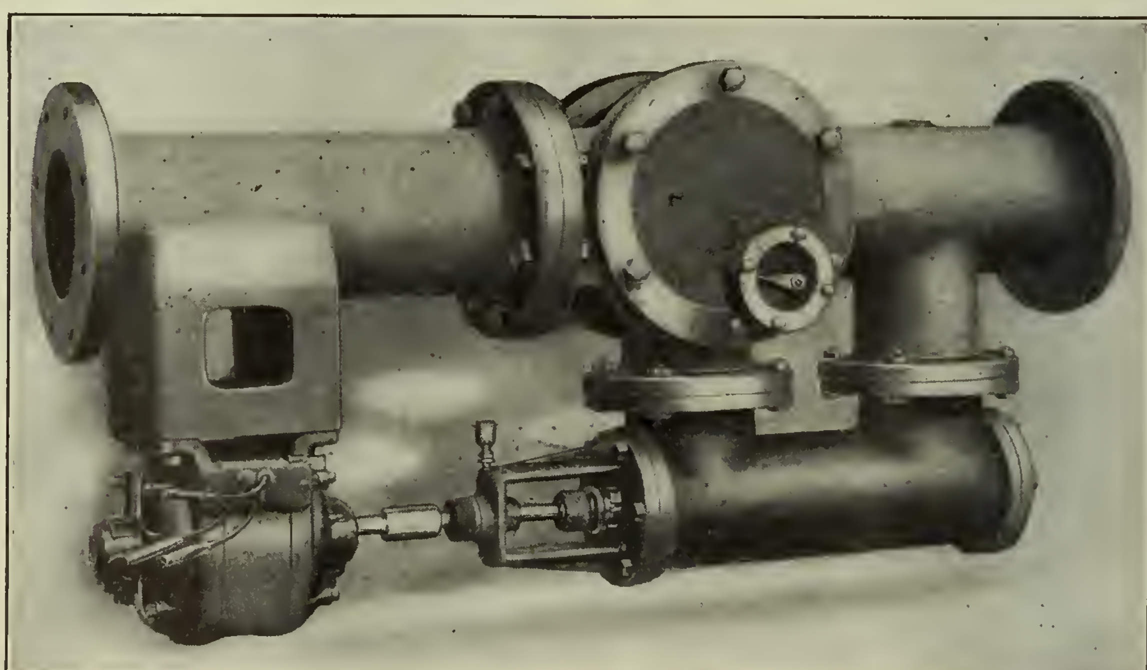

Fig. 2. Motor-driven Water Circulator

tings and valves. By circulating the water rapidly, the returns are but a few degrees lower in temperature than the supply lines; consequently, less coal is used to heat them again and the rapid circulation insures the greatest possible efficiency of the radiating surfaces. This rapid circulation is produced by the Castle circulator. It is small in size and design and requires but little power to operate it. It need be run but a short time per day and as soon as it is stopped, expenses cease. Sudden temperature drops are met by the circulator and it is not necessary to maintain an extra hot fire.

There are many actual examples of coal saving by means of this system. Unsatisfactory results from heating systems installed with piping of insufficient size or with many sharp angle turns can be prevented. This circulator is made in three sizes and is manufactured by the American Auxiliary Heating Company, Boston, Mass.

Sea View Plant Changes Hands

Among the improvements to be made by the Sea View Railroad Company, which has recently been purchased by President Sherman, of the Providence & Danielson Railroad, will be the enlargement of its power plant. A new 500-horsepower Babcock & Wilcox boiler has been ordered, and a new 125-foot brick chimney will be erected, to supplant the two sheet-iron stacks now in use. When the new boiler is installed the plant will have a capacity of 1400 horsepower. The Sea View company operates a trolley line from East Greenwich to Wickford, Saunderstown, Narragansett Pier and Wakefield, R. I. The main office is in Providence, R. I.

Institute Organizes First Branch

The members of the Institute of Operating Engineers of New York City and vicinity, with the exception of the Long Island members, met at the national headquarters on Saturday evening, March 18, and organized the first branch in New York State, which will be known as Branch No. 1 of District 2 of the I. O. E.

The election of officers resulted as follows: Branch chairman and branch representative, Willis Lawrence, chief operating engineer of the Interborough Rapid Transit Company; secretary-treasurer, W. P. F. Hill, chief engineer, Woman's Hospital; chairman of committee on education, F. C. Flickinger; chairman of committee on apprenticeship requirements, L. M. Glodell, chief engineer in the United States Express Company building.

Thirty-five members of the branch were present at the meeting and much enthusiasm was shown by the speakers. The organization starts out with about 80 members all told, and will in the future conduct the New York City meetings for the presentation of papers.

New Chemists' Building

The Chemists' building, which was inaugurated on March 17 at 50 to 54 East Forty-first street, New York City, is believed to be the first of its kind in the world. It combines the features of a first-class club, including restaurant and members' bedrooms, with finely equipped laboratories for analytical and consulting chemists and for investigators in pure and applied science, not to speak of a carefully planned scientific lecture room, a large library and scientific museum.

The building occupies 50x100 feet and cost upward of half a million dollars. It is owned by a stock company, whose shares have been taken by prominent chemists and by individual manufacturers and companies whose business largely depends upon chemical process, and who have realized that industrial progress depends upon scientific research. While it is expected that the building will be more than self-supporting, the shareholders limit themselves to 3 per cent. dividends, all surplus to be devoted to the betterment of the building and to the ultimate benefit of the science. The chief tenant is the Chemists' Club, which occupies the lower half of the building.

Engineering Societies Protest to Public Service Commission

A committee representing five engineering organizations—the International Union of Steam Engineers, the National Association of Stationary Engineers, the Marine Engineer's Benevolent Association, the New York Engineer's Protective Society and the Blue Room Engineering Society—have presented a letter to the Public Service Commission and to Mayor Gaynor protesting against the alleged discriminating rates employed by the New York Edison Company. It was claimed that nearly one-half of the electric current sold in the Boroughs of Manhattan and Bronx by the Edison company is charged at a rate over 300 per cent. greater than the average rate charged for the remainder, and that 40 per cent. of the total current sold is disposed of at a rate less than the pro rata interest and depreciation charge; hence these charges are carried by the small consumer paying 10 cents per kilowatt-hour. Accompanying the letter of protest was a petition signed by over two hundred and fifty small consumers, asking for legal action to prevent the alleged discrimination.

Nearly 400 employees were thrown out of work for about two days by the blowing out of the cylinder head of the main engine at the Consumers Rubber Company's factory at Bristol, R. I., on March 15. A new head was cast in Providence.

NEW PUBLICATION

MATHEMATICS FOR THE PRACTICAL MAN. By George Howe. Published by D. Van Nostrand Company, New York, 1911. Cloth; 143 pages, 5x8 inches; 42 illustrations. Price, $1.25.

Beginning with the fundamentals of algebra, elementary geometry, plain trigonometry, analytical geometry and calculus are taken up in order. The book has been kept within the limits of its title and no attempt has been made to go deeply into these subjects, only such portions being covered as are essential to the needs of the engineer. The author is to be complimented upon the simple yet adequate treatment of the subjects, which should enable anyone of ordinary intelligence and having a fair knowledge of arithmetic to acquire a working knowledge of them. Having made such a good start, it is to be regretted that the author did not go a step farther and include a number of engineering problems showing the application of the pure mathematics to the practical cases. This would have materially increased the value of the book to the practical engineer.

SOCIETY NOTES

On Thursday evening, April 13, the regular monthly meeting of the Institute of Operating Engineers will be held in the Engineering Societies building, 29 West Thirty-ninth street, New York City, commencing at 8 p.m. sharp. J. C. Jurgensen will deliver a paper on the "Economical Aspects of the Institute of Operating Engineers." This will be discussed by prominent engineers.

The American Electric Railway Manufacturers' Association announces the opening of the offices of this association at room 1002, 165 Broadway, New York City. This office will be the official headquarters of the association, and all members are cordially invited to visit same, out of town members being welcome to use this headquarters for the receipt of their mail and for carrying on correspondence, etc., while in the city.

The problem of making the earth yield an increase adequate to supply the needs of the population will be considered on Tuesday evening, April 11, at a meeting of the American Society of Mechanical Engineers, in the Engineering Societies building, 29 West Thirty-ninth street, New York, when a paper upon the "Economic Importance of the Farm Tractor," by L. W. Ellis, will be presented. Following this paper, Dr. Charles E. Lucke, professor of mechanical engineering of Columbia University, will give a talk on the mechanical equipment of farm tractors which will be illustrated by views taken last summer at the Canadian industrial exhibition held in Winnipeg, Manitoba.

The Cleveland branch of the American Chemical Society at its March meeting was addressed by W. R. Hulbert, manager of sales, Goldschmidt Thermit Company, on the thermit-welding process. In addition to a general description of the process and its various applications, with lantern slides, Mr. Hulbert gave a demonstration of thermit welding, comprising a number of experiments to show how the process is used commercially for repairing wrought-iron and steel sections, and for welding pipes up to 4 inches in diameter. Much interest was shown in the demonstration, which was witnessed not only by the local members of the American Chemical Society, but by members of the American Society of Mechanical Engineers and others who came from cities as far out as Akron and Lorain and towns in the vicinity of Cleveland.

PERSONAL

The Crocker-Wheeler Company announces the appointment of Clarence E. Delafield, *vice* R. N. C. Barnes, resigned, as district manager with headquarters at the company's offices in the Boston Safe Deposit and Trust building, 201 Devonshire street, Boston, Mass.

H. H. Laughlin has been placed in charge of the branch office recently opened in Pittsburg, Keystone building, 324 Fourth avenue, by the Richardson-Phenix Company, of Milwaukee, Wis. Mr. Laughlin has been with the Richardson-Phenix Company for several years and is familiar with the methods of lubrication of all kinds of machinery.

At a recent meeting of the board of directors of the Pawling & Harnischfeger Company, Milwaukee, Wis., S. H. Squier, who has been with the company for a number of years, was elected secretary and a director of the organization. W. H. Hassenplug, sales manager, was elected a director and second vice-president, and F. P. Breck, also associated with the company for many years, was elected a director.

NEW INVENTIONS

Printed copies of patents are furnished by the Patent Office at 5c. each. Address the Commissioner of Patents, Washington, D. C.

PRIME MOVERS

TURBINE. Gustaf de Laval and Ernst Elis Fridolf Fagerstrom, Stockholm, Sweden. 986,472.

INTERNAL COMBUSTION ENGINE. Nelson Edward Davies, San Francisco, Cal. 986,552.

ROTARY ENGINE. Thomas H. Lindley, Cedar Rapids, Iowa, and Herman Schreier, Sheboygan, Wis. 986,636.

ROTARY ENGINE. William L. Merrill, Portland, Me. 986,641.

WAVE POWER GENERATOR. Robert Max Morius, San Diego, Cal. 986,740.

WAVE AND CURRENT MOTOR. Joseph T. Cross, San Francisco, Cal., assignor to Frank H. Howard, San Francisco, Cal. 985,802.

FLUID-OPERATED TURBINE. Eric Brown, Baden, Switzerland. 986,902.

CURRENT MOTOR. Lincoln Guynn, Seattle, Wash. 986,919.

ROTARY STEAM ENGINE. Robert I. Miller, Sandusky, Ohio, assignor of sixteen and one-third one-hundredths to William F. Thomas and sixteen and one-third one-hundredths to William J. Duffy, McMechen, W. Va., and sixteen and one-third one-hundredths to Martin J. Malooley, Wheeling, W. Va. 986,932.

TURBINE. Charles Algernon Parsons, Newcastle-upon-Tyne, England. 986,942.

STEAM ENGINE. Nathaniel Greene Herreshoff, Bristol, R. I. 986,982.

BOILERS, FURNACES AND GAS PRODUCERS

STEAM-GENERATING PLANT. Minott W. Sewall, Roselle, N. J., assignor to the Babcock & Wilcox Company, Bayonne, N. J., a Corporation of New Jersey. 986,648.

STEAM-GENERATING PLANT. Minott W. Sewall, New York, N. Y., assignor to the Babcock & Wilcox Company, Bayonne, N. J., a Corporation of New Jersey. 986,649.

ARTIFICIAL-GAS BURNER. Jacob Weintz, Cleveland, Ohio, assignor to the Strong, Carlisle & Hammond Company, Cleveland, Ohio, a Corporation of Ohio. 986,663.

HYDROCARBON BURNER. Virgil H. Mills and John H. T. Mills, Hubbard, Tex. 986,739.

STEAM BOILER. Charles William Todd, Manchester, N. H., assignor of one-third to Lewis W. Crockett, Manchester, N. H., and one-third to D. Arthur Burt, Boston, Mass. 986,876.

MECHANICAL STOKER. Levi F. Torrey, Buffalo, N. Y., assignor to Margaret E. Torrey, Buffalo, N. Y. 986,877.

FURNACE. Carl Wegener, Berlin, Germany. 986,881.

FURNACE. Harry Moor, Philadelphia, Penn. 986,934.

HYDROCARBON BURNER. Rudolph Hoffman, Battle Creek, Mich., assignor to American Stove Company, St. Louis, Mo., a Corporation of New Jersey. 987,067.

POWER PLANT AUXILIARIES AND APPLIANCES

VALVE MECHANISM. William K. Rankin, Philadelphia, Penn., assignor to John E. Reyburn, Philadelphia, Penn. 986,592.

AUTOMATIC DAMPER REGULATOR. William J. Turner, Providence, R. I., assignor to Putnam Foundry and Machine Company, Providence, R. I., a Corporation of Connecticut. 986,658.

THERMOSTATIC VALVE. Frederick W. Robertshaw, Pittsburg, Penn. 986,760.

ENGINE GOVERNOR. John W. Sargent, Providence, R. I. 986,762.

VALVE. Conrad C. Schoeneck and Ivar F. Warme, Syracuse, N. Y. 986,765.

STEAM, AIR AND WATER-TRAP VALVE. John E. Boegen, Berwyn, Ill., assignor to Charles P. Monash, Chicago, Ill. 986,797.

CENTRIFUGAL PUMP. Franklin H. Jackson, West Berkeley, Cal., assignor to Byron Jackson Iron Works, West Berkeley, Cal., a Corporation of California. 986,827.

LUBRICATING DEVICE. John Christopher Nichol, Ottawa, Ontario, Canada. 986,849.

ELECTRICAL INVENTIONS AND APPLICATIONS

ELECTRIC SWITCH. Horace Hull, Denver, Colo. 986,714.

DYNAMO ELECTRIC MACHINE. Carl M. Page, Chicago, Ill., assignor of one-half to Horace D. Reynolds, Chicago, Ill. 986,748.

ELECTROPLATING MACHINE. John W. Heaphy, Philadelphia, Penn. 986,823.

ELECTRIC SWITCH. Columbus Woods and Whitman H. Sayles, Peoria, Ill. 986,958.

SAFETY COUPLING FOR ELECTRIC CONDUCTORS. Angel Belgorder, Mexico, Mexico. 987,036.

DYNAMO ELECTRIC MACHINE. James Burke, Erie, Penn., assignor to Burke Electric Company, a Corporation of Pennsylvania. 987,044.

POWER PLANT TOOLS

WRENCH. Peder Roisum, Edmore, N. D. 986,593.

LIFTING JACK. Jotham B. Taylor, Auburn, N. Y. 986,781.

JACK. Ralph F. Schofield, Olathe, Kan. 986,868.

ENGINEERING SOCIETIES

AMERICAN SOCIETY OF MECHANICAL ENGINEERS

Pres., Col. E. D. Meier; sec., Calvin W. Rice, Engineering Societies building, 29 West 39th St., New York. Monthly meetings in New York City. Spring meeting in Pittsburg, May 30 to June 2.

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS

Pres., Dugald C. Jackson; sec., Ralph W. Pope, 33 W. Thirty-ninth St., New York. Meetings monthly.

NATIONAL ELECTRIC LIGHT ASSOCIATION

Pres., Frank W. Frueauff; sec., T. C. Martin, 31 West Thirty-ninth St., New York. Next meeting in New York City, May 29 to June 2.

AMERICAN SOCIETY OF NAVAL ENGINEERS

Pres., Engineer-in-Chief Hutch I. Cone, U. S. N.; sec. and treas., Lieutenant Commander U. T. Holmes, U. S. N., Bureau of Steam Engineering, Navy Department, Washington, D. C.

AMERICAN BOILER MANUFACTURERS' ASSOCIATION

Pres., E. D. Meier, 11 Broadway, New York; sec., J. D. Farasey, cor. 37th St. and Erie Railroad, Cleveland, O. Next meeting to be held September, 1911, in Boston, Mass.

WESTERN SOCIETY OF ENGINEERS

Pres., O. P. Chamberlain; sec., J. H. Warder, 1735 Monadnock Block, Chicago, Ill. Meeting first Wednesday of each month.

ENGINEERS' SOCIETY OF WESTERN PENNSYLVANIA

Pres., Walter Riddle; sec., E. K. Hiles, Oliver building, Pittsburg, Penn. Meetings 1st and 3d Tuesdays.

AMERICAN SOCIETY OF HEATING AND VENTILATING ENGINEERS

Pres., R. P. Bolton; sec., W. W. Macon, 29 West Thirty-ninth street, New York City.

NATIONAL ASSOCIATION OF STATIONARY ENGINEERS

Pres., Carl S. Pearse, Denver, Colo.; sec., F. W. Raven, 325 Dearborn street, Chicago, Ill. Next convention, Cincinnati, Ohio, September 12-15, 1911.

AMERICAN ORDER OF STEAM ENGINEERS

Supr. Chief Engr., Frederick Markoe, Philadelphia, Pa.; Supr. Cor. Engr., William S. Wetzler, 753 N. Forty-fourth St., Philadelphia, Pa. Next meeting at Philadelphia, June 5-10, 1911.

NATIONAL MARINE ENGINEERS BENEFICIAL ASSOCIATIONS

Pres., William F. Yates, New York, N. Y.; sec., George A. Grubb, 1040 Dakin street, Chicago, Ill. Next meeting at Detroit, Mich., January 15-19, 1912.

INTERNAL COMBUSTION ENGINEERS' ASSOCIATION

Pres., Arthur J. Frith; sec., Charles Kratsch, 416 W. Indiana St., Chicago. Meetings the second Friday in each month at Fraternity Halls, Chicago.

UNIVERSAL CRAFTSMEN COUNCIL OF ENGINEERS

Grand Worthy Chief, John Cope; sec., J. U. Bunce, Hotel Statler, Buffalo, N. Y. Next annual meeting in Philadelphia, Penn., week commencing Monday, August 7, 1911.

OHIO SOCIETY OF MECHANICAL ELECTRICAL AND STEAM ENGINEERS

Pres., O. F. Rabbe; acting sec., Charles P. Crowe, Ohio State University, Columbus, Ohio. Next meeting, Youngstown, Ohio, May 18 and 19, 1911.

INTERNATIONAL MASTER BOILER MAKERS' ASSOCIATION

Pres. A. N. Lucas; sec., Harry D. Vaught, 95 [illegible] street, New York. Next meeting at [illegible] Neb., May 23-26, 1911.

INTERNATIONAL UNION OF STEAM ENGINEERS

Pres., Matt. Comerford; sec., J. G. Hannahan, Chicago, Ill. Next meeting at St. Paul, Minn., September, 1911.

NATIONAL DISTRICT HEATING ASSOCIATION

Pres., G. W. Wright, Baltimore, Md.; sec. and treas., D. L. Gaskill, Greenville, O.

POWER

NEW YORK, APRIL 4, 1911

THE watch engineer was making his tour of duty. Day after day, month after month, he had gone the rounds of engine stops, receivers, traps, etc., and everything was always found in good working order. Little whisperings at times urged the watch engineer to skip things here and there which, of course, were all right (?). Tonight the whisperings said the engine stops were all right. It was a winter evening and the peak load would be on in a few moments, and there were many little things to do to prepare for it. Why not let the nonessentials slide? Old No. 5 wouldn't run away—not under the load that was coming. But the watch engineer was obdurate. Every little thing must be done. There should be no slighting of the smallest detail.

The stops were of the type that closes the throttle valve. The stop of No. 5 tripped all right, but there was something queer about it. Instead of running down, the valve hung still and the engineer's hand caught a vibration of the wheel as though the stem were dancing up and down. The fact was that the throttle was open less than a turn. On the light load it had not been noticed. Had it not been found out, a "down-and-out" would have been registered against the station.

Another engineer, of another sort, relieved Dave that night before No. 5 went down. When the switchboard man interrupted him in the midst of the closing scenes of "The Great Diamond Robbery," he reluctantly tossed the paper down and went over and closed the throttle of the big engine. He glanced over No. 2, which would run till morning, saw that the oiler was at work, then went over and lay down on the big broad belt of No. 4. No. 5 would be needed for the morning load, but the only preparation she got was the little wiping the oiler gave her.

At five o'clock in the morning steam was turned on again and—snap, bang—the low-pressure rocker arm had broken off. The station got a black mark that time, of course, for part of the load had to be dropped—and the cause? Well, they found the wrist plate had run hot, and when she shut down it "froze." After several attempts to free it, the stud was removed from the cylinder and the whole thing sent to the shop, where 14 tons pressure was required to pull the wrist plate from the stud.

A month later, the watches had been shifted. Dave was now on the night run. His program was of another sort. While the big engine was slowing down he felt each bearing. The moment she stopped he was at her with wrenches. Wedge bolts, keys, set screws and lock nuts were all gone over and the oil pipes examined.

As he was trying the lock nut on the low-pressure crank-pin oiler, his sharp eye discovered something wrong. It was another little thing, a tiny little thing, but so important. In the oilers on this engine there were holes opposite the center of the crank pin through which a wire might be inserted for the purpose of cleaning. Tiny plugs screwed into these holes. If a plug worked out the oil would decorate the crank case instead of lubricating the crank pin—and trouble was not far ahead. And this was just what Dave had noticed. The plug was missing. A search light was brought to the scene, and after a short hunt the plug was found. No black mark that morning. But suppose the other fellow had been on the job!

It is a little thing to go over the wedge bolts and set screws every day, but it will often save you a shut-down and a black eye.

How many engineers, when it comes to regularly feeling the bearings of their engines, "let George do it"? And how many of those who regularly go over their engines every hour or every half hour, shut the throttles and leave the engines, not knowing what has happened to the bearings in the last half hour? It is a little thing, but do it. Go over the engine after you shut it down. It may help you to start up.

Power Plant of C. & N.W. Ry. Terminal

By Osborn Monnett

First new plant which has installed low-pressure turbine in connection with engine units. Special arrangement of boiler settings for heavy overloads. Piping connections of heating system of unusual interest.

One of the most important real-estate improvements made in Chicago in late years is that of the new terminal station of the Chicago & Northwestern Railway, with passenger entrance fronting on West Madison street, from Canal to Clinton street. The property extends north to the junction of Clinton and Milwaukee avenue, the elevated tracks admitting street traffic underneath the structure and also permitting entrance to the Washington street tunnel, which has lately been reconstructed. The power house to light, heat, ventilate and is other ways serve the public at this station, occupies a triangular shape of land between Lake street, Clinton street and Milwaukee avenue, and is an ingenious utilization of an area which would ordinarily be useless. The plant has been laid out with special reference to the unusual ground-plan conditions, with the stack occupying the apex of the triangle and the arrangement has been such as to secure all necessary room for the desired purposes. Pressed brick on the inside walls, set off with a green Rockwood tile wainscoting around the visitors' gallery and the engine room and in the engineer's office, adds greatly to the appearance of the station and gives the impression of attention to detail which is characteristic of the entire work.

In the boiler room are six 500-horsepower Babcock & Wilcox boilers, the type of setting being similar to that lately used in one other of the large plants around Chicago, and specially designed to permit forcing the boiler to heavy overloads. They are, as will be noted in the drawings, of the vertical-header type, with three gas passes through the tubes and are set in the reverse position to that ordinarily followed, with the chain-grate stokers under the mud drum. This gives large combustion space wherein the products of combustion may mix, and the setting has been unusually successful from the standpoint of eliminating smoke. Directly over the stoker arches, which are protected by water-tight sheet-iron pans, three blowoff connections are brought off to the side of the stoker, as shown in the photograph of the boiler room. These are easily manipulated by

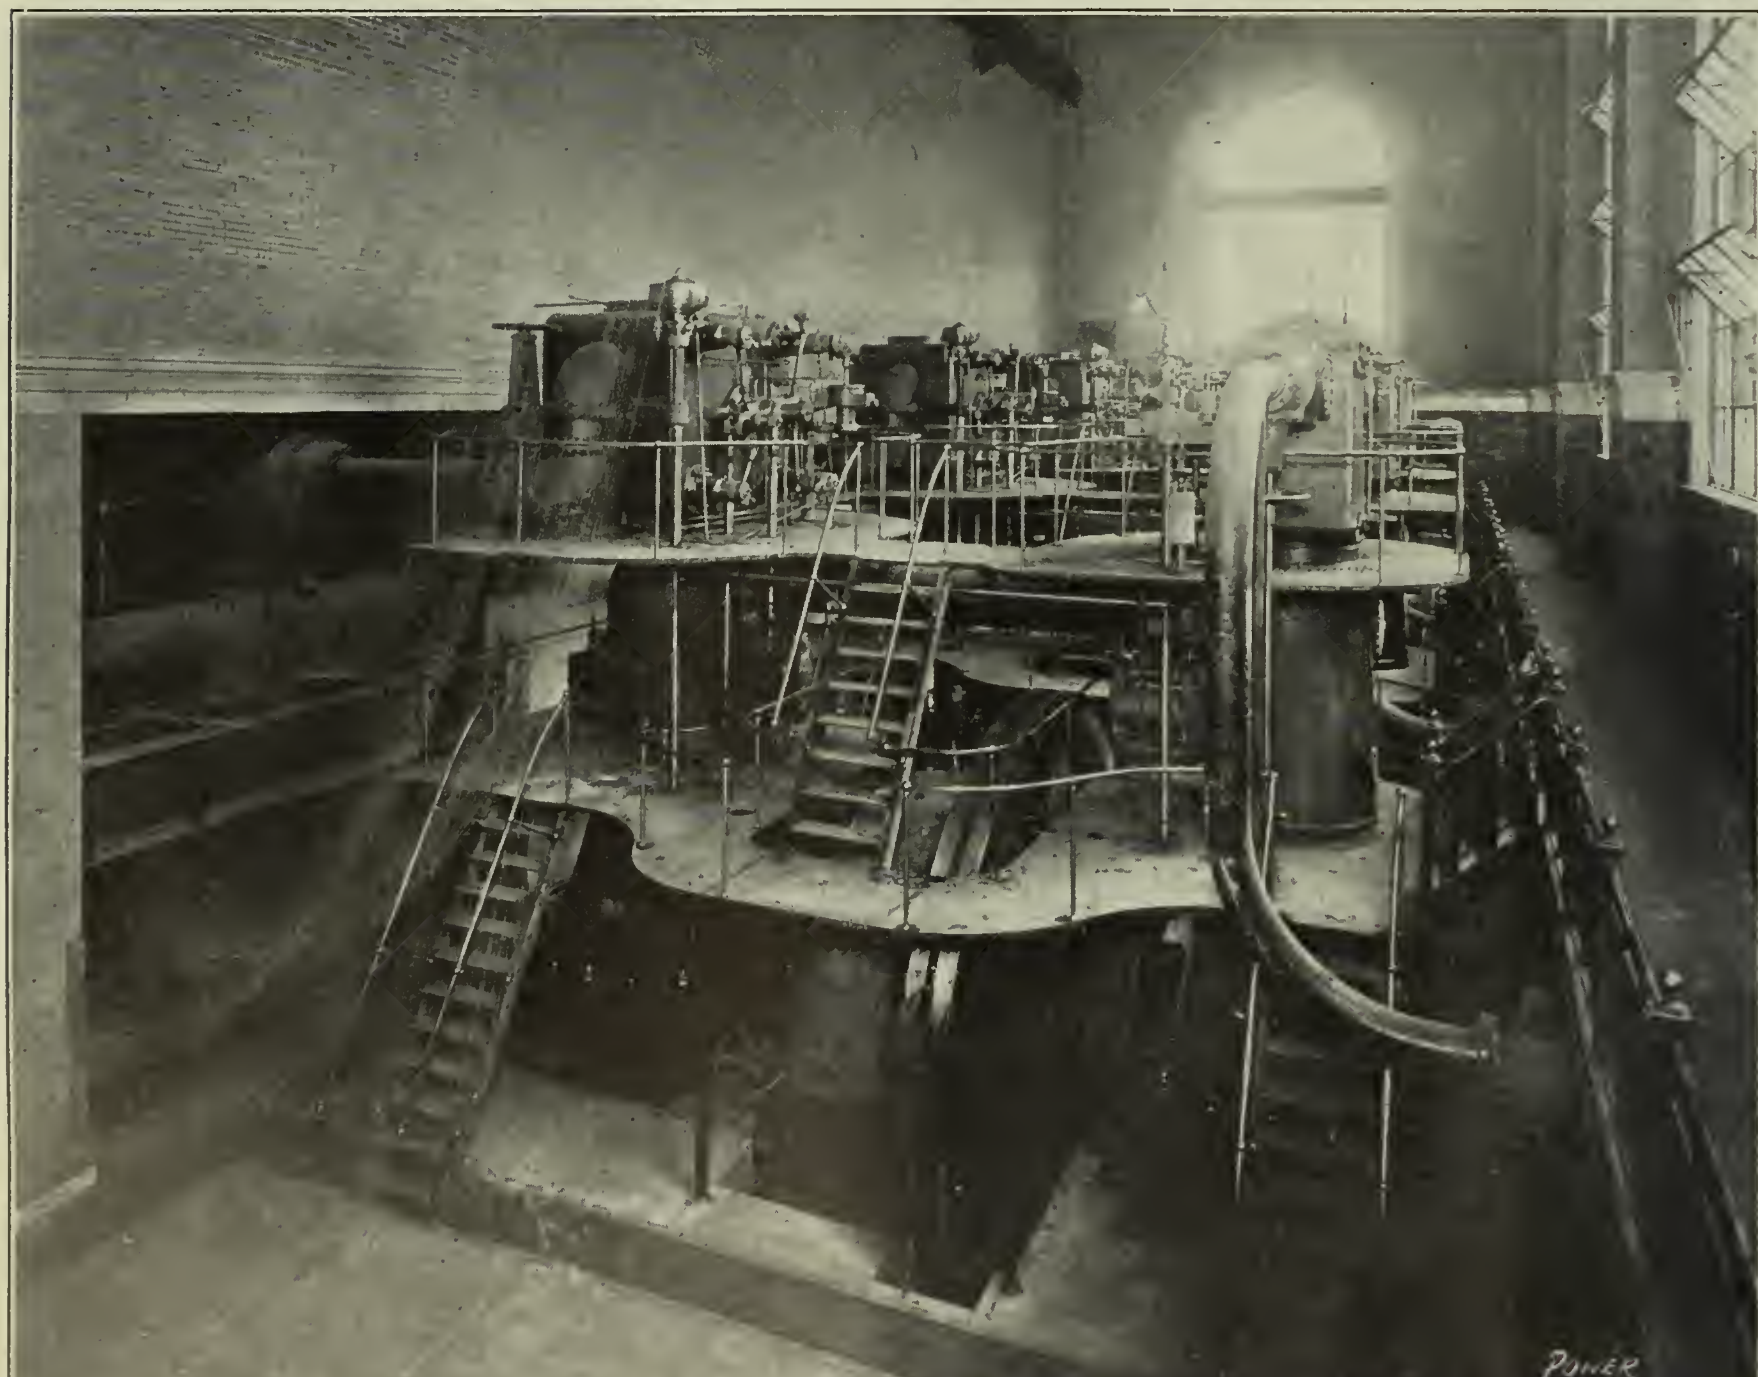

Fig. 1. General View of Main Engine Units

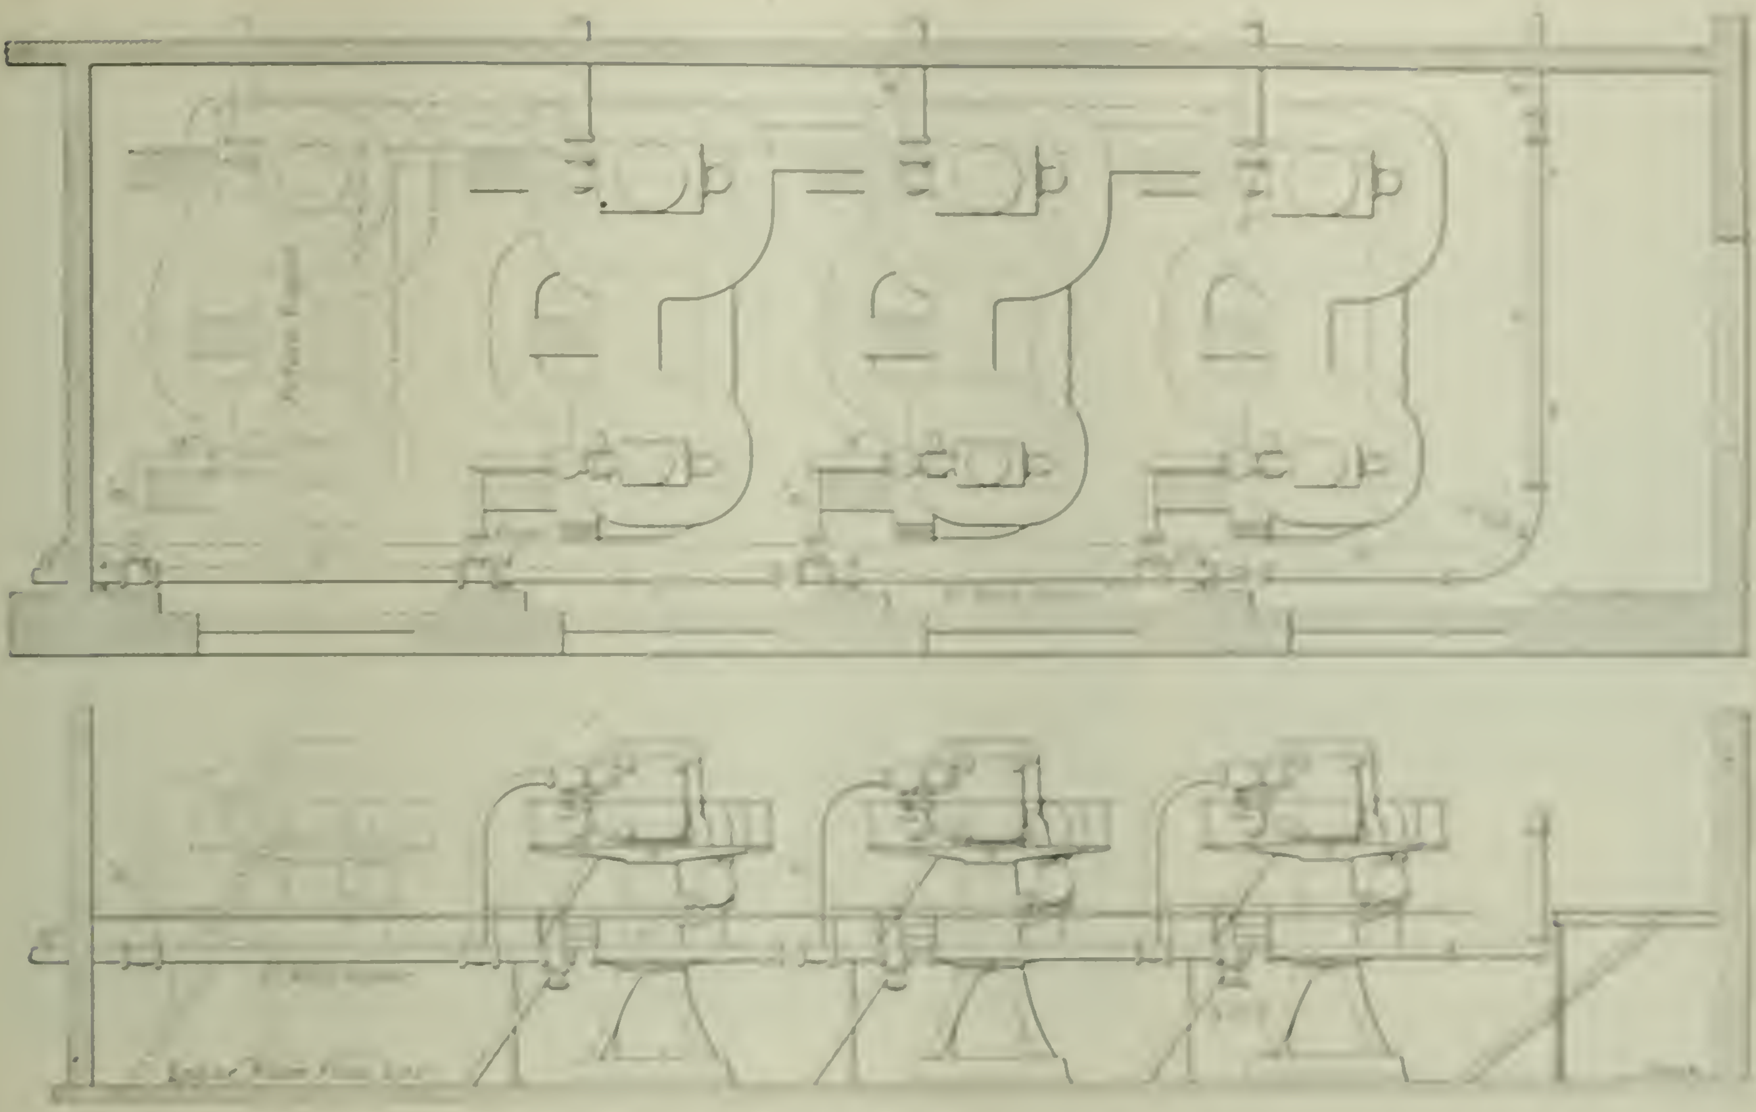

Fig. 2. Piping Connections in Engine Room

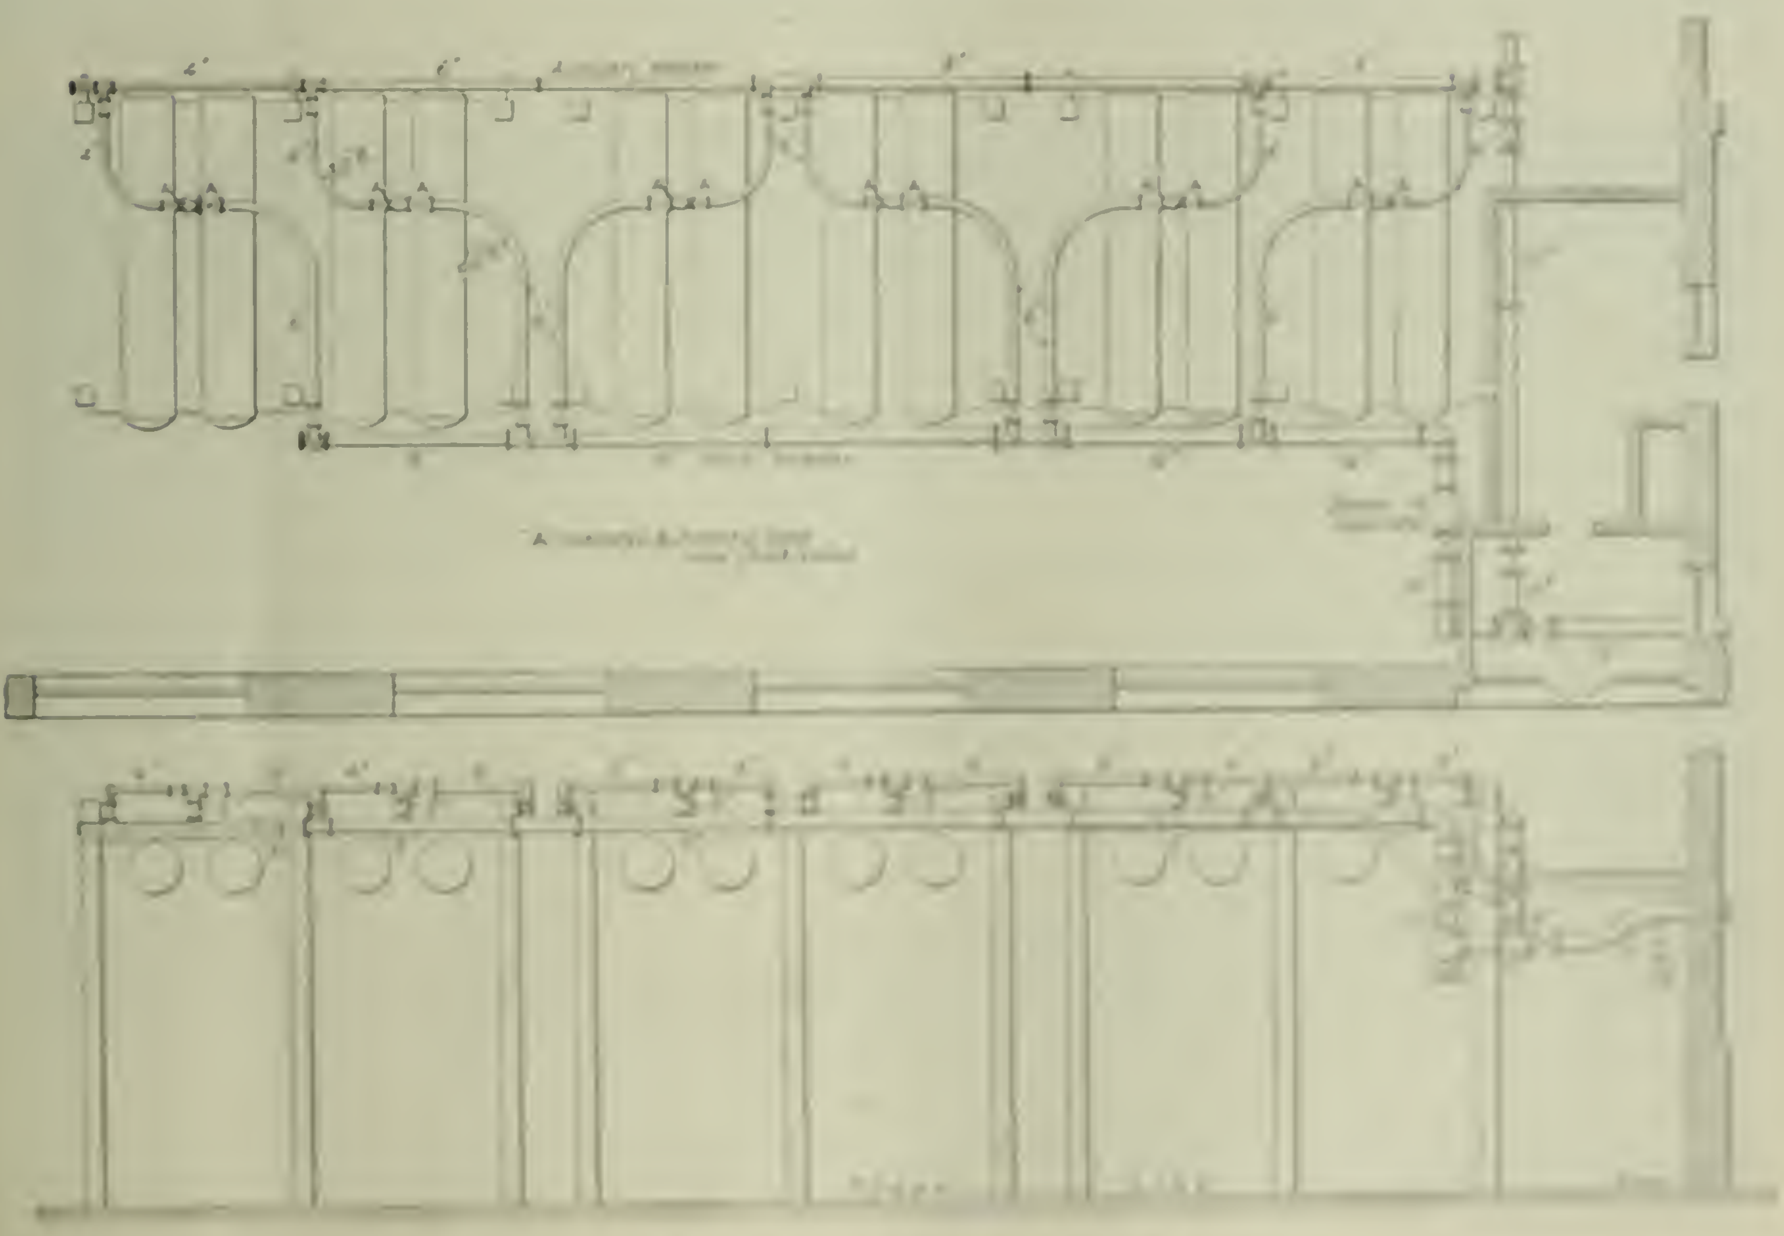

Fig. 3. Plan and Elevation of Boiler Piping

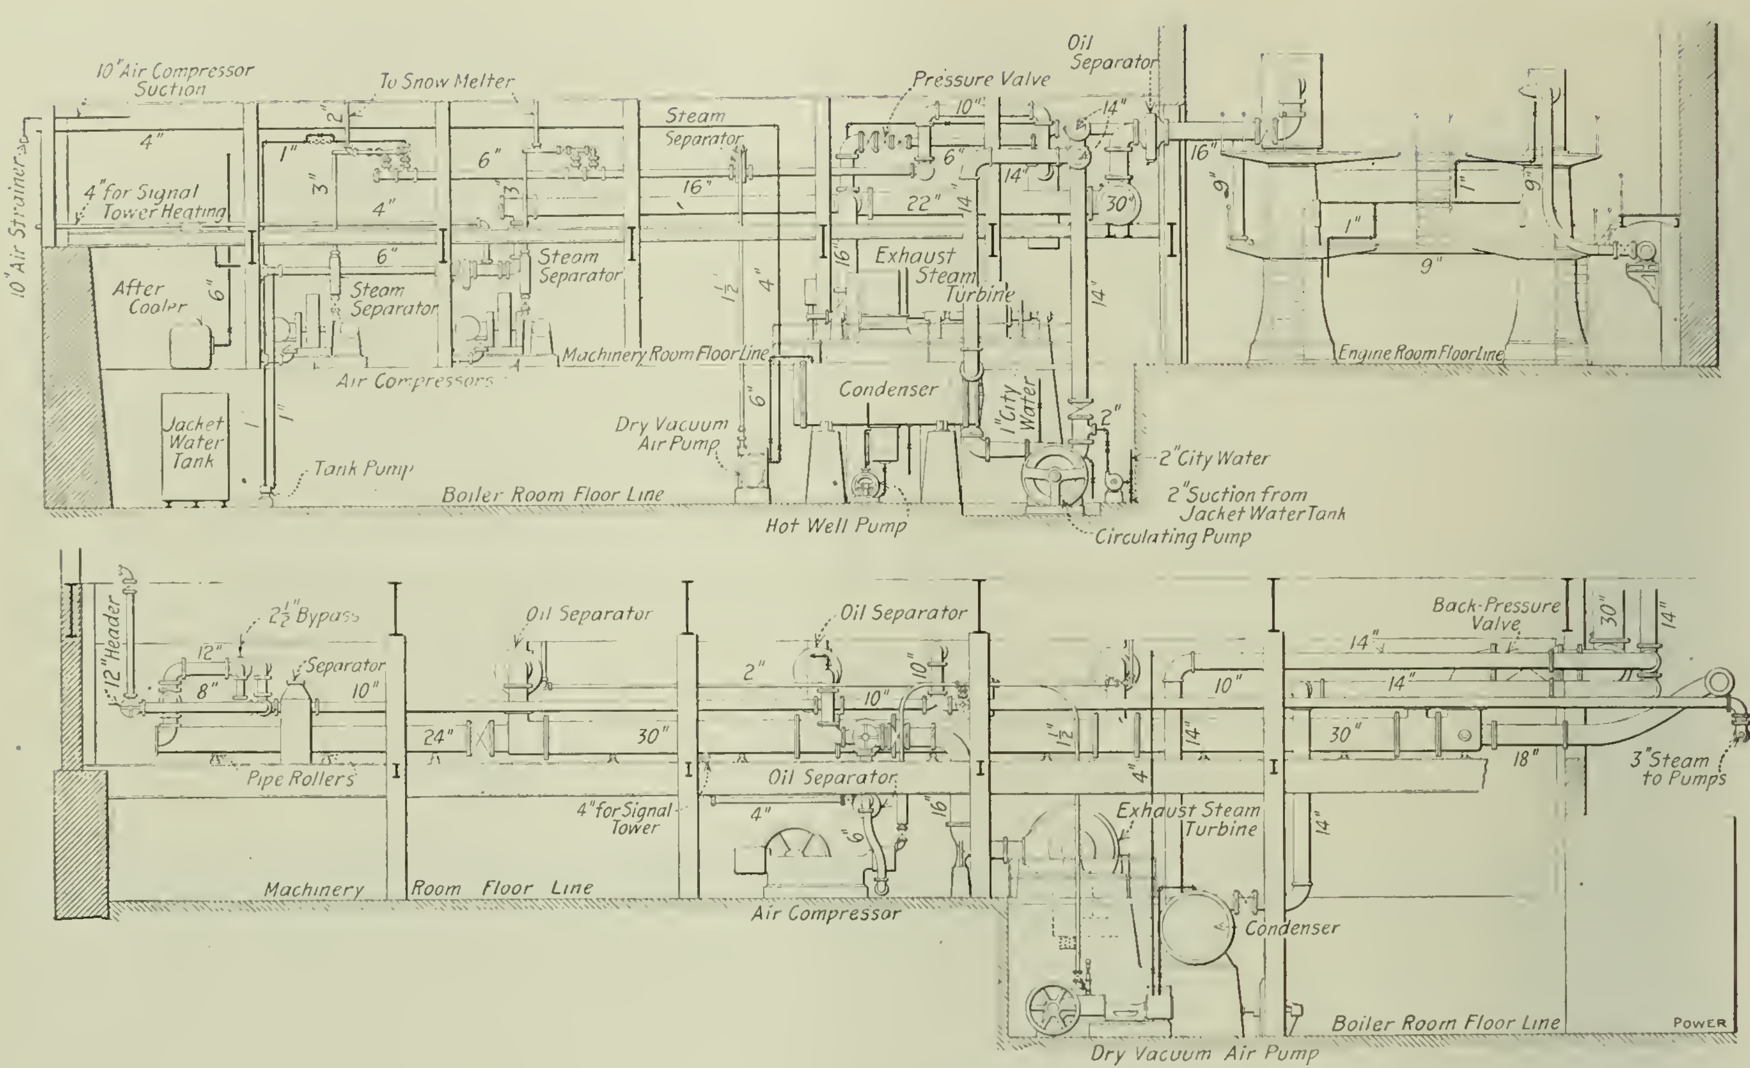

Fig. 4. Sectional Elevations through Engine and Machinery Rooms

the fireman, who is not required to go behind the boilers for any purpose, the feed valve also being conveniently located at this point. Every detail in the boiler setting has been worked out for the greatest efficiency. Vulcan soot blowers are installed for keeping the heating surfaces clean, and if desired it is possible to run the boilers at 75 to 100 per cent. above rating, or approximately 800 to 1000 horsepower per boiler.

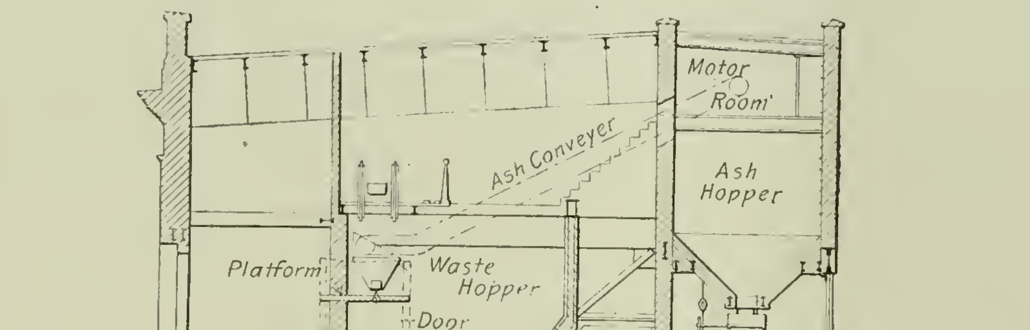

Fig. 5. Transverse Section through Boiler Room

Coal- and ash-handling apparatus has been so designed as to handle coal in carload lots from the track elevation. The unloading hopper has a capacity of 300 to 400 tons and a length which will permit two cars being unloaded at one time. From the bunker underneath the tracks the coal passes on to a horizontal conveyer, through a crusher into a Peck, continuous, pivoted, bucket conveyer, which elevates it to concrete bunkers over the boilers, the latter having a capacity of 750 tons without trimming or 1000 tons if trimmed.

Ashes are discharged from the grates into hoppers below the boiler-room floor line and carried by the same conveyer which transports the coal, to an inclined pan conveyer discharging into an ash bunker located above the coaling track and capable of holding 100 tons of ashes. The unloading arrangement has a rated capacity of 40 tons per hour.

Although the type of boiler setting chosen necessitates extremely high headroom, still there is plenty of space provided for convenient operation and the boiler plant is unusually light and roomy. Auxiliary storage capacity of approximately 300 tons of coal is provided under the sidewalk on the Canal street side, immediately in front of the boilers. This storage space is liberally supplied with sidewalk lights, while the boiler-room floor itself between the boiler settings is

Fig. 6. The Boiler Room

Fig. 7. Power House of Northwestern Terminal

also fitted in this manner, lighting up the ash tunnel. A feature worthy of note is the special means of taking care of expansion in the boiler breeching. This is supported on saddles and springs resting on the building I-beams and allows for free movement with varying temperatures. The breeching is covered with 2 inches of vitribestos and the method of suspension insures that no leaks or cracks will develop in the structure. Passing to the stack, which is of Custodis construction, 11 feet in internal diameter at the base and 10 feet 6 inches at the top, the gases are discharged 225 feet above grade or 247 feet above the boiler-room floor line.

One of the unusual features in the design of the plant is the convenient location of the engineer's office. This is at the grade line, with the entrance on Clinton street, and is located between the boiler and engine rooms with windows on each side so that both departments are visible from this central point. In case of trouble in any part of the plant the point can be

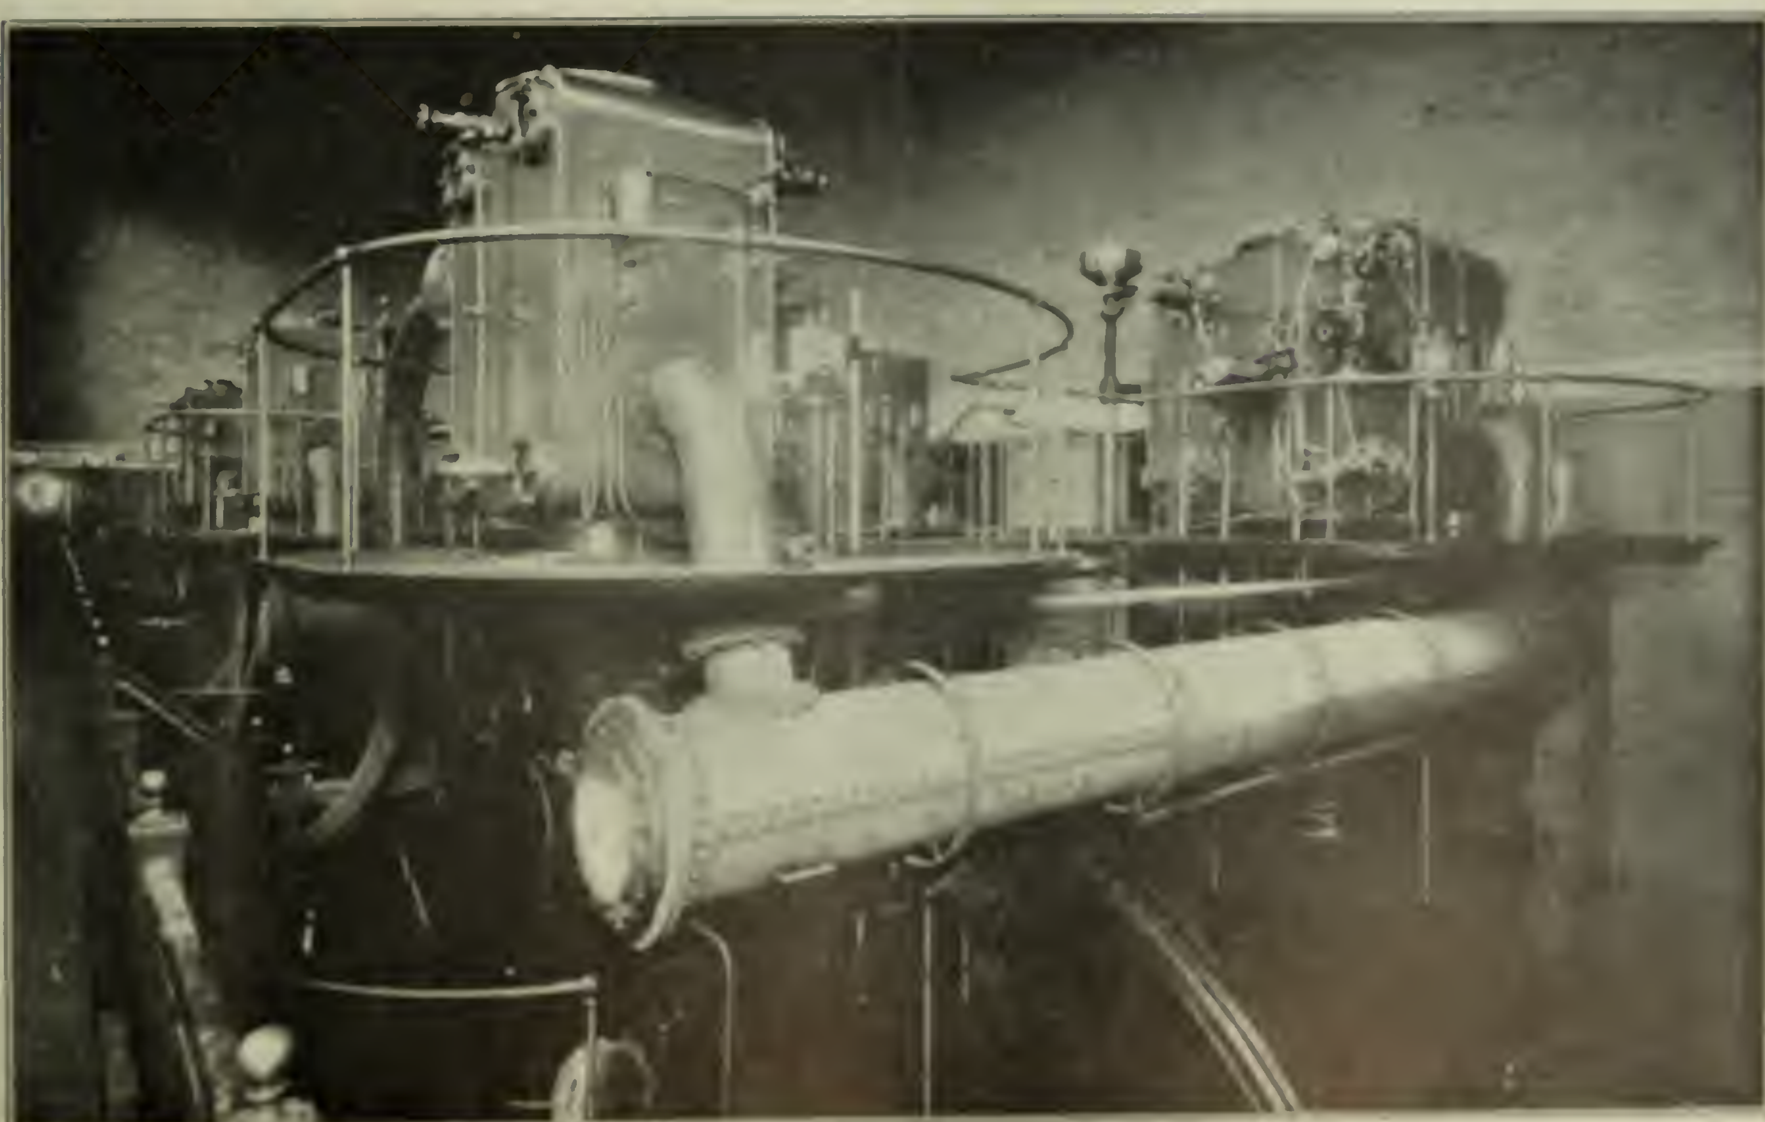

Fig. 8. View of Engine Cylinders from Gallery Level

conveniently reached from the engineer's headquarters in the shortest possible time. This central division of the power house continues to the roof so that both engine and boiler rooms can be entered at any level by means of stairways conveniently located. A gage board is located here with all the usual instruments for checking operation.

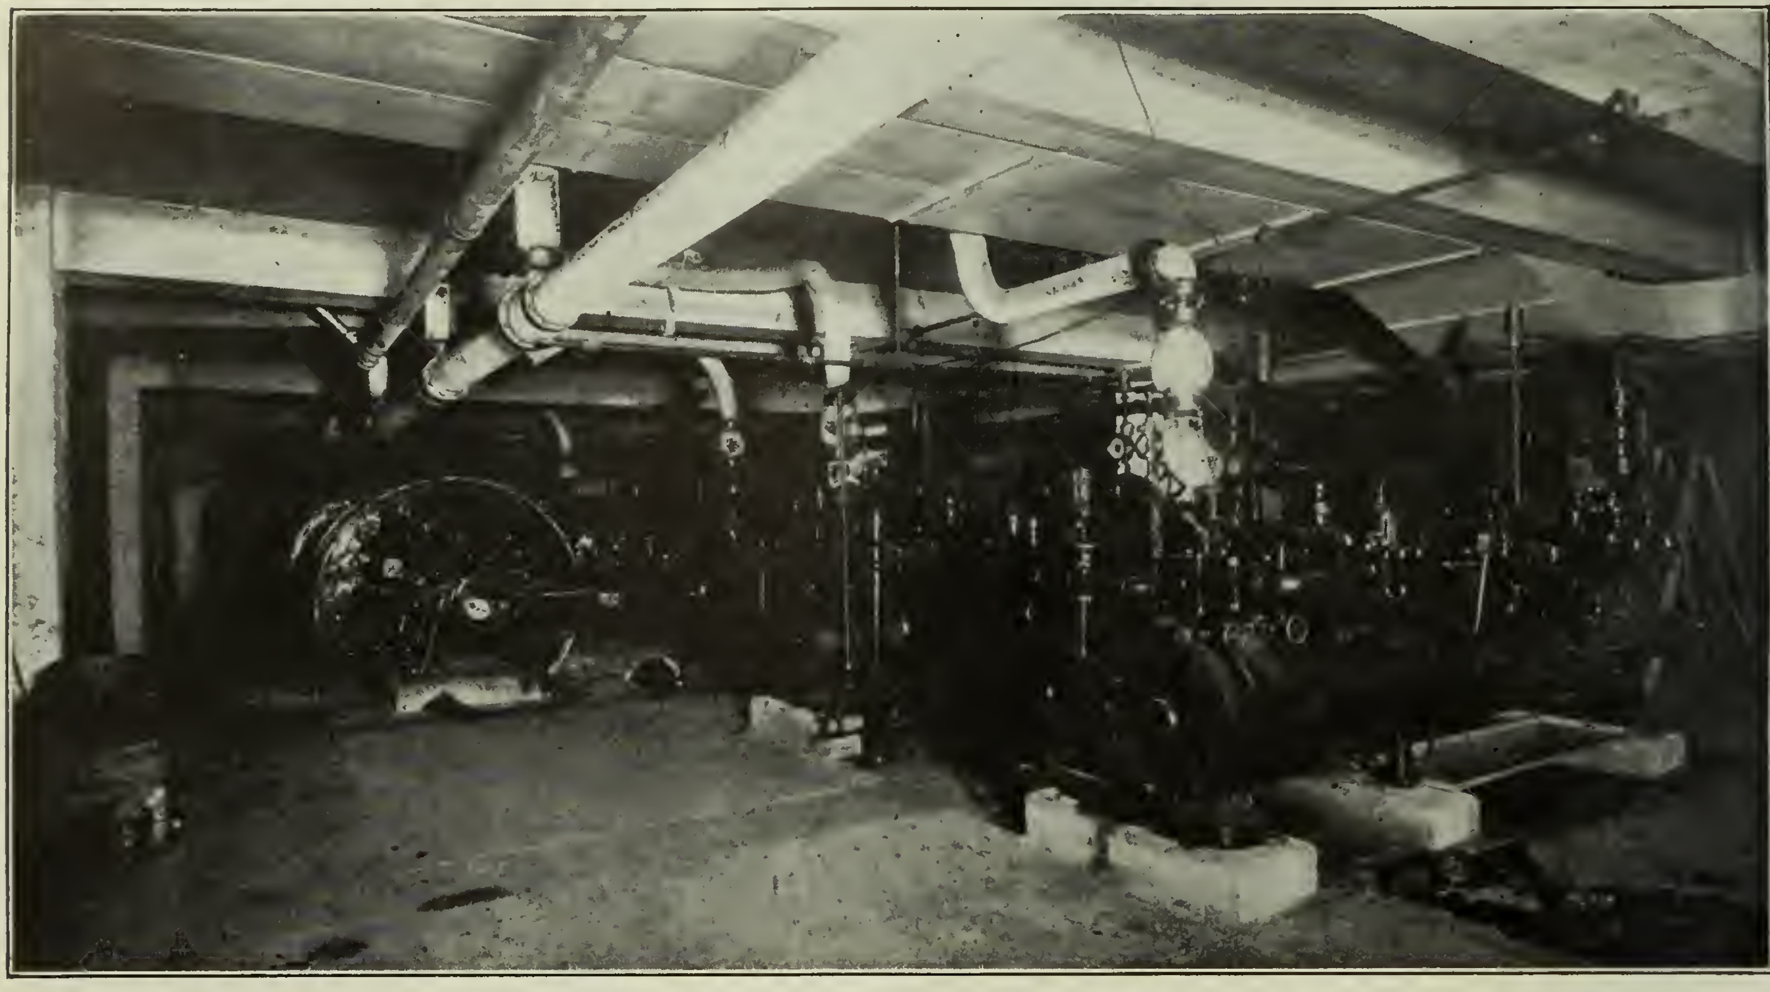

FIG. 9. ELEVATOR PUMPS UNDER MADISON STREET END OF STATION

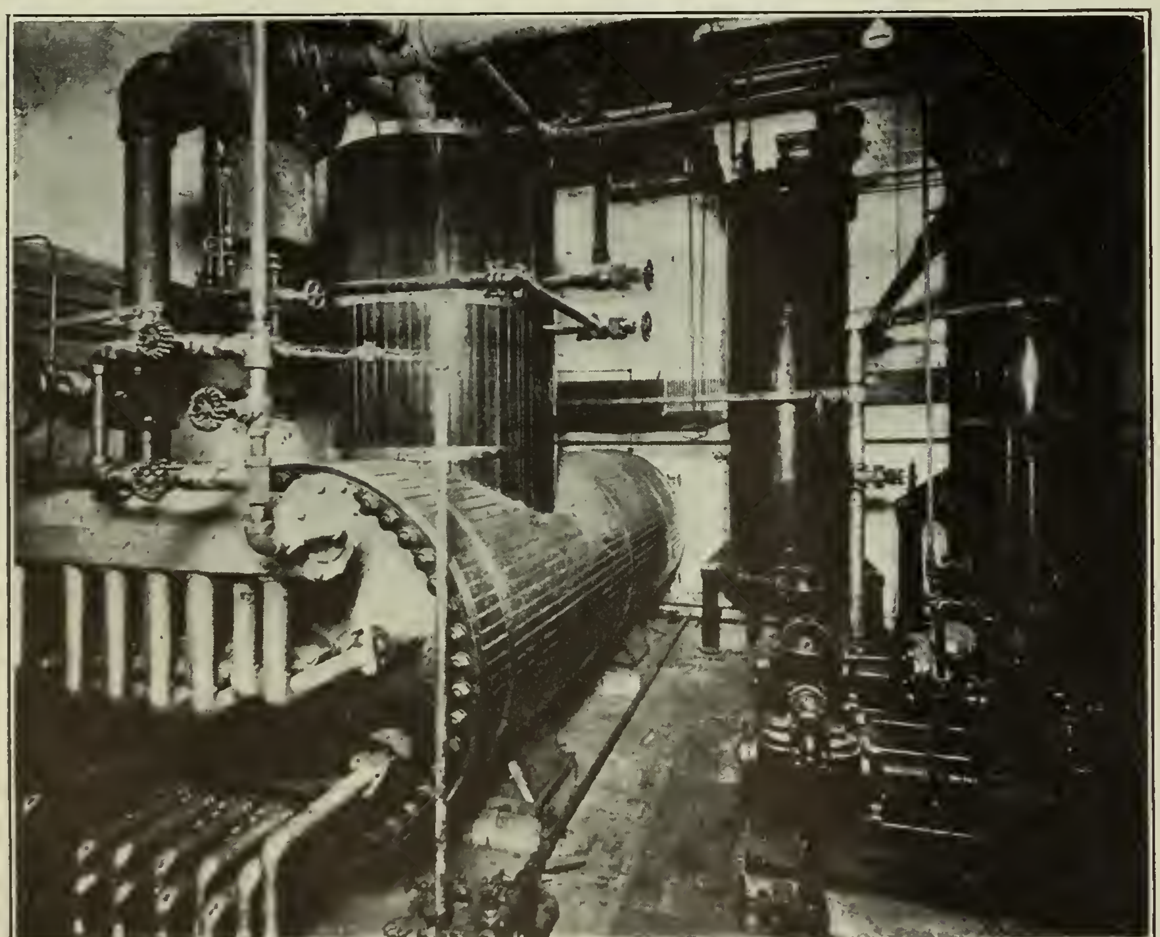

FIG. 10. ABSORPTION REFRIGERATING SYSTEM

In the engine room there are at present installed three vertical cross-compound noncondensing Allis-Chalmers Corliss engines, with 25 and 44 by 42-inch cylinders, each rated at 1150 indicated horsepower, at 100 revolutions per minute, with steam pressure at 155 pounds and 60 degrees, Fahrenheit, superheat. Space has been left for an additional engine and dynamo unit of the same size as above. The engine platforms are all interconnecting and arranged for maximum convenience of the operators. One Curtis low-pressure steam turbine and generator unit of 500 kilowatts capacity is installed in the machine room. It is the intention to run noncondensing during seasons when steam for heating will be necessary and use the low-pressure turbine only at such times as exhaust steam would ordinarily be allowed to waste to the atmosphere. When not running on the heating system the light loads will be taken care of by one of the Corliss engines and as the load increases beyond the capacity of one engine unit it will be thrown on to the low-pressure turbine up to a point where the combined units are fully loaded, when another engine outfit will be cut in and so on. The engine sets are guaranteed to run on 18.6 pounds of steam per indicated horsepower at full load, against 16.5 pounds absolute back pressure. This will mean 21,400 pounds of steam exhausted to the low-pressure turbine. The latter has been installed under a guarantee to deliver a kilowatt-hour on 43.5 pounds of exhaust steam, or a horsepower-hour on 32.7 pounds. Using the 21,400 pounds of steam exhausted from the engine unit, the low-pressure machine will develop an additional 786 horsepower, making a total of 1936 horsepower for the combined outfit, on 21,400 pounds of steam, or a horsepower-hour on 11.8 pounds of steam.

Under present conditions it is possible to operate the turbine for eight months in the year and if plans under consideration go through, the turbine will be used the year round.

As far as the writer is aware, this is the first time an exhaust-steam turbine, installed in connection with engine units, has been included in the original layout.

Fig. 11. Engineer's Office at Power House

This, of course, is largely due to the newness of this type of machine in this country. The reduction in steam consumption per horsepower-hour developed in this particular installation is considerable, and besides it would be difficult to devise a more flexible system for utilizing to the best advantage the supply of exhaust steam.

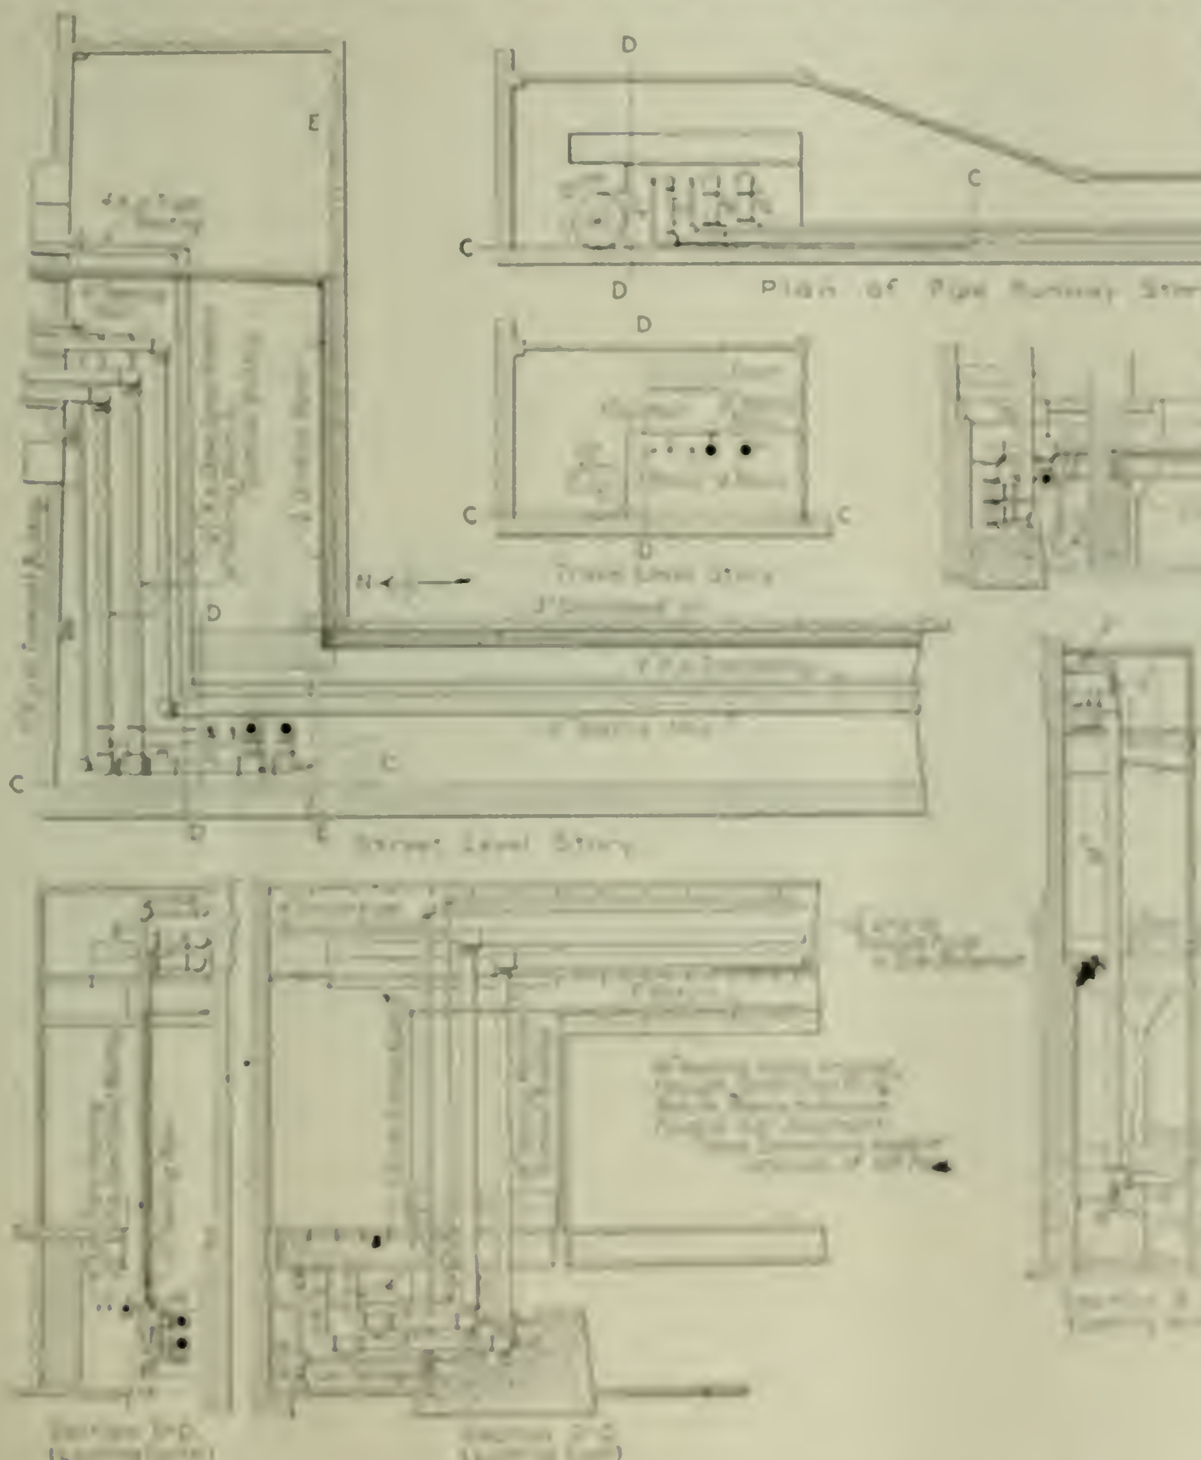
The connection of the turbine to the exhaust piping of the plant is clearly shown in Fig. 4, which shows sectional views running through the engine and machinery rooms. From these views it may be seen that it is possible to use in the low-pressure turbine the exhaust steam from the auxiliaries as well as from the main engine units.

There are already installed in the machine room, two 500-kilowatt motor-generator sets, which will be used to convert the 250-volt, direct-current, generated in the plant, to 6900-volt three-phase 60-cycle currents for lighting service along the Northwestern line inside the city limits. This current will be used for the entire switch and signal system and lighting the Chicago terminal, subways, freight houses, yards, etc.

When running condensing the exhaust from the turbine is discharged into a Worthington surface condenser with 4000 square feet of cooling surface, guaranteed to hold a vacuum within 3 inches of absolute when condensing 23,000 pounds of steam per hour, with circulat-

Fig. 12. Switchboard

ing water at 75 degrees Fahrenheit. In connection with this condensing outfit a cooling tower has been installed on the roof. This tower will cool the necessary amount of condensing water when the atmospheric temperature is 75 degrees Fahrenheit with relative humidity of 70 per cent. The tower is of the four-fan type, the fans being driven by two 25-horsepower motors. All jacket water



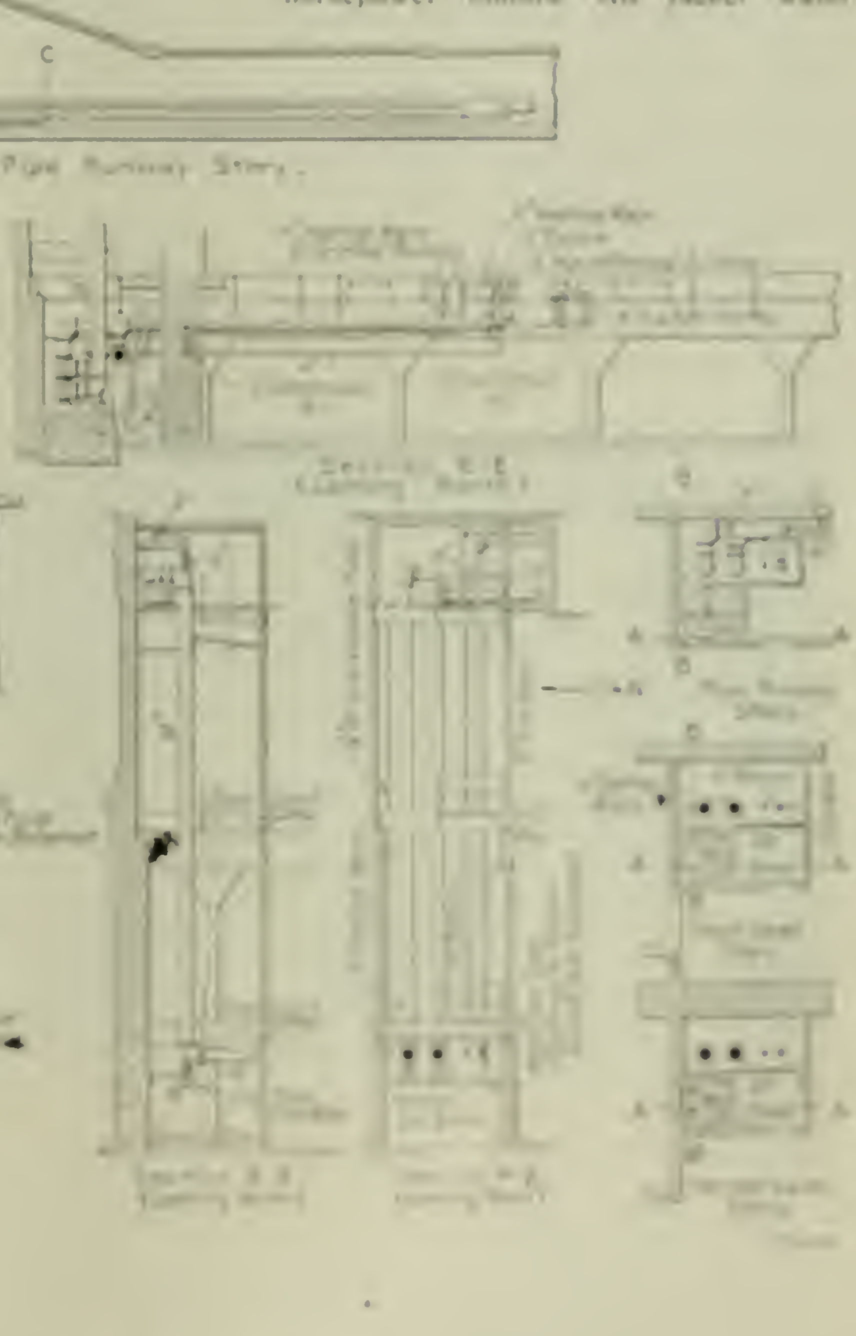


Fig. 13. Details of System Designed to ... West Terminal

from the air compressors, main engine journals, aftercoolers, etc., is collected in a tank from which a small centrifugal pump furnishes the make-up water for the cooling tower. In this way water which is supplied from the city mains is economized.

In the south end of the engine room on the balcony are located the switchboard and benchboard for controlling the electrical units. The operator stands facing the machines and makes all connections by means of remote-control switches. A busbar tunnel runs under the engine-room floor, with circuit breakers on the generator leads. The generator rheostats are controlled by push-botton switches on the benchboard. The main buses in the busbar tunnel run to the distributing switchboard which is furnished with switches connected to circuits leading to the main building, outgoing lines, etc.

Unusual precautions have been taken to guard against breakdown in the piping system. From the steam nozzles the steam passes through 6-inch stop and check valves into the main header lying in front of the boilers at a level with the drums. This header, starting at 8 inches in diameter, increases to 10 inches and finally in the engine room to 12 inches, extends under the balcony and entirely around the engine room, where it meets a 10-inch auxiliary header and forms a loop so that steam can be supplied in either direction from the boilers. The auxiliary connection from the boilers starts at the boiler nozzles in a 4-inch connection, the auxiliary header behind the boilers being 6, 8 and 10 inches in diameter as shown on the piping layout. Superheated steam is used in all of the main and auxiliary piping. It is the intention to maintain the entire system of live-steam headers under steam at all times, so that in case of a break in any portion of the system, manipulating one or two valves will shut off the section of header affected without delaying operations in the plant and without danger of turning superheated steam suddenly into a length of cold piping. Extending along one side of the engine room, as shown in the plan, is the 30-inch main exhaust header with an atmospheric relief run to a point above the roof. From this header a 16-inch connection leads to the low-pressure turbine. There is also a connection from the auxiliary header to the throttle of the low-pressure machine, enabling it to be supplied with live steam independent of the exhaust from the engine units. This makes it possible to generate 500 kilowatts of electricity and still shut down the entire system of main headers and low-pressure piping, other than the auxiliary header, for repair.

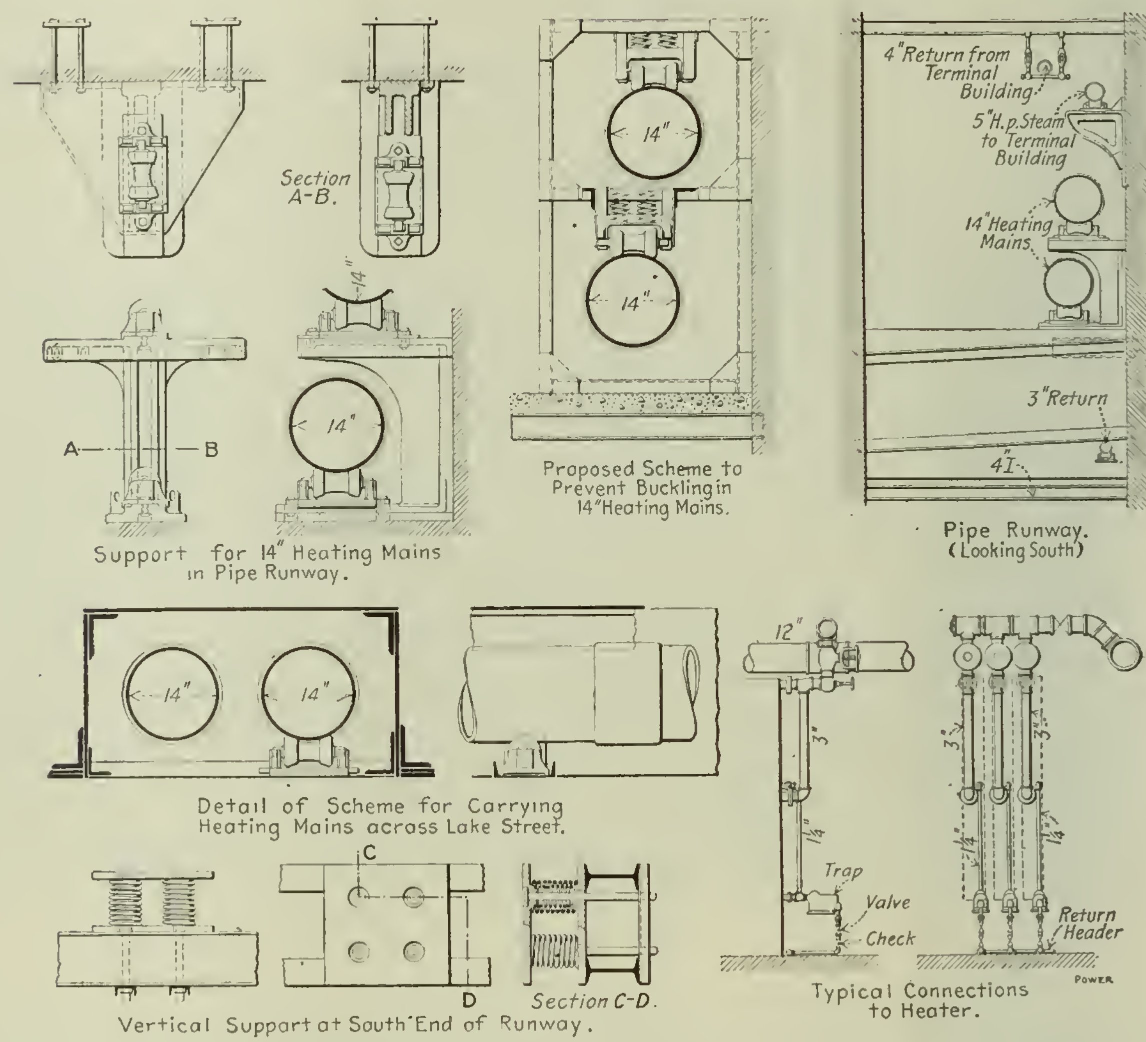

Fig. 16. Supports for Heating Mains and Typical Connections to Heater

To act as an auxiliary on the heating and elevator load in the station building should a breakdown occur in the transmission piping from the main power house, a steam plant has been installed in the passenger-terminal building at Madison street. This consists of two 150-horsepower single-drum Babcock & Wilcox boilers fitted with Water-Arch hand-fired furnaces. All of the elevator-pumping equipment is installed in this end of the plant. There are in all thirteen hydraulic elevators in the passenger-terminal station, four for passengers and nine for

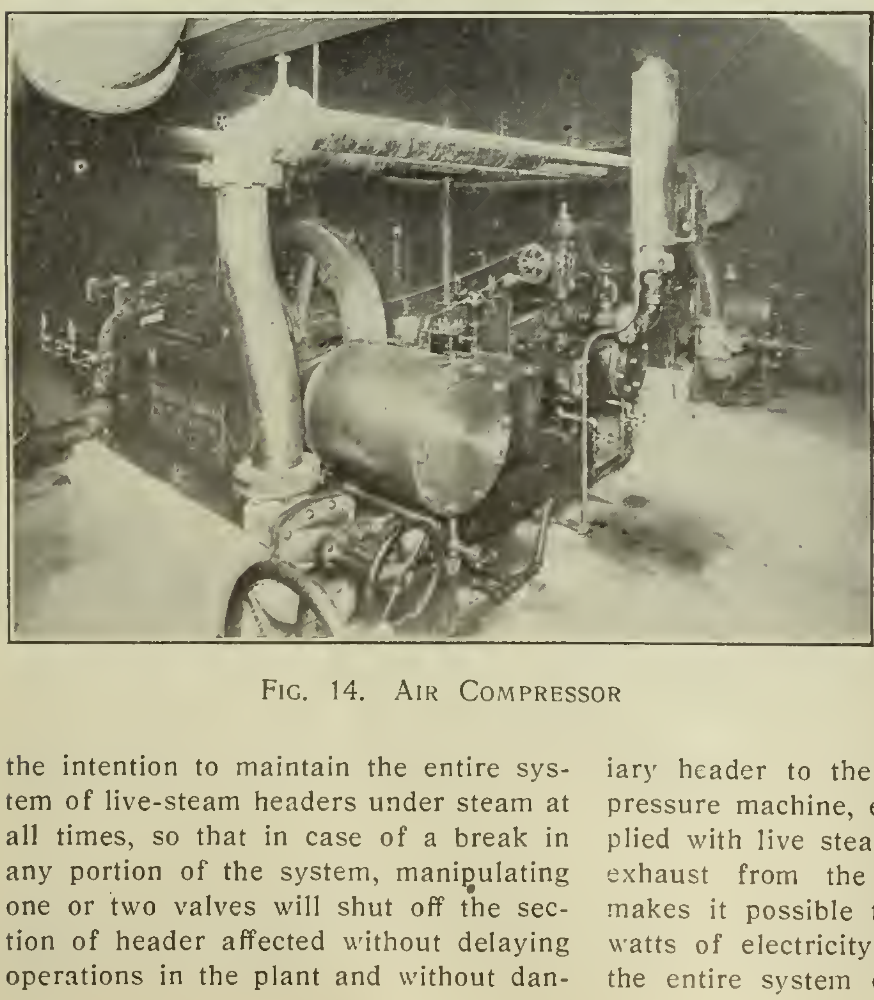

Fig. 14. Air Compressor

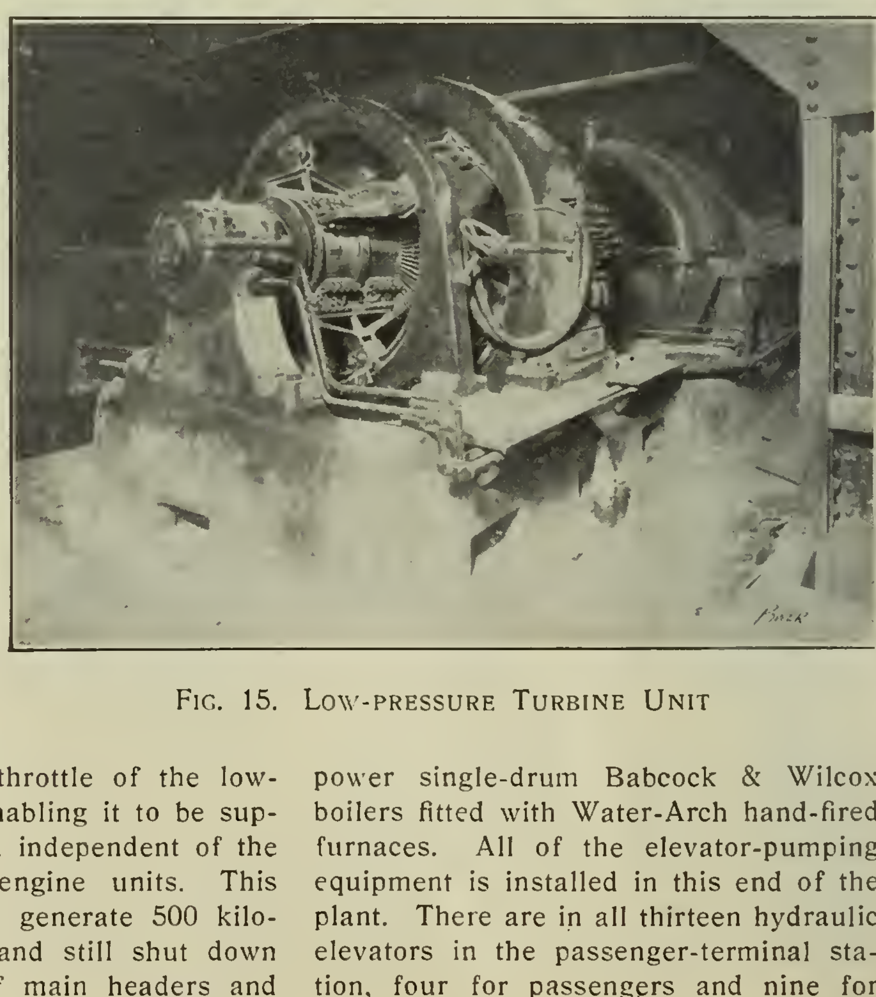

Fig. 15. Low-pressure Turbine Unit

baggage. They are all operated with water at 800 pounds per square inch. Two three-cylinder compound, crank-and-flywheel elevator pumps, and two tandem-compound pot-valve pumps take care of this service. In addition to this there are ten electric elevators for baggage, express and mail, and three dumb waiters with push-button control.

A complete Carbondale absorption refrigerating installation of 50 tons capacity is also located in the basement of the station for cooling drinking water and furnishing refrigeration for the various ice boxes in the restaurants and lunch rooms located throughout the building.

Of special interest is the heating and ventilating arrangement in the passenger station. This is done by the indirect blast system, except a small amount of direct radiation installed to take care of building losses. One of the largest air-heating plants ever installed in one chamber is located in the basement, having 25,000 square feet of Vento heaters, consisting of cast-iron elements taking steam from the low-pressure mains. All main supply ducts are in concrete tunnels carried beneath the floor line and the blast is supplied by electrically driven Sirrocco fans. Starting at the plenum or tempering chamber, galvanized-iron ducts distribute the heated air to the different portions of the building. The plenum chambers are centrally located and provided with automatically controlled dampers which temper the air delivered to the ducts. A complete system of exhaust ducts parallel the supply ducts throughout the building, with the exhaust fans located in the attic regulated by remote-control switches placed in the basement on the same operating board from which the corresponding supply-fan unit is controlled.

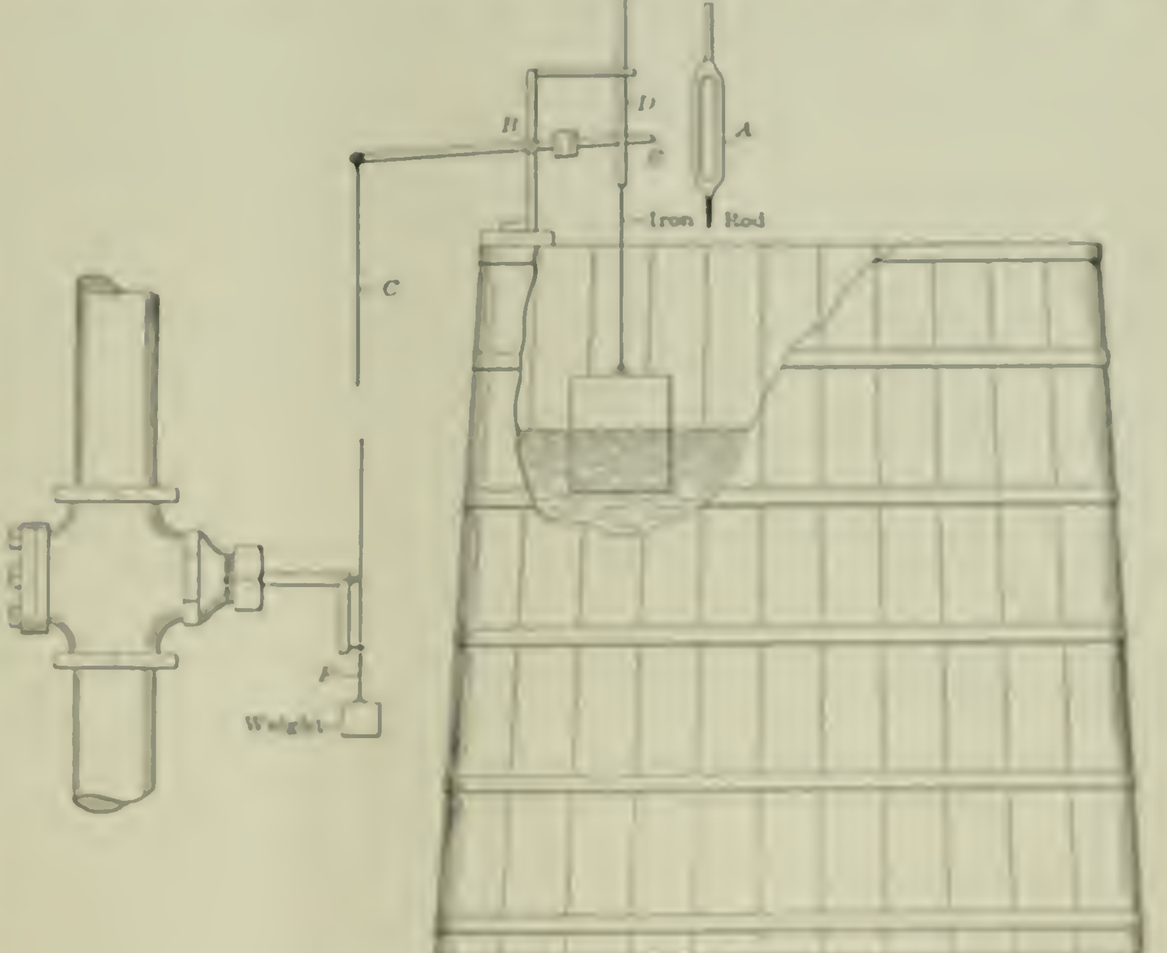
As the main and auxiliary plants are separated by no less than 1300 feet, some of the piping problems encountered are worthy of notice. There are two 14-inch exhaust-heating mains coming from the central plant; one 5-inch live-steam line for power; one 4-inch train-heating steam line, and one 3½-inch down-spout heating line. The 4- and 5-inch lines are fitted with automatic stop and check valves to automatically shut off the steam in case of accident. No expansion joints were used in the 14-inch lines, the expansion being taken up entirely by swing joints at either end as shown in the drawings. These lines are anchored at the center and expand both ways, being supported on special cast-iron brackets, allowing for the removal of any length of pipe without disturbing the bracket or the other piping. They are made up in sections of three lengths of pipe, fitted with extra-heavy screw couplings and at the end of each section with flange unions. The stretch of pipe between flanges constitutes a pipe unit and the presence of the flange unions three lengths apart permit a flexibility that would not otherwise be possible, as too many flanges would tend to stiffen the line and cause leaks. When steam is first applied to the lines they expand on top and the sections between the flanges raise from their supports until the pipe has been brought to a uniform temperature, and the condensation has been drawn out. The line then settles to its position on the brackets without shock or jar. In the design of the brackets it was arranged to bring the weight on the foot and relieve any stress on the side walls. It was calculated that there would be an expansion of 14 inches in the length of 1300 feet and in practice a movement of 14½ inches has been observed.

One of the special problems worked out in connection with the station was the method of keeping the horizontal runs of down-spout piping draining the roof of the train sheds from freezing in cold weather. The ordinary method of solving this problem is to let live steam blow into these spouts, which not only proves unsightly and wasteful, but also tends by condensing in the pipe, to increase the trouble from freezing. In this installation the horizontal runs are each fitted with a steam line laying immediately underneath the drain pipe and inside the lagging of same. This heating pipe is supplied with live steam at 40 pounds pressure throughout the entire train shed and has the effect of keeping the down-spouts entirely clear of frost in all weather and at the same time in the entire area underneath the train shed there is no steam escaping to the atmosphere. These heating lines are trapped, the condensation being discharged into the main heating system of the building. As this hot water is at 40 pounds pressure the effect of liberating it into the heating system at exhaust steam pressure is to cause it to flash into steam and it thus becomes useful for heating in the building after it has served its purpose in the down-spout system.

The steam and electrical work for the complete plant was designed by and erected under the supervision of Pierce, Richardson & Neiler, consulting engineers, Chicago. F. J. Ravile, chief engineer of power stations for the Chicago & Northwestern Railway, is in direct charge of operation of the plant.

Unusual Float Control of Pump

In this instance the steam pipe supplying the pump is fitted with a quick opening valve, the valve stem of which is fitted with a lever instead of a hand wheel, as shown in the accompanying illustration. To the top of the tank is securely fastened a rod which is bent at right angles and serves as a guide to the rod attached to the float. The float rod is slotted, as shown at A, and the slot limits the distance through which the water is allowed to fall before the steam valve is opened and the pump brought into operation. Pivoted to the supporting rod at B is a lever at one end of which a hole is drilled for the cord C. The cord extends over pulleys, conveniently arranged, down to the steam valve of the pump. The other end of this rod passes through the slot A of the float rod. From the sketch the operation will be apparent.



Steam Valve Controlled by Float

Flow of Water in Clean Iron Pipes

By Albert E. Guy

Darcy's formula for the flow of water in pipes converted into United States units and applied to a convenient chart, whereby having given any two of the three quantities, gallons per minute, diameter of pipe and frictional head, the third can be read directly from the scale.

The chart herein given is based upon the work of Darcy, the well known hydraulic engineer who was assigned, by the French government the task of establishing a water system at Dijon in Burgundy. He found that the formulas in use at that time for determining the flow of water, the frictional loss of head and consequently the proper diameters of pipes, were very unsatisfactory; therefore, in order to bring about effective results with a minimum cost, he found it necessary to undertake new experiments from which, it was hoped, reliable data would be derived.

The experiments, numbering about one hundred and ninety-eight, were conducted on pipes made of various materials and sizes, these including pipes of drawn wrought iron, of lead, of iron coated inside with tar, of glass, of cast iron both new and clean, and also coated with deposits. The wrought-iron and cast-iron pipes were over 330 feet long; those of lead over 170 feet, and those of glass 146 feet. They were all well calibrated and the diameters were determined with extreme care. The lead pipes were about $\frac{9}{16}$, $\frac{13}{16}$ and $1\frac{5}{8}$ inches in diameter, and the wrought-iron and cast-iron pipes varied from $\frac{1}{2}$ to $19\frac{3}{4}$ inches in diameter.

The quantity of water was measured in each case by means of calibrated tanks, and velocities as high as $19\frac{1}{2}$ feet per second were used. The slopes of the pipes were carefully regulated so as to avoid all possible perturbations from elbows, abrupt changes of direction, or from air chambers sometimes formed through lack of care in assembling. The pressures at various points of the conduits were measured by means of piezometer tubes.

The thoroughness of the undertaking brought about splendid results, and these enabled Darcy to establish extensive tables which have proved very useful to engineers. The main points ascertained by Darcy were:

1. The friction of liquids is independent of the pressure.
2. The friction is proportional to the area of the surfaces in contact with the flowing liquid.
3. The condition of the surfaces of contact has a great influence on the friction.

Regarding the last point, he found that through the tar-coated and glass pipes, one-third more water was discharged than was indicated by the formula theretofore in use, and that deposits, even when forming but a very thin coating, caused an appreciable reduction in the amount discharged when no coating was present.

From the tables established, Darcy derived the following formula, which is known by his name:

$$hR = \left(a + \frac{\beta}{R}\right) u^2$$

in which,

R = Radius of pipe, in meters;
h = Frictional loss of head in fraction of a meter per meter of pipe length;
u = Velocity in meters per second;
$a = 0.000507$, $\beta = 0.00000647$ } constants for clean wrought-iron and cast-iron pipes;
$a = 0.001014$, $\beta = 0.0000013$ } constants for slightly coated wrought-iron and cast-iron pipes.

The transformation of the formula from the metric to United States measures is very easy. First,

$$hR = \left(a + \frac{\beta}{R}\right) u^2 \qquad (1)$$

which may be rearranged so that

$$u = \frac{R\sqrt{h}}{\sqrt{aR + \beta}} \qquad (2)$$

But if q is the volume in cubic meters discharged per second,

$$q = \pi R^2 u \qquad (3)$$

From (2) and (3),

$$u = \frac{q}{\pi R^2} = \frac{R\sqrt{h}}{\sqrt{aR + \beta}} \qquad (4)$$

whence,

$$q = \frac{\pi R^3 \sqrt{h}}{\sqrt{aR + \beta}} \qquad (5)$$

With the United States measures, q should be expressed in gallons per minute instead of cubic meters per second; the radius of the pipe in meters should be replaced by the diameter in inches; the frictional head h should be expressed in feet per 1000 feet of pipe length.

One cubic meter = 264.13 United States gallons.

One cubic meter per second = 15,848 gallons per minute.

One meter = 39.37 inches, and R (in meters) =

$$\frac{D\ (\textit{diameter in inches})}{2 \times 39.37}$$

Equation (5) then becomes

$$\textit{Gallons per minute} = \frac{D^3 \times \sqrt{h} \times 15{,}848 \times \pi}{(2 \times 39.37)^3 \times \sqrt{\dfrac{(0.000507 \times 2 \times 39.37 \times D) + 0.00000647 \times (2 \times 39.37)^2}{(2 \times 39.37)^2}}}$$

This reduces to

$$\textit{Gallons per minute} = \frac{40.152 \times D^3 \times \sqrt{h}}{\sqrt{D + 1}}$$

But h is here expressed in meters per meter length of pipe; to express it in feet per 1000 feet of length, it must be written:

$$\textit{Gallons per minute} = \frac{40.152 \times D^3 \times \sqrt{h}}{\sqrt{(D + 1) \times 1000}}$$

$$= \frac{1.27 \times D^3 \times \sqrt{h}}{\sqrt{D + 1}} \qquad (6)$$

Another convenient form is

$$\textit{Gallons per minute} = \frac{D^3}{\sqrt{0.62 (D + 1)}} \times \sqrt{h} \qquad (7)$$

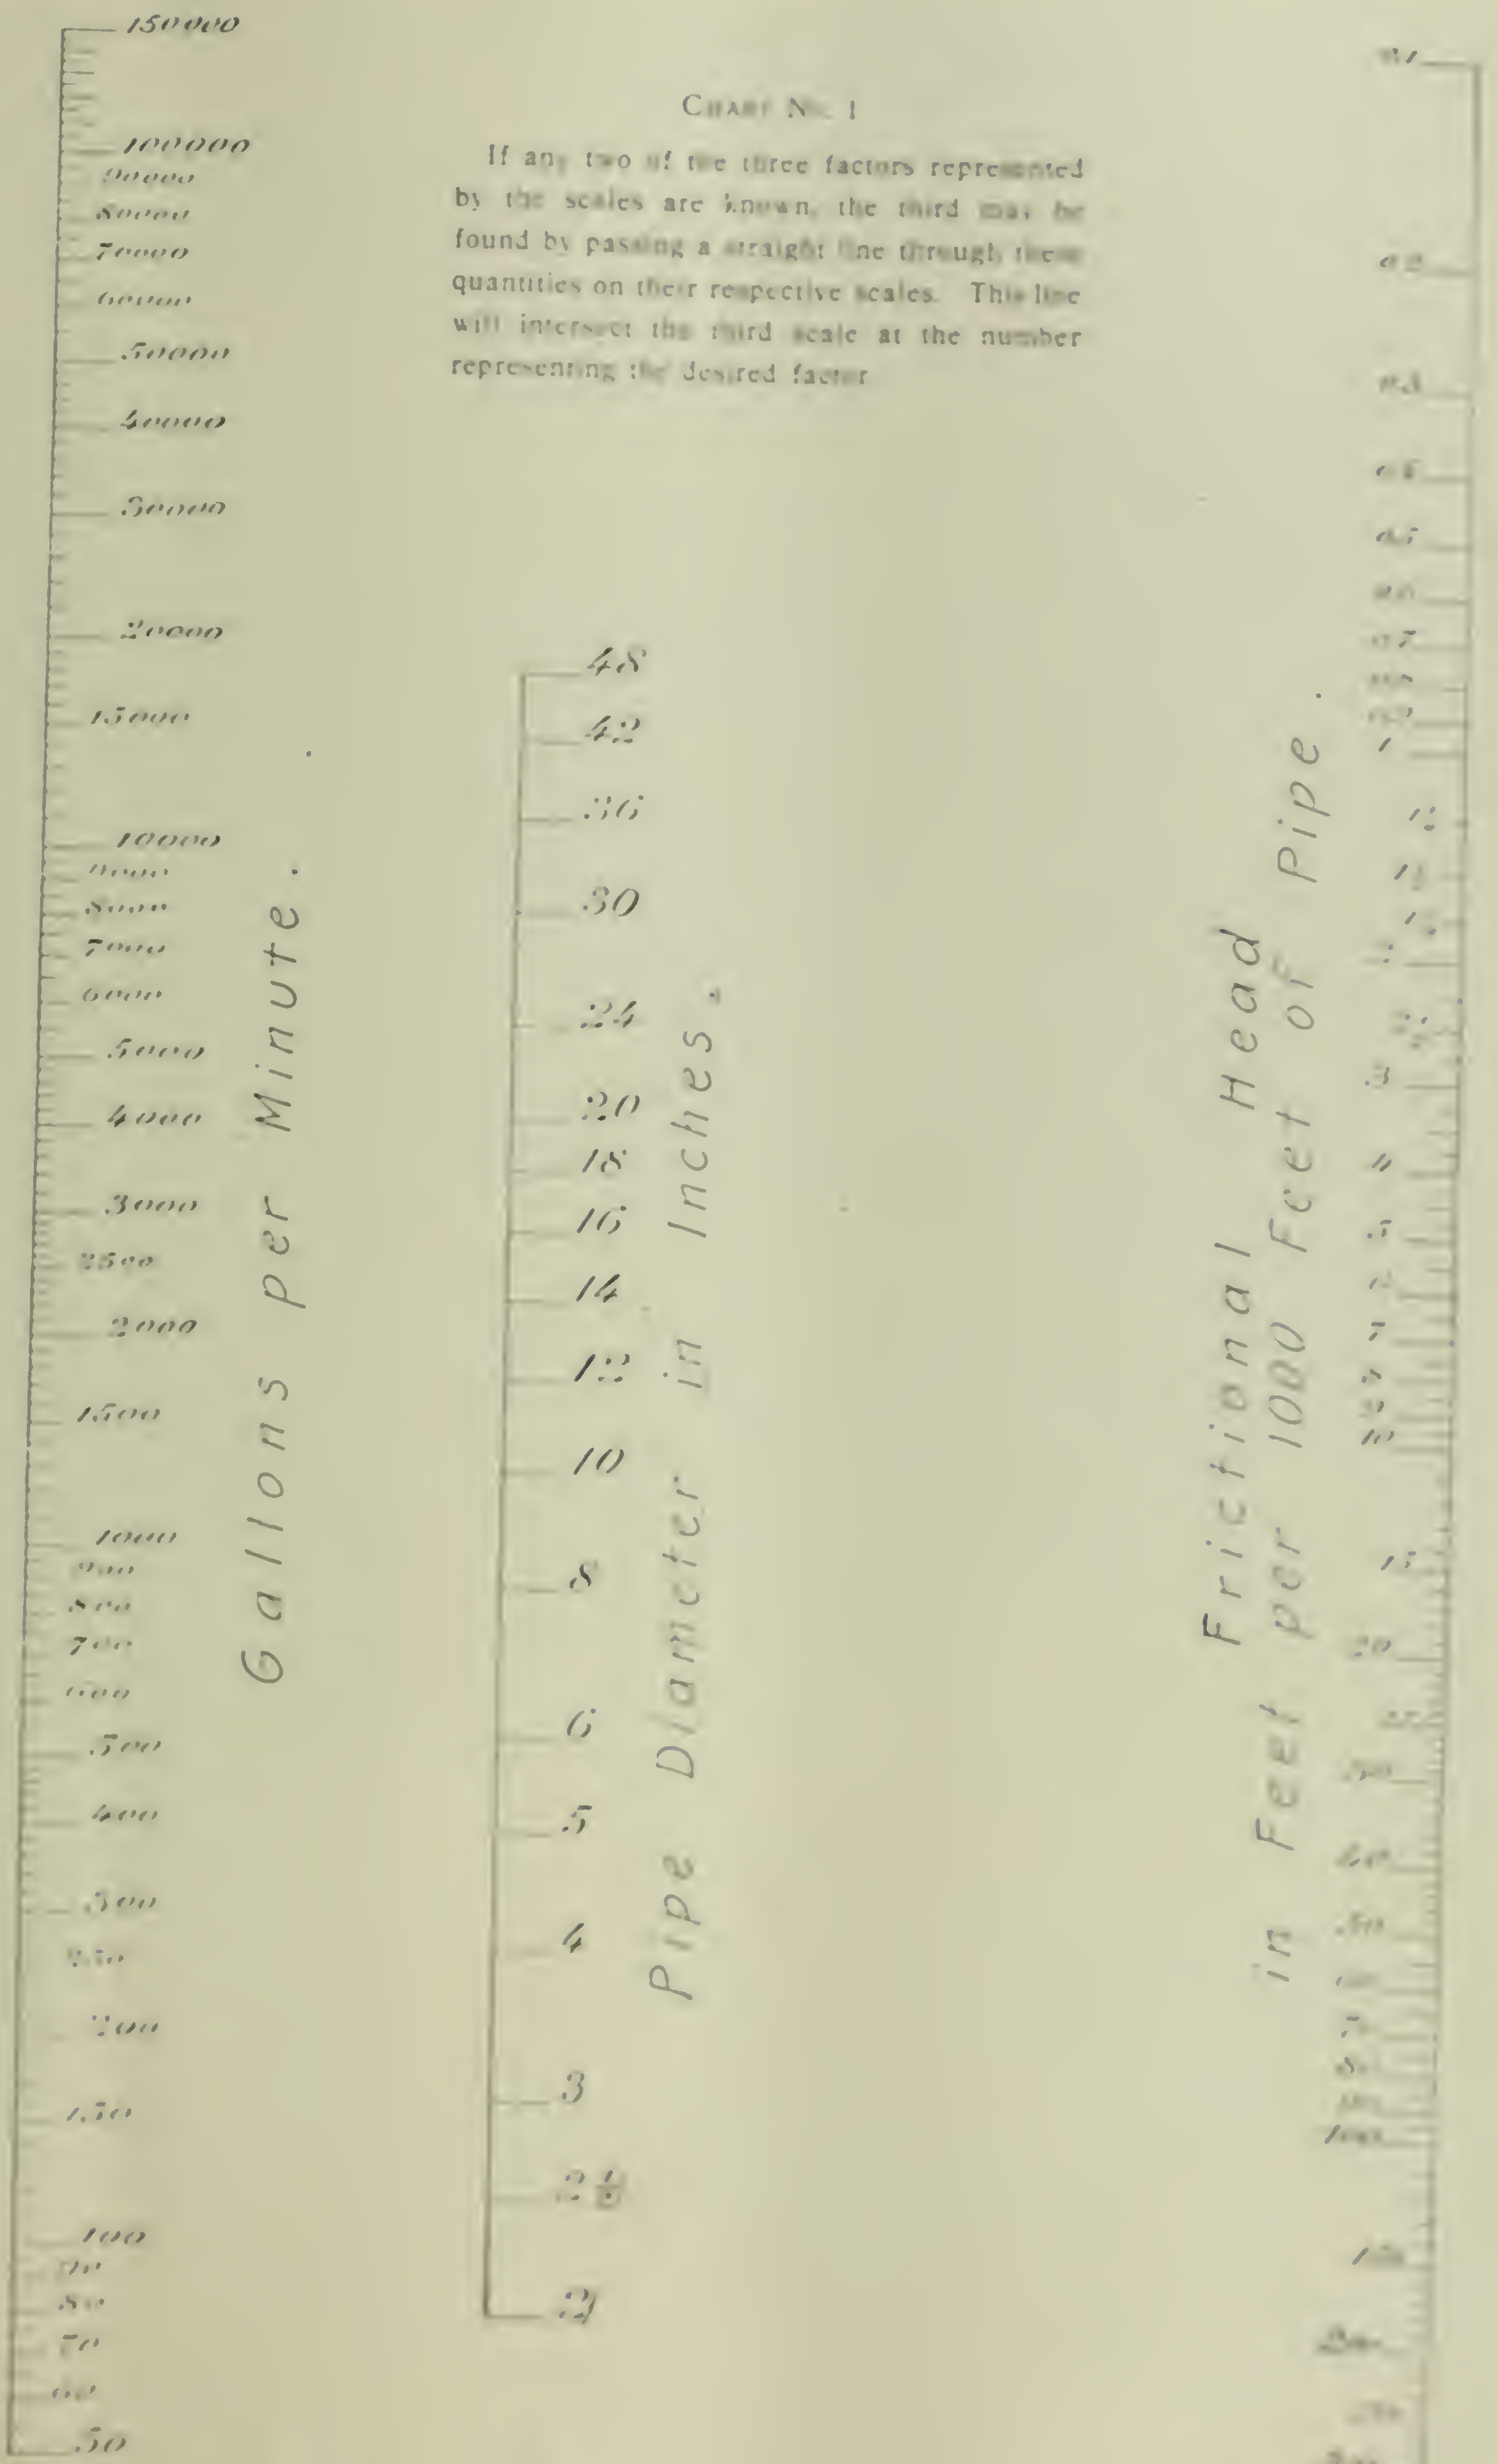
It is usual to employ the values of the constants a and β given for clear pipes. They have been found very reliable under a great variety of conditions. It would be practically impossible to establish, even through careful experiments, a series of values for such constants, that would cover the various conditions of coated inside surfaces of pipes likely to be encountered in actual practice. Hence, it seems proper to use as a first approximation a formula established for clean pipes, and then, according to one's experience, to so modify the results obtained in the calculations as to finally be on the safe side. The formula has been used successfully for many years by the writer, and is recommended in the convenient form, shown hereafter. Transposed to English units this formula becomes,

$$1.27 \frac{D^3}{\sqrt{D + 1}} \sqrt{h}$$

Chart No. 1 is intended for capacities between 50 and 150,000 gallons per minute, for pipes of 2 to 48 inches diameter, and for frictional losses of head varying from 0.1 foot to 300 feet per

CHART No. 1

If any two of the three factors represented by the scales are known, the third may be found by passing a straight line through these quantities on their respective scales. This line will intersect the third scale at the number representing the desired factor.



thousand feet of length of pipe. The chart consists of three parallel scales, the first of which represents the gallons per minute; the second, the diameter of pipe in inches, and the third, the frictional head in feet. These scales are logarithmic and are so arranged that a straight line intersecting the three scales will show the result at a glance; for instance, 1600 gallons passing through an 8-inch pipe per minute will entail a loss of head of 54½ feet, for each 1000 feet of length of pipe. For a lesser or greater length, the loss will be proportional.

The lengths of the scales depend on how close the readings are desired. Sometimes it is found very convenient to make two or more charts to cover a certain range of values. The distance between the first and the last scales must be such that a diagonal line joining the extreme

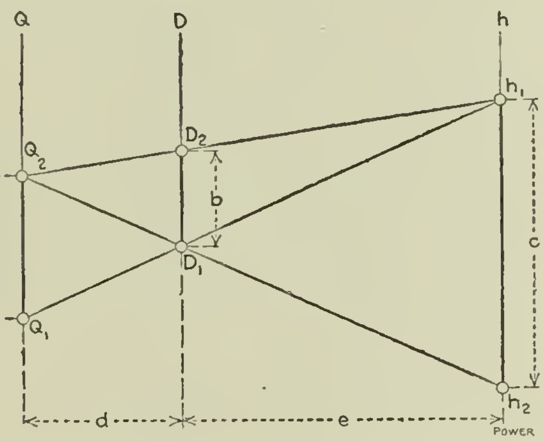


Fig. 1. Showing Method of Constructing Chart No. 1.

values of these scales would lie at an angle not much less than 45 degrees; if the angle were 20 degrees, for instance, it would be difficult to estimate correctly the readings.

The problem in making the chart is first to determine the relative positions of the scales and the "modulus" proper to each. By modulus is meant the length in inches, or more usually in millimeters, of a logarithmic scale ranging from 1 to 10. Neglecting, for the present, the denominator in equation (7), that is, considering it as a constant to be introduced later on, there remains:

$$\textit{Gallons per minute} = D^3 \sqrt{h} \qquad (8)$$

Let the gallons per minute be represented by Q (for quantity) and Fig. 1 the chart to be established. The straight *lines* $Q_1 h_1$, $Q_2 h_2$ and $Q_2 h_1$ are drawn through the three scales, $Q_1 h_1$ and $Q_2 h_1$ intersecting exactly at point h_1 on the third scale. Similarly $Q_2 h_1$ and $Q_2 h_2$ intersect exactly at point Q_2. This can be read as follows: For a quantity Q_1 passing through a pipe of diameter D_1, the frictional loss of head h_1 is precisely the same as for a quantity Q_2 traversing a pipe of diameter D_2. Also, a quantity Q_2 traversing a pipe of diameter D_2 will entail a loss of head equal to h_1, while in passing through a pipe of diameter D_1 the loss will be h_2 feet.

Let a, b and c be the distance in millimeters between the readings representing respectively the numbers Q_1 and Q_2, D_1 and D_2, h_1 and h_2. With m_1, m_2 and m_3, respectively, the modulus of the Q, D and h scales,

$$\left.\begin{array}{l} a = (log.\ Q_2 - log.\ Q_1)\ m_1 \\ b = (log.\ D_2 - log.\ D_1)\ m_2 \\ c = (log.\ h_2 - log.\ h_1)\ m_3 \end{array}\right\} \qquad (9)$$

The similar triangles, in Fig. 1, show

$$\frac{c}{b} = \frac{d+e}{d} \qquad (10)$$

$$\frac{a}{b} = \frac{d+e}{e} \qquad (11)$$

whence,

$$\frac{a}{c} = \frac{d}{e} \qquad (12)$$

Assuming the following values:

Q_1 = 1,000 gallons per minute [log. = 3],
Q_2 = 10,000 gallons per minute [log. = 4],
D_2 = 30 inches [log. = 1.4771213],

by equation (8)

h_1 = 0.13717 [*log.* = 1.1372722]
h_2 = 13.717 [*log.* = 1.1372722]
D_1 = 13.925 [*log.* = 1.1437879]

Replacing a and c in equation (12) by their values,

$$\frac{(log.\ Q_2 - log.\ Q_1)\ m_1}{(log.\ h_2 - log.\ h_1)\ m_2} = \frac{(4-3)\ m_1}{(1.1372722 - \bar{1}.1372722)\ m_2} = \frac{m_1}{2\ m_2} = \frac{d}{e}.$$

The quotient of the extreme values on scale Q and scale h_1 being the same, that is,

$$\frac{150{,}000}{50} = \frac{300}{0.1} = 3000$$

it follows that, other things considered, these scales can be made of equal length, and the same modulus can be adopted for the two. Then $m_1 = m_2$, and $e = 2d$.

From equation (9) and (10)

$$\frac{b}{c} = \frac{d}{d+e} = \frac{(log.\ D_2 - log.\ D_1)\ m_2}{(log.\ h_2 - log.\ h_1)\ m_3}$$

or,

$$\frac{d}{d+e} = \frac{1.4771213 - 1.1437879}{2} \times \frac{m_2}{m_3} =$$

$$\frac{0.3333\ m_2}{2\ m_3} = \frac{1}{6}\frac{m_2}{m_3}$$

but $e = 2d$, and

$$\frac{d}{d+e} = \frac{d}{d+2d} = \frac{1}{3}$$

then

$$\frac{1}{3} = \frac{1}{6}\frac{m_2}{m_3}$$

and

$$m_2 = 2\ m_3$$

The proportion between all the elements of the three scales are now established and there remains only to select the moduli most convenient for laying out the scales. Since,

$$\frac{150{,}000}{50} = \frac{300}{0.1} = 3000$$

$log.$ 150,000 — $log.$ 50 = $log.$ 300 — $log.$ 0.1 = 3.4771213,

and the length of the first and of the third scales will be 3.477 × the modulus selected. On the 10-inch slide rule the scale of numbers measures 250 millimeters and that of the cubes 83⅓ millimeters. If this length is adopted as a modulus, the first and third scales will be

3.477 × 83⅓ = 289.7 *millimeters,*

or about 11.4 inches long. This, of course, is somewhat reduced in chart No. 1 for reproduction, but the proportions remain the same.

Finally,

m_1 = 83⅓ millimeters
m_2 = 166⅔ millimeters
m_3 = 83⅓ millimeters.

Resorting now to the constant

$$\frac{1}{\sqrt{0.62\ (D+1)}}$$

each diameter marked on the second scale must be so located as to take this constant into account. The plan followed in this instance is as follows: The diameters selected ranged from 2 to 48 inches, and the expression of the constant was transformed thus:

$$\frac{D^3}{\sqrt{0.62\ (D+1)}} = \left(\frac{D}{\sqrt[6]{0.62\ (D+1)}}\right)^3$$

For each diameter, the corresponding value $\frac{D}{\sqrt[6]{0.62\ (D+1)}}$ was calculated and inserted on the scale instead of the diameter itself. Instead of plotting, for instance, 8, 12, 20, 36 and 48 inches, there were inserted 6.007, 8.475, 13.04, 21,357 and 27.111 inches.

This case is somewhat out of the ordinary, and if it had been necessary to have the scale of diameters continuous, the process would have been extremely tedious.

To locate the beginning of the second scale it is necessary to calculate exactly the corresponding value of the frictional head for one given diameter and a given value of gallons per minute. The position of the number representing the diameter is given by the intersection of the straight line joining gallons per minute and the friction head with the line on which the diameter scale is established.

The treatment of boiler water with lump and with hydrated lime has been tested by C. E. Thomas, general foreman of waterworks, Illinois Central Railway, whose findings regarding the comparative merits of the two materials are embodied in a paper before the Illinois Water Supply Association. A test was made on 24 tanks, each containing 65,000 gallons of water; 12 tanks were treated with hydrated and 12 with lump lime, 3432 pounds of hydrated lime and 2808 pounds of lump lime being used. Although about 22 per cent. more of hydrated lime than lump lime was used, the lower cost of the hydrated lime showed a saving of about 3 cents per tank over the lump lime. A more uniform treatment was maintained by the use of the hydrated product and the uncertain and deteriorating effects of storage upon lump lime were eliminated.

Uses of the Steam Engine Indicator

By H. T. Fryant

The importance of a proper reducing motion, the uses and limitations of an indicator, and some of the faults in engine adjustment as shown by the diagram.

Many engineers own indicators but comparatively few make a study of them with a view to what can be accomplished by their use. First, the indicator shows how nearly correct the valves are set; second, whether the valves or piston rings are leaking; third, the drop in steam pressure between the boiler and the engine; fourth, whether the compression is correct for the speed and weight of the moving parts of the engine; fifth, the back pressure; sixth, if the governor rods (when the engine is of the Corliss type) are properly adjusted to obtain the same cutoff at both ends; seventh, if the engine will run away when the governor is at its highest position, and eighth, the horsepower of the engine. Several other things can be learned from an indicator diagram, but these are the principal uses.

The most important thing to do when attaching an indicator to an engine is to have the drum move in unison with the crosshead; otherwise the diagram will be misleading. To illustrate this, assume that the engine has a 36-inch stroke and the indicator diagram is 4 inches long. In this case, one-ninth of the length of the card represents 4 inches of the stroke of the engine and a loss or gain of 7/32 inch in the travel of the drum would throw some of the events out nearly 2 inches. This shows the absolute necessity of having a correct reducing motion. The indicator is poor enough at its best, but, at the same time, it is the only thing which shows what is going on in the cylinder, and if properly attached it will be correct within 1 per cent. A few years ago the expert was the only man who did indicator work; the engineer had to take a back seat and was not supposed to know anything about this mystery; this day, however, is fast passing.

Considering the uses of the indicator as enumerated, the first is valve setting. Some claim to be able to set the valves by shop marks just as well as with the aid of an indicator. It is a fact, however, that every engine builder uses an indicator to prove the correctness of the shop marks. Even assuming that it is possible to set the valves on a simple Corliss engine by the shop marks, it is not so easy to take off all the bonnets to ascertain which valve is out of adjustment when there is a twisted stem or something else causing the engine to run badly or use more steam than necessary.

Regarding leaks, the indicator shows these better than any other way, and it does not require much study of the subject to be able to detect them. Many managers are learning to read this much about a diagram, realizing that if steam is leaking by the piston or valves, it means more coal.

The drop in steam pressure between the boiler and the engine as shown by the indicator is important. If this is found to be great, it may be reduced in some cases by taking out some of the short bends, small pipe, etc., which obstruct the flow of steam. The greater the drop in pressure, the longer the cutoff will be for a given load; the terminal pressure rises and so does the coal bill.

It is a well known fact that greater compression is required for a crank type of engine than for one of the disk type, and that it requires more on the head end than on the crank end. The greater the speed the greater the amount of compression necessary, but an indicator is about the only thing which will show how much compression the engine is running with.

The diagram will show whether the back pressure is higher than it should be, and if this is found to be the case, it may often be lessened by straightening the exhaust pipe.

As for equal cutoff, some claim they can tell this by the sound of the exhaust. This may be true, but sometimes it is hard to tell which end has the earlier cutoff. If the cutoff on one end is so late that it produces 15 pounds terminal pressure and the other is so early as to expand down to 3 inches of vacuum, it will not only cause a bad running engine, but will take much more steam than if the cutoff were the same on both ends. This can be detected accurately only by applying an indicator.

If the engine takes steam when the governor is at its highest position, it will run away. This has caused a number of flywheel explosions. It is possible to detect this without the indicator, by blocking the governor and turning over the engine, but it is much easier to use an indicator.

Considering the diagram itself, if the steam valve opens at the instant the piston is at the end of its stroke, the admission line will be vertical and at right angles to the atmospheric line, because the drum will be practically standing still. If this line leans in it shows that the valve is opening late, and if it leans out the valve opens before the piston reaches the end of its travel. If the card is 4 inches long with the stroke of the engine 36 inches and the admission line leans out 1/8 of an inch, the engine will be taking steam one inch before the piston reaches the end of its stroke; or if the line leans in, the engine will be taking steam one inch after the piston leaves the end of the stroke. Now, consider that portion of the diagram representing the travel of the piston from the beginning of the stroke up to cutoff. For this line to be theoretically correct, it should be parallel with the atmospheric line, but in practice this is never so, as the piston travels faster than steam is supplied to hold the pressure up, and as the piston moves faster at the head end, the drop is always more marked at this end of diagram. The next portion of the line is curved, this being caused by the closing of the valve; the slower the valve closes the more rounding this line will be. If a square corner were present instead of the curved line it would show that the valve had closed instantaneously. Next comes the expansion line, which closely resembles the hyperbolic curve; the variation of this expansion line from the theoretical line is due chiefly to leaks, reëvaporation, reopening of the valves, etc. If the engine is of the simple, single-eccentric type, this line should extend down to the atmospheric line at the end of the stroke. Many engines are too small to do the work required of them. This makes the cutoff so late that the full benefit of expansion is not attained.

At release the line makes a sharp turn, forming what is called the toe of the diagram. Sometimes this toe will turn down and even go below the atmospheric line, but on most single-eccentric engines it does not get down to the atmospheric until the piston has moved back 4 or 5 inches on its return stroke. This could be remedied to some extent by moving the eccentric ahead, but this is not advisable on most engines, as it makes the range of cutoff too short and the valves will not release.

Next is the back-pressure line. This line is usually above the atmospheric line, which is caused by pressure backing up in the exhaust pipe. It is good practice to take a diagram direct from the main steam pipe just above the throttle, and then, without removing the card, connect the indicator to the cylinder and take another diagram.

As to the amount of compression which should be used it may be said that just enough should be employed to make the engine pass over the centers without a pound. If an engine has a compression pound, it is nearly always on the head end. This is because the speed at that end is the highest, caused by the angularity of the connecting rod.

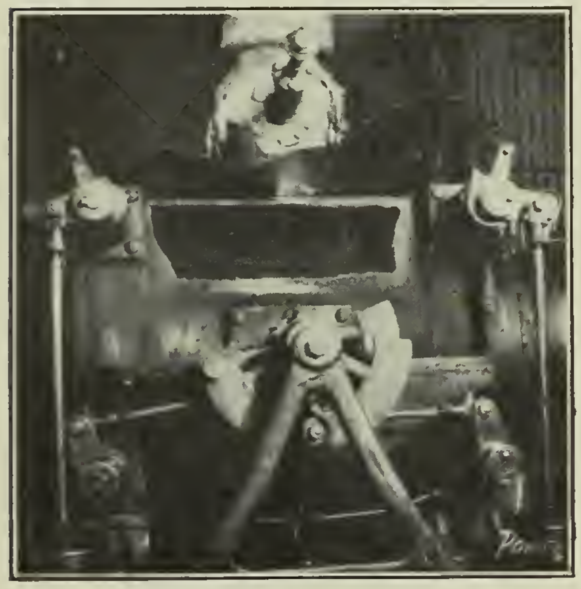
Any man who is interested and lets his boss see that he is interested, will not have much trouble in securing an indicator.

A Wrecked Engine Cylinder

By C. L. Greer

The accompanying photograph shows an unusual mishap to a 1000-horse-power compound engine which necessitated the buying of a new cylinder and which might have occasioned loss of life which it fortunately did not.

While operating, the side wall of the steam chest of the high-pressure cylinder let go on the valve-gear side with the result shown. As may be seen, the whole side was blown out. The flying fragments left only the hub of the throttle handwheel on the stem, broke both steam cranks smooth off, took away the top of both steam and exhaust wrist-plates (made in wheel form) and broke one of the reach rods on the low-pressure side.



Wreck of High-pressure Cylinder

The plant being overloaded a temporary steam line was run to the low-pressure cylinder, the high-pressure crank was disconnected and the engine delivered half power from the low-pressure side. The cause of the break is not known.

Smoke Abatement

Professor Watkinson, Liverpool University, delivered the fourth of the lectures for stokers and others interested in furnace management in the lecture theater of the Walker engineering laboratories at Liverpool on Friday evening, February 17, taking as his subject, "The Setting and Construction of Boilers and Furnaces, and the Methods of Producing Natural, Forced and Induced Draft."

After a few opening remarks dealing with the general aim and purpose of the lectures, and with the importance of accurate measurements of draft, temperature, steam pressure and of the composition of the exit gases as an aid to good work in boiler management, the lecturer dealt with the three conditions requisite to obtain good combustion of solid bituminous fuels and showed experimentally how essential these were to smokeless combustion. The details of construction of a Lancashire boiler were then illustrated by aid of lantern slides in order to prove the difficulty of obtaining smokeless combustion in this type of boiler, a difficulty due to the small furnace and the arch of water-cooled plates over the furnace grate. The purpose of the bridge was then discussed, and the lecturer stated that it produced eddies in the gases as they passed over it into the flue beyond, and therefore tended to promote mixture of the hot air and hydrocarbon gases given off from the burning fuel. A high bridge was therefore better than a low one, if sufficient draft could be obtained to work the boiler fires with it. In the absence of good draft the use of steam jets was often resorted to in order to increase the air supply and to promote the better mixture of the air and furnace gases. In the Belleville type of marine boiler, air at 30 pounds pressure was employed in place of steam, and the Howden system of forced and preheated draft was now generally employed for marine work; but this system in spite of its many advantages had not been adopted for boiler installations on land. Natural draft produced by a chimney rarely exceeded ½ to ¾ inch, measured by a water gage. This low draft limited the thickness of the fires and rendered it exceedingly difficult to keep the fuel lying on the furnace bars free from holes. For good combustion with thick fires, on the other hand, forced or induced draft was essential, and this was now generally recognized and adopted. The different methods of obtaining artificial draft were then discussed, and the comparative advantages of steam jets, air jets and fans were dealt with by the lecturer. As compared with steam jets, fans were more costly to install, but saved largely in running cost, a good fan requiring only 5 per cent. of the steam produced, in place of the 10 to 12 per cent. used by steam jets. The statements made by the makers and other interested parties that steam jets only consumed 3 per cent. of the steam were absolutely inaccurate.

The different methods of furnace construction and the use of firebrick arches for conserving heat and promoting good combustion were then dealt with. It was pointed out that a firebrick arch by increasing the temperature of a furnace may actually increase smoke production, owing to the greater rapidity with which the hydrocarbon gases will be evolved from the freshly charged fuel, unless precautions are taken to greatly increase the air supply at the same moment. The dutch-oven type of furnace construction for Lancashire boilers was condemned by Professor Watkinson for the reason that from 40 to 60 per cent. of the heat transfer in this type of boiler is by radiation from the glowing solid carbon lying on the bars of the grate to the plates above, and this radiation can only occur to the full extent when the furnace is inside the boiler. Luminous flames radiate heat also, but not to the same extent as glowing solids. Although steam boilers can be worked efficiently with the gaseous fuel, they require to be specially constructed for this duty, and no ordinary type of Lancashire boiler will give high efficiency with external furnace or with producer gas. The use of economizers was finally discussed, and the two chief types were described.

The lecture was illustrated by numerous experiments and lantern slides, and was followed by an exhibition of apparatus for making draft, temperature and the other measurements incidental to good boiler management.

The Stumpf Unidirectional Flow Steam Engine

In previous issues of Power, and particularly the January 31, 1911, number, the design and method of working of this type of engine have been given considerable attention. Since the date mentioned above, some illustrations of a marine engine and locomotives employing the straight-flow principle have come to hand and are presented herewith.

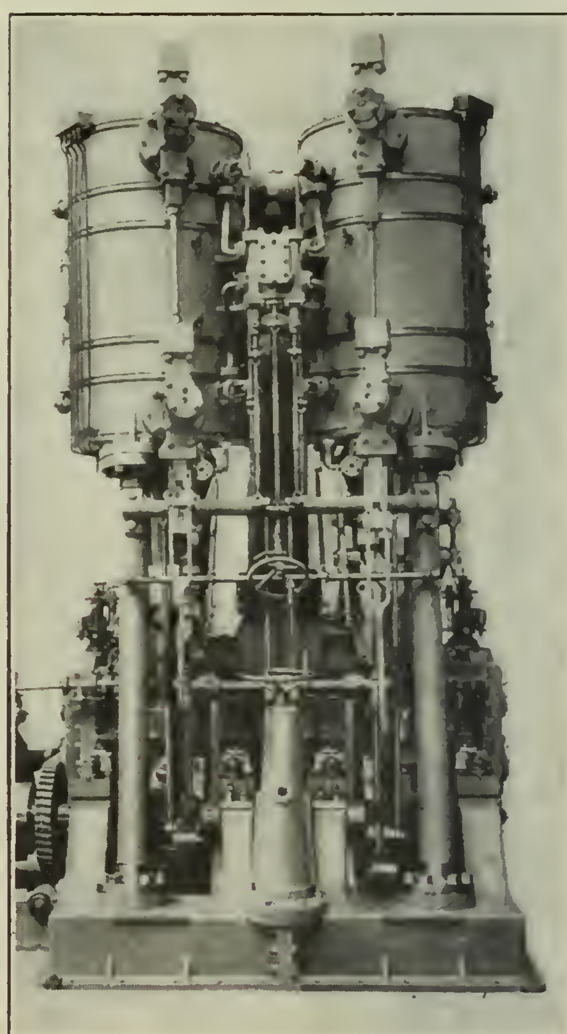


Fig. 1. Second Marine Engine Built of Straight-flow Principle

Fig. 1 is a photo-engraving of the second marine unidirectional-flow steam engine of this system. It was built by the Stettiner Maschinenbau Aktien Gesellschaft at Stettin-Bredow.

Fig. 2 illustrates an express locomotive, and Fig. 3 is a view of a locomotive

FIG. 2. AN EXPRESS LOCOMOTIVE UTILIZING STUMPF PATENT

exhibited at the Brussels exposition. Both of these locomotives have been in successful operation for several months, and six duplicates of the type exhibited have recently been put into successful operation.

Fig. 4 is a cross-sectional view of the cylinder of a locomotive which has five drivers and weighs approximately 85 tons. Five of these locomotives have been ordered by the Moscow Kasan Railway, and at present are in the course of construction.

Engines working on the unidirectional-flow principle are apparently making great headway in Europe, and it is only natural that they should for the efficiency of a single cylinder is practically equal to the best figures obtained with compound and triple-expansion engines.

On a 300-horsepower engine with a cylinder 23.5 inches in diameter, a steam consumption of 8.5 per indicated horsepower-hour was obtained. Besides the merit of high economy the straight-flow engine has a flat-efficiency curve, which means a steam consumption on fractional load or overload of but little more than at normal load.

A Thriving Power Plant Developed by Protecting Low Ground from Floods

By D. A. Willey

The extent and variety of operations that may be actuated from a small water power are well illustrated by a canal in the Salt river district of Arizona. The locality which it serves has no available coal or wood for generating steam and depends entirely upon the electric current generated by the water flowing from the Salt river through this canal. To obtain the necessary hydraulic head the head gates of the canal were located on the Salt river 20 miles above the power station. The width of the canal is 15 feet at the top and 10 feet at the bottom; the minimum depth is 10 feet. The water is delivered from the canal through steel pipes to turbines direct-connected to alternating-current generators. Three of these units are rated at 900 kilowatts each, working under a head of 226 feet. The other three units comprise two of 900 and one of 1500 kilowatts, getting water under heads which range from about 70 to 220 feet.

Fig. 1. Dam and Power House at End of Canal

A maximum of 4400 electrical horsepower is generated and is utilized for the following purposes: Lighting two communities, operating a tram road six miles long and operating a series of electric pumps to irrigate 50,000 acres of land. During the construction of the Roosevelt dam the plant furnished power for actuating aërial cableways for conveying stone blocks, cement and other material for dam construction, and driving the motors in a cement mill producing 1000 barrels daily.

The current is stepped down to the proper voltage for service and distributed from the transformer station by a steel-tower transmission line carrying six wires of stranded hard-drawn copper. For the irrigating pumps the wires are carried on tripartite poles of varying hight, depending on location and the length of the line and topography of the country through which it passes. At a point about a mile east of the town of Mesa, a switching station is installed from which a line leads south into the pumping territory where 1000 horsepower is used for pumping. The wells have been drilled and many of the lateral canals built into which the water is pumped and otherwise diverted from the Salt river during floods. In all, thirty pumps are operated.

Seven miles south of Mesa the line enters another pumping territory and here ultimately from 20,000 to 40,000 acres will be served when the necessary machinery is installed. The pumping units are vertical-shaft centrifugal pumps direct-connected to 50-horsepower induction

Fig. 2. Part of 20-mile Canal from Salt River to Power Station

motors supplied with current at about 220 volts and 25 cycles.

The main transmission line carries current at 45,000 volts and the main distributing lines operate at 10,000 volts. The line mentioned as running south to the Indian reservation is a 45,000-volt line. There is a substation eight miles south of Mesa in which the transformers change this voltage from 45,000 to 10,000. The main transmission line continues through Mesa and terminates at the present time in Phœnix, 78 miles from the power source, where power is furnished to light the city.

The cement mill was constructed to furnish concrete for the Roosevelt dam and dismantled after the dam was completed. Its equipment, consisting of the separators, material conveyers, grinding and pulverizing apparatus, was operated by a number of motors through shafting and belting. The operation of this cement mill was one of the principal objects for which the power plant was established but the other industries which it serves have given it permanent usefulness.

LETTERS

Geared Dynamos and Turbines

The article by George W. Malcolm on "Reduction Gears for Turbine-driven Direct-current Generators," in the issue of February 14, comparing the efficiency of turbine-driven direct-current generating sets with and without gears, fails to include several important elements. Mr. Malcolm attempts to show that in order to attain an overall efficiency from steam to switchboard of 52.2 per cent., as claimed by advocates of the geared outfit, it is necessary to assume either an impossibly high generator efficiency or an impossibly high turbine efficiency.

For one thing, Mr. Malcolm's assumption of 97 per cent. as the efficiency of a gear of this character is too low, if applied to accurately cut gears; 98½ per cent. would be nearer the correct figure. The efficiency of such gears is not a matter of doubt or guess-work, since it can be determined within a very small percentage of error. With a gear efficiency of 98½ per cent. the figures for turbine efficiency and geared generator efficiency would be as follows:

Turbine Efficiency.	Generator Efficiency.
54 %	[illegible]
56	94.[illegible]
58	91.[illegible]
60	[illegible]

A turbine efficiency of even 60 per cent. is well within the limits of possibility for a 1000-kilowatt turbine, especially if advantage be taken of the gear to increase the speed of the turbine, as well as to reduce the speed of the generator. Doubling the speed of the turbine would reduce the number of stages of a velocity-stage turbine to one-half or those of a pressure-stage turbine to one-fourth, resulting not only in increased efficiency but possibly also saving more than enough on the cost of the turbine to pay for the cost of the gear.

Moreover, according to the above table, the generator efficiency would need to be only 88½ per cent., although there should be no difficulty in reaching 95 per cent. if the speed of the geared generator be only one-fifth that of the direct-coupled generator.

Further, Mr. Malcolm entirely ignores the many practical advantages of the standard-speed direct-current generator as compared with the high-speed generator for direct connection to turbines. Among the many disadvantages of the high-speed direct-current machine may be mentioned the following: Proper commutation involves carefully designed interpole construction; as the diameter of the commutator is limited by the allowable peripheral speed, it is usually necessary to use a double-length commutator in order to obtain the requisite area and keep down the current density within satisfactory limits; the number of commutator bars and distance required between brushes limits the number of poles which may be used; with very long commutators, or with two commutators in tandem, there is difficulty in securing uniform distribution of current between the different brushes on each brush arm; very careful shop work is required; the increased length of shaft necessary to accommodate the commutator increases trouble from vibration, which in turn interferes seriously with the commutation, especially if carbon brushes be used; while it is difficult to compute the critical speed of a direct-current armature, it is very important that that speed be not approached, also that the commutator and armature be in perfect balance; due to drying out or other change in the insulation after the commutator and windings have been assembled, there may be a displacement of the center of gravity which will give rise to vibration entirely beyond the skill of the attendant to remedy, making it necessary that the armature be sent back to the manufacturer for readjustment; the necessity of limiting the diameter of the armature restricts the space available for insulation and for armature windings, so that it is doubtful if the increased windage, iron losses and friction would be neutralized by a decrease in the purely electrical losses, as claimed by Mr. Malcolm; due to the very high speeds at which the armature must run, and the necessity of passing a large amount of air through it in order to keep it cool, there is a great tendency for the collection of dust, including carbon dust from the brushes, and it is found that under high-speed conditions, this dust assumes a very compact form, which frequently results in short-circuits or grounds; finally, while the standard speed electrical generator is entirely familiar to the ordinary operating man, who can make any small repairs as they may be required, the repair of the high-speed generator is entirely beyond both his knowledge and his facilities.

The majority of dynamo designers appear to be of the opinion that units of 1000 kilowatts should not exceed a speed of 1500 revolutions per minute and this speed has in fact been found most suitable also for much smaller machines, even down to 500 kilowatts. However, by installing a 10 to 1 gear, the speed of the generator can be reduced to 300 revolutions per minute, which is moderate and the usual speed for waterwheel-driven generators; at the same time the speed of the turbine can be doubled to 3000 revolutions per minute, which will permit the use of a much shorter, simpler structure, less liable to give trouble by vibration, rubbing, etc., than a longer turbine running at a slower speed. In addition to the saving by the reduced size of the turbine, there will be some saving in the cost of the generator, so that there will be no difficulty in covering the added cost of the gear.

GEO. H. GIBSON.

New York.

Mr. Gibson's assumption that I "attempt to show" that Mr. MacMurchie's economy figures are impossible appears to be due to a lively imagination; it certainly has no foundation in fact. All that my tables were intended to show is a list of possible combinations which would fit Mr. MacMurchie's steam figures. For the benefit of Mr. Gibson and any other readers who may feel impelled to read into my article a forced and sinister meaning, it may be advisable to state that the argument of the article was merely to the effect that the use of the Melville-Macalpine gear for connecting direct-current dynamos with turbines other than the De Laval would not make possible a higher dynamo efficiency and would probably not be of enough advantage to make it pay.

As I am informed that the builders of the gear claim only 98 per cent. efficiency for it, Mr. Gibson's slightly generous allowance is academic; furthermore, as no machinery except waterwheels and grindstones has ever succeeded in maintaining in actual service an efficiency equal to that developed in the maker's test, my allowance of 97 per cent. is quite rational.

Mr. Gibson's attempt to explain the effect of speed upon the design of a direct-current dynamo would be more interesting if it were entirely accurate and if even a corrected version referred to were relevant to any argument that I have advanced. Anyone who has the least familiarity with the subject knows that very high speeds entail serious commutation difficulties; if I had claimed the contrary to be true, Mr. Gibson's fifth paragraph might have been justified. As it is, he has merely indulged in the superficial pastime of demolishing a Frankenstein of his own construction.

Geo. W. Malcolm.

Brooklyn, N. Y.

Cutting Out the Compounding of an Alternator

I was once called to correct trouble on a single-phase compound-wound alternator which was reported as failing to hold the voltage up when running at full load. Fig. 1 shows the connections of the alternator as they were found. To simplify the sketch only two commutator segments are shown, but in reality there is always the same number of segments as of field-magnet poles.

Those familiar with this type of alternator know that the main armature current is rectified by the commutator *A* and passes through the series field winding. In this way the extra field excitation is obtained that is necessary to overcome armature reaction and to hold the voltage normal at full load.

After testing for faults in the machine, I found that the commutator was short-circuited, cutting out the current that should have gone to the series field winding. The repair of this commutator would have been a somewhat difficult job without having factory facilities, so I decided to do away with the compensating feature and connect the machine as shown in Fig. 2, also reinforcing the short-cir-

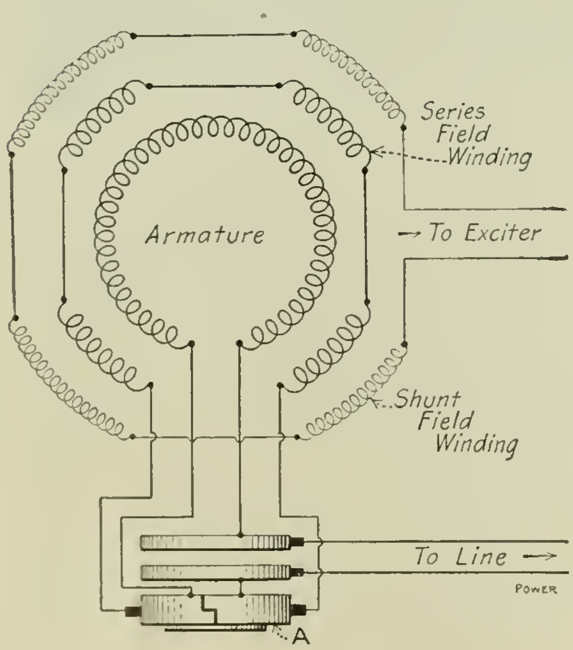

Fig. 1. Original Connections

cuit of the rectifying commutator *A*; a piece of wire was wound around the commutator for this purpose. The series field winding was connected in series with the main field winding, the coils of which were connected in parallel-series, as shown, and the combination was connected to the exciter. This increased the load on the exciter, but it was large enough to stand it. We had no difficulty in holding the voltage at full load and the operator was so pleased that the com-

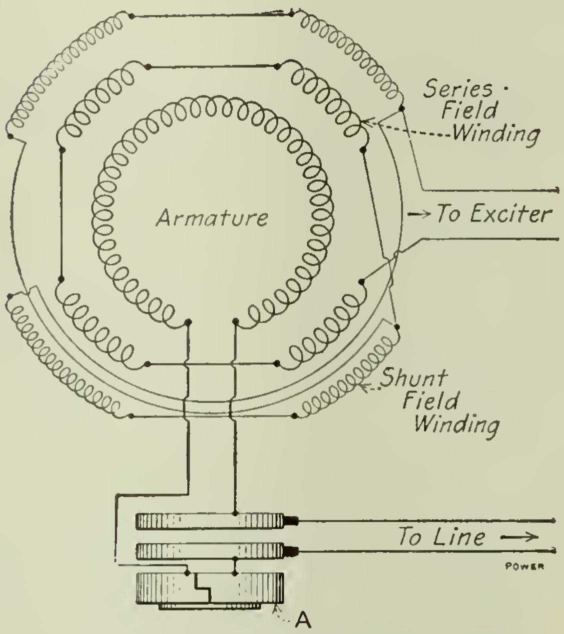

Fig. 2. Changed Connections

mutator and brushes had been cut out that we decided to leave the machine connected that way permanently.

Anniston, Ala.

Mr. Hull's Erratic Belt

From reading Mr. Hull's letter in Power of February 14 it is evident that the two pulleys do not line up or the two shafts are not parallel, that is, one of them is not level—perhaps both.

The reason the belt runs true with the center of the pulleys when loaded and shifts from one side to other in stopping and starting is that the crown on the pulley guides the belt true with the center when it is pulling a load and tight, but when starting or stopping the belt is slack enough to run to the edge in response to the unsymmetrical influence of the pulleys.

If it is an endless belt it may have been glued together crooked, that is, with one edge longer than the other.

N. E. Woolman.

Danbury, Iowa.

The erratic belt behavior described by W. S. Hull in the February 14 issue of Power appears to be a duplicate of an experience I had with a similar outfit. In my case the trouble was due to the fact that oil worked out onto the flywheel from the engine bearing and moistened the inside half of the belt when running, causing that half to stretch. This forced the outside half to carry most of the load and that half, under the extra strain, stretched also; this enabled the belt to adjust itself true to the center of the pulley when the load was on it. As the outside half was dry, however, it contracted back to its original length when the load was taken off and then the belt was crooked, which accounts for its not staying on the center of the pulley when starting and stopping.

I opened the seams on the stretched side and tried taking up on them, but this did not help much as the belt was still stretched between the seams. I then tried to stretch the short side to match the other side by moistening it while it was running, also putting more tension on it, but with no better results.

By experimenting with the belt-adjusting wheel on the generator I learned that by reducing the tension on the belt before shutting down and increasing it before starting, the belt would run true with the center of the pulley. The amount of tension in each case must be determined by experiment.

This remedy, however, is not absolute, for, although an engineer may be able to operate the belt in this manner by careful attention, the load may suddenly change on the generator when he is not near to attend to the belt, or someone else may start the engine and cause a wreck that would be far more costly than having the belt put in proper condition. It should be sent to a belt manufacturer to be cleaned and straightened and the seams made over. In the mean time, I advise Mr. Hull to make sure that the pulley is in line with the driving wheel and the foundation bolts are tight; also, not to allow the generator to swing when the load is on it and to see that no water is allowed to drip on the belt from the roof or piping.

J. W. Blake.

New York.

If Mr. Hull, who had a letter in Power for February 14 regarding a dynamo belt, will test the face of the pulley with a straight-edge he will probably find that it has worn slightly hollowing in the center. This can be corrected by building up the center of the pulley by winding strips of thick paper around it. The paper can be fastened on with either glue or shellac; shellac will resist both oil and water, but Mr. Hull probably does not let either get on his dynamo pulleys. By using strips of paper of different widths the pulley can be built up so that it will have any desired crown. I have had a similar experience which was corrected in the manner described.

G. E. Miles.

Salida, Colo.

German interest is greatly aroused in the proposal to utilize the power of the Tinfos, which is estimated at 15,000 horsepower, to supply the energy for electrifying the whole of the Tinfos iron works. By the summer of 1911 it is estimated that one-third of the power will be in use for the electric furnaces, and that twelve months later the head of water will be fully utilized.

Gas Power Department

Everything worth while in the gas engine and producer industry will be treated here in a way that can be of use to practical men

A Composite Pressure and Suction Producer Plant

The accompanying engravings illustrate an equipment of pressure gas producers in a New England manufacturing plant, together with some details of the producer construction. Figs. 1 and 2 show the plant of three generators and the charging floor, respectively. Fig. 3 is a sectional elevation of one of the generators. The inside diameter is 8 feet and the generator is rated at 400 pounds of coal per hour on a 24-hour basis, burning approximately 12 pounds of coal per hour per square foot of grate surface. The generator is a heavy steel cylindrical shell, firebrick lined and set in a concrete pan; the shell is supported by four legs of structural steel, one of which is visible in Fig. 3. Coal is charged through double-sealed hoppers which rest on water-cooled tops, and poke holes are located at convenient points; the holes are closed by finished plugs and the construction is such that the poking bars cannot injure the finished surface and wear the holes out of true. A simple cast-iron bell is used in the feeding hoppers, held to its seat with a counterweight, as indicated in the illustration.

A notable feature of the generator is the annular tuyere, of dog-house cross-section, which distributes air and steam throughout the bed of fuel with an unusual approach to uniformity. The annular outline of the tuyere facilitates the removal of ash, as the latter can descend both around the outside and through the inside opening of the annulus. The tuyere is supplied with air and steam by two blowers of the Körting type, located at opposite ends of the diameter of the tuyere; this, of course, tends to uniform distribution.

The gas from the generator passes through an economizer consisting of two concentric circular shells of heavy steel plate, the gas passing through the inner shell and the air for the generator passing through the outer one in the opposite direction. Most of the available sensible heat that is in the gas when it leaves the generator is taken out in the economizer by the air passing to the blowers, with the result that the air is heated considerably beyond the condensing temperature of the steam used in the blower; consequently, no moisture is precipitated in the bottom of the generator.

Two scrubbers of the combination type are used. In the bottom part of the scrubber the gas is cooled and cleaned by means of a spray of water and a bed of coke and the upper portion is filled with excelsior for removing the moisture entrained by the gas passing upward.

Fig. 4 is a sectional elevation of a three-way water-sealed valve that is used at the junction of the purge and scrubber pipes. With the valve bucket in the position shown, the purge pipe is sealed off and the gas passes to the scrubber through the bottom outlet.

Fig. 3. Generator Construction

An unusual feature of this plant is the use of both suction and pressure to create the draft through the generator. Perhaps it would be more accurate to say that suction is used incidentally in addition to the steam blowers, not necessarily. Positive blowers are connected between the scrubber outlet and the delivery main

Fig. 1. The Producer Plant

Fig. 2. The Charging Floor

in order to maintain an actually constant pressure in the main, and these, of course, subject the generators to suction. The inlet and outlet of each blower are connected by a bypass in which is a regulating valve that allows some of the gas

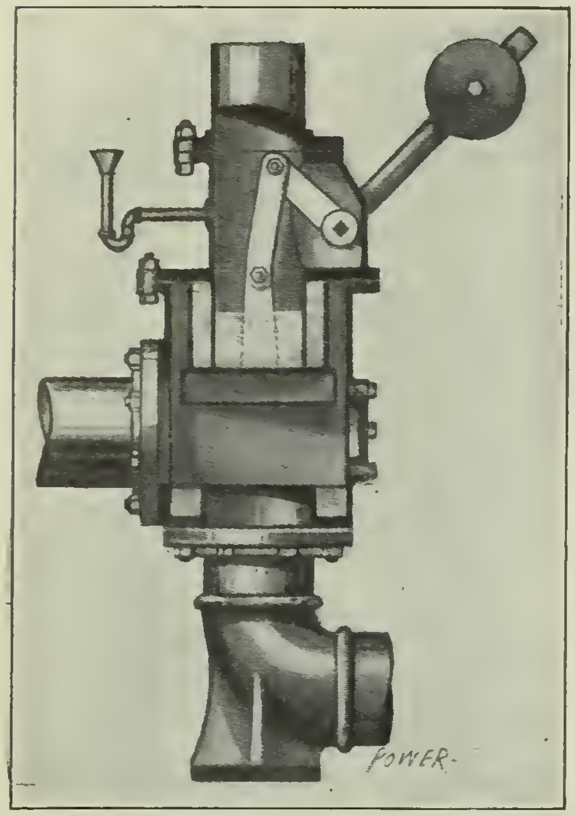

FIG. 4. WATER-SEALED VALVE

merely to circulate in the pump when the pressure in the main is normal. The pumps or blowers and their connections are illustrated by Fig. 5. To reduce the liability to shutdowns, one of the blowers is driven by an electric motor supplied with current from the central station of the town and the other one, which is nor-

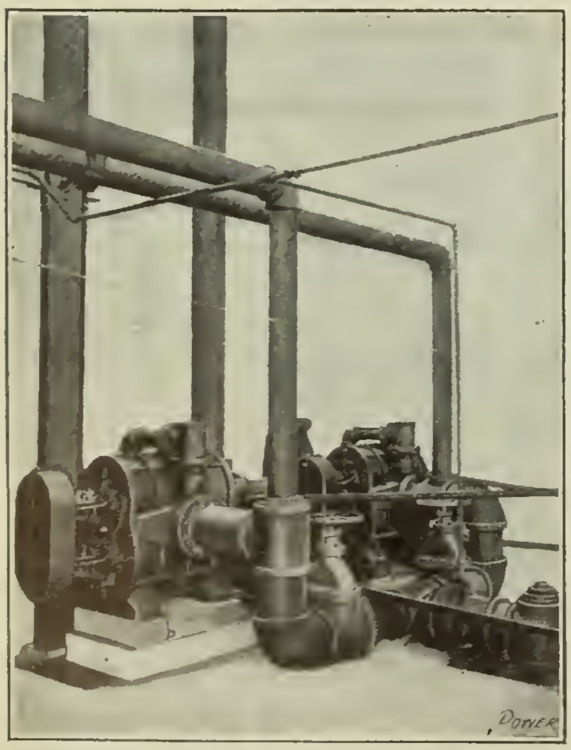

FIG. 5. THE GAS PUMPS

mally used, is driven by a small vertical engine supplied from the boiler which makes steam for the gas generators.

The coaling arrangements are so clearly shown in Fig. 2 that a verbal description is not necessary. A simple but excellent feature of the building is that the charging floor is open on the side toward the auxiliaries on the floor below, so that the operation of the pumps can be observed from the charging platform.

The equipment was designed and built by the Flinn & Dreffein Company, of Chicago.

Gas Power Plant Erectors and Operators

By W. E. Nelson

Do gas engines and producers need engineers, and do gas-engine and producer manufacturers need information or advice from the erecting men? Many manufacturers depend upon their engineering talent in the office and drafting room to work out the details and turn out a machine that will give reliable service, depending upon an indicator card, a brake test of two hours and one or two observations of the engine's performance while running nicely under a moderate load.

Two plants practically alike were installed under different conditions; one of them was accepted and the other rejected. The one that was rejected was installed by an engineer from the office and the other one by an erector from the test floor. Before the office engineer had gained enough practical experience to get his plant to operating successfully it was too late for a practical man to do any good.

On the other hand, many gas-engine installations that were installed by practical men have been rejected through the fault of the manufacturers in not sending men that were adapted to the particular line of work to be done. An experience with a small municipal electric-light plant will serve to illustrate one way in which the manufacturers are to blame for poor installations and unsatisfactory operation. The plant equipment consisted of a 55-horsepower engine and suction producer which was sold by a gasolene-engine agent, who, in an endeavor to save as much as possible, sent his regular gasolene-engine erector to install it. The erector was of the type that can use his hands to a good advantage but not his head. In the first place he hired a hobo who was looking for a day's work to put in the firebrick; the result was a leaky lining. He next piped the jacket water from the engine into the scrubber; the result was that the engine got warm gas laden with tarry vapors and small particles of dust that were carried over in the vapor. The next mistake and most serious was neglecting to open a drain which relieves the vaporizer of the water that does not vaporize, which resulted in filling it up to the air intake and shutting off the supply; this caused the engine to back-fire, slow down and finally stop. The manufacturers left a 2-inch pipe flange on the engine intake after testing it on natural gas; the erector connected about four feet of 2-inch pipe to the intake and connected that to the 5-inch gas main with a reducing coupling.

I am not criticizing the man; my object is to emphasize the advisability of employing men trained to do this particular kind of work intelligently; they cannot be hired for $60 a month.

The erector left the plant in the condition described and the town hired a local man to run it; he burned out a dynamo bearing the first week. They tried two or three other men and finally shut the plant down and notified the agent to take it out. He, as a last possible resort, wired the factory for a man, informing them that he must be a diplomat as well as an expert in every sense. The man who was sent was neither a diplomat nor an expert in the usual sense of that title, but he was instrumental in putting the plant in good condition and getting it accepted. In order to get a settlement the agent had to sacrifice the profit and considerable more, which would have made up the extra cost of a good man for several years.

In another plant, poor repair work on a generator lining was done by the operating engineer. The firebrick being badly burned out in the lower half of the generator, he decided to replace all of the badly burned brick; in finishing up the lower half of new brick he found that it did not connect with the upper half, of old brick, by nearly half an inch, so he filled the crack with fire clay. It held until it dried out; then the engines would slow down and would not carry full load, the producer would get a mixture of air and gas in the top and ignite it and blow dust and fine coal out at every joint. The greatest inconvenience would occur when cleaning the fire with the cleaning door open. It was not long before the engineer telephoned the factory for a trouble man; he had blown the fire several hours and could not get good gas at the engine. Upon inspection it was found that a trowel could be inserted all the way around the lining, in the crack between the old and the new parts of the lining.

A good rule to follow in replacing burned-out brick is never to replace them higher than half way to the extreme fire line, and then the greatest care should be taken to fit them perfectly; in case it becomes necessary to replace any more it is best to remove all the brick to make sure of getting a good tight lining. It may cost a little more at the time but will be a great saving in the long run.

Up to the present time there has been very limited publication of the experiences of gas-engine and producer men. Talking with several of them has given me the impression that they are laboring under the delusion that their experiences are too valuable to give away; the other fellow can find them out the same way they did. This is about as unprogressive and senseless as anything can be.

Practical information from the man on the job. A letter good enough to print here will be paid for. Ideas, not mere words wanted

The Oil Disappeared

During the summer months it was the custom to stop the engine, and not close the stop valve on the boiler, but as cold weather set in it was closed, and after draining the pipes, the throttle was also closed to prevent any leakage running into the drains and freezing.

Since that time I have been wondering why the engine took so much oil, as the oil pump had not been tampered with. One morning the engine had been running about an hour when the cylinder began to groan.

I looked into the oil-pump reservoir, which had been filled the day before, and found it empty. In thinking it over I came to the conclusion that, closing the stop valve and throttle created a vacuum in the pipe and drew all the oil out of the pump in the effort to supply the pipe with air. A cure was effected by opening the bleeder on the oil pump, thus supplying the pipe with air.

FRANK GARTMAN.

Sheboygan, Wis.

Graphite as a Boiler Compound

The value of graphite as a boiler compound is not generally known by operating engineers, and a recent experience in using graphite in boilers that were supposed to be perfectly free from scale may be of interest.

There were two 150-horsepower boilers of the shell type, when the plant came under my supervision, and a chemical compound, costing about $1 per day, was used to prevent scale from forming. The two boilers are in constant use, and evaporated on an average of 3000 cubic feet of water in 24 hours' service. The engineers claimed the boilers were free from scale, and all internal surfaces appeared to be very clean. I decided to try graphite as a scale preventive, on account of its supposed affinity for metals. When graphite is once in a boiler, the circulation of the water carries it to all portions and the graphite forms a thin coating on the metal which prevents the scale from forming. The graphite was ground to a powder, as ordinarily supplied as a lubricating graphite.

For the first two weeks one pint of graphite was mixed with one gallon of water and fed to the suction of the pumps between the feed water heater and pumps each day. At the end of two weeks the boilers were opened for cleaning and about 100 pounds of sludge was removed from the bottom of the boilers; this sludge contained considerable scale, about 1/16 inch thick, which appeared to be old scale from the back head. The boilers had been blown down twice a day, and the amount of sludge recovered was about twice that recovered when using the compound. The amount of graphite was then reduced to a pint every other day, and at the end of another two weeks the boilers were again opened and considerable white coating appeared on the surfaces, which at first appeared to be new scale, but on close examination was found to be old scale with the outer surface dissolved. In some places the old scale came off in large pieces, showing that the boiler had been covered with a scale so hard that it had been mistaken for the metal.

At the end of eight weeks one of the boilers showed but a few patches of scale. This boiler was nearest the pump and appeared to receive most of the graphite; however, the other is in as good a condition now, and both appear to be free from scale.

When the compound was used the feed-water line had to be removed every two months, and the scale cleaned out, but since using graphite the feed lines have not been taken down or does it appear necessary to do so; the pumps are now clean and are not coated with a gritty substance as formerly.

Pieces of scale which came loose from the surface of the boiler showed graphite adhering to it. My experience with graphite shows that it will work in between the scale and the surface of the metal, causing the scale to loosen and fall off. I am unable, however, to explain the apparent dissolving action of the graphite on the surface of the old scale, as there is nothing in its composition to cause this action, that I am aware of, and the amount of graphite used was very small. On account of the steam being used in bleach tanks to heat and agitate the product manufactured in this plant, the color of which must be very white to command the best prices, I was at first doubtful of the results of this point, but during the period the greatest amount of graphite was used, the bleached product was of an excellent color.

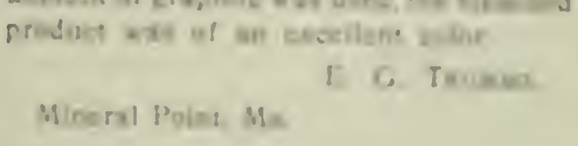
Air Chamber on a High Pressure Water Line

In the Singer Tower, New York City, the water service to the various offices was originally maintained by a single pipe line from a pump in the engine room to a tank located about [illegible] feet above the level of the pump. The outlets to the various offices were tapped directly from this line. The pressure, due to head, was so great that whenever a faucet in one of the lower floors was turned on and off a severe water hammer occurred, which was transmitted over the whole line. The natural remedy was to run a new and separate line from the pump to the tank, and to disconnect the line feeding to the faucets from the pump. Conditions were such, however, that this could not be done for some time and the following simple, but extremely effective device, was used.



SECTIONAL VIEW OF AIR CHAMBER

It consisted of a piece of [illegible]-inch pipe about 18 inches long filled with solder at one end and fitted with a cap as shown. A piece of round, medium soft rubber that easily fitted in the pipe, and about 15 inches long was placed inside. This device was then connected, in a horizontal position, with a valve and nipple to the line about half way between the pump and the tank. After this was installed no more water hammer occurred whenever a faucet was turned on or off in any part of the line, as the rubber absorbed all of the shock and relieved the air chamber entirely.

Later, when it was convenient, a second pipe was put in so that the pump delivered water directly to the tank, and the old line was used to connect the tank to the faucets. After this was done the rubber cushioning device was no longer needed, but its success demonstrated that, in a case of high-pressure heads in water lines, a rubber cushion is superior to an air chamber on the pump to absorb shocks from water hammer.

H. B. LANGE.

New York City.

Feed Pipe Scaled

The difficulties began with the packing in the boiler feed pump giving out more frequently than a good packing should. It was decided that the packing was at fault and a new brand was tried. This played out in even less time than the previous lot, so the old kind was again used, but for each renewal of packing the pump worked harder than ever.

Pump valves and check valves were carefully examined, but nothing was found amiss, except the remains of the packing. At length the trouble became more serious and it became difficult to keep enough water in the boiler.

Finally the problem was solved. The feed pipe entering the boiler was carried 5 feet inside the shell before discharging. Just outside the boiler head, an angle valve was placed to facilitate cleaning this pipe. When the bonnet was removed the 1½-inch pipe was found so badly scaled as to be reduced to ¼ inch in size.

After reaming out this feed pipe, first with a ¼-inch, then a ½-inch and finally with a 1-inch pipe with teeth filed in the end, the pump was started up and worked as smoothly as could be desired.

After this experience a special point was made at boiler-cleaning time to investigate such feed pipes and also the connections to the gage glasses.

F. H. STACEY.

Montreal, Can.

Water Coils Burn Out

What causes my 2-inch hot-water coils to burn out, and how can I remedy the trouble?

Boiler tubes, ten in number, connected with long return cast-iron ells, extend from the rear of the setting to the bridgewall, which is on a level with two courses of brick, which rest on bars, placed 32 inches from the boiler shell. The grating and bridgewall measure 5½ feet over all by 6 feet wide. The distance between the boiler shell and coil is 4½ feet.

In about four months, these coils turn up at the furnace end of the combustion chamber, the bend extending back about 3 feet.

I am not bothered with scale. I burn oil and the burners are set 2 inches above the brick, or 30 inches from the boiler shell.

The flame takes a straight line to the end of the bridgewall, and then leads up slightly to the boiler.

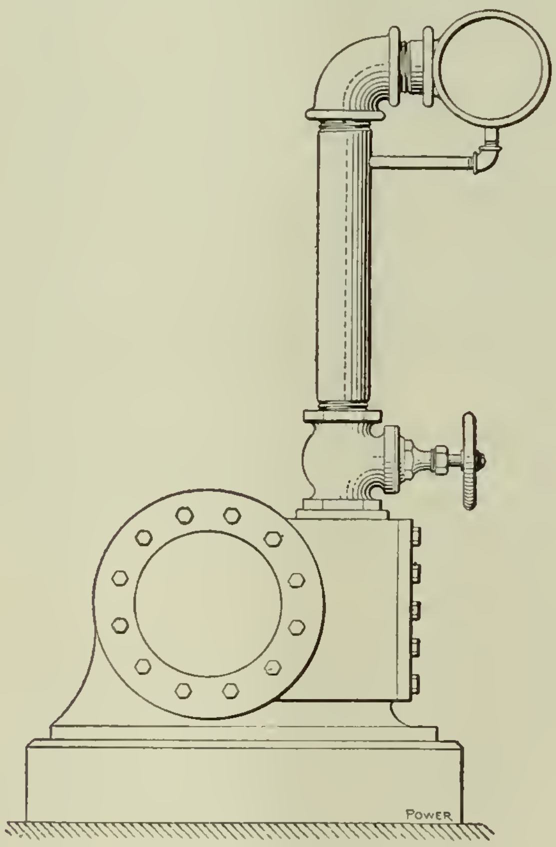
Water enters these coils from the boiler-feed pump at about 120 degrees Fahrenheit, thence to the boiler. Do these coils increase the efficiency or capacity of boiler, or both? I would like to hear from those who have had experience with coils placed beneath their boilers, in the furnace, and what advantage they have, if any, over other ways of heating the feed water.

R. A. BOOTH.

Riverside, Cal.

Steam Pipe Drips

Drips for steam mains are often neglected, and the direct drain, as shown in the accompanying sketch, is as good and safe as any plan that can be adopted. This type of drain will carry the water directly into the steam pipes leading to the



DRAINING STEAM LINE TO ENGINE CYLINDER

cylinder and consequently will drain off the condensed water above the throttle before the engine is started. This eliminates the danger of an accident to the engine. Connecting all leads to a main drip line to which many drains are led, is bad practice, as in some cases a trap is depended on to carry the extra condensation away and if it fails to operate will allow a charge of water to come over into the engine cylinder and wreck it.

When drains are carried away from the steam line leading to the engine it is best to have individual traps to carry away the surplus water rather than one trap to care for a whole line.

C. R. MCGAHEY.

Baltimore, Md.

Firing a Boiler

Most boiler attendants recognize in a general way that the economical working of a boiler furnace depends largely on the way in which the air supply is distributed and regulated and endeavor to do the best they can to comply with proper combustion conditions, but few of them can give an intelligent reason for the procedure they adopt. But a small proportion of engineers secure the best attainable furnace results and in a great many cases the matter is so imperfectly understood that there is a serious waste of fuel.

The total amount of air required for the proper combustion of fuel in a boiler furnace depends on the nature of the fuel used. With ordinary coal the theoretical minimum quantity required for combustion is about 11 pounds of air per pound of coal, but because the film of gases escaping from a burning surface interferes with the access of the fresh-air supply, it is impossible to burn a pound of coal with anything approaching so small an amount; consequently 19 to 22 pounds of air represents more approximately the quantity used under ordinary conditions, or between 8 and 11 pounds more than theoretically required. As this large quantity of air is finally expelled into the atmosphere at the chimney temperature it is desirable to keep the air supplied as low as is consistent with the efficiency of combustion. With badly designed or inefficiently worked furnaces as much as 25 pounds to 30 pounds of air is not infrequently passed through the furnace for every pound of coal burned, a fact which serves to illustrate the possibilities of economy or extravagance in connection with air distribution and regulation.

The great bulk of the air supply is drawn through the grates and the rate of flow is determined by the thickness of the fire and the draft, which is generally controlled by a damper. Under ordinary conditions the thickness of the fire does not vary very much and the air supply, if the dampers are not moved, is reasonably constant.

When the furnace receives a fresh charge of bituminous coal, the volatile gases are at first driven off very rapidly and, therefore, require a corresponding increase in the air supply just as the air flow through the grates is diminished, due to the thicker bed formed by the fresh fuel. In order to supply the necessary air the furnace doors are generally fitted with openings which the fireman can open or close at will, and in many cases the bridgewall is also arranged to admit a supplementary air supply by means of a damper operated from the furnace front.

In the hands of a skilled man the manipulation of these appliances can be made to materially contribute to the efficiency and economy of the boiler. Very often, however, the appliances are used in either an imperfect manner or are so neglected as to be almost unworkable.

Frequently the bridgewall-damper connection is so disabled that the air orifices are either permanently stuck open or closed. Air admitted through the fire door serves to better advantage than when admitted through the bridgewall because it passes the length of the furnace before mingling with the gases liberated from the fuel. Some designs of furnace door are fitted with a box from whence the air emerges into the furnace as a spray through a perforated baffle plate. Frequently these plates are removed, or burnt away with the result that the air supply is not well distributed. After the fires have been charged the ventilating grids should be opened wide and allowed to remain so for a minute or two, the length of time depending on the character of the coal and determined by the fireman from his observations of the fire and the chimney, or better still from the readings of the CO_2 recorder.

Manchester, Eng. J. F. GRESLAND.

Bonus System in the Fireroom

The efficiency of the human machine has a greater effect upon the profits of a power plant than is thought to be the case by many engineers and, in many cases, a greater saving may be made by increasing the efficiency of the men employed in a plant than could be accomplished by increasing the efficiency of the machinery.

This point is well illustrated by an experience I had in the plant of which I am chief engineer. Oil is burned as a fuel and two Mexican firemen attend to the boilers. Let me say right here that a careless fireman can waste dollars mighty fast, when burning liquid fuel. My hardest proposition was to get the firemen to do their work properly, as their only thoughts seemed to be of their *señoritas* and the next *baile*.

Some months ago I decided to try the bonus system and so offered to each man a 5 per cent. bonus of the fuel he could save over a certain specified amount. The effect was magical. The men are "on their toes" all the time and I never have to call their attention to the water level in heater or boilers, or to the condition of the fire. Each man received $3.75 bonus the first month, $2.50 the second, $3.30 the third and $7.80 the fourth month. The plant was only running half time the first three months and from all indications the bonus of each fireman will be from $7 to $10 per month in the future.

Result: In four months each man received $17.35 extra pay, and the *fuel account was benefited by a saving of* $312.30, which was *all "velvet,"* as no money had been invested by the company to accomplish the saving. The firemen are continually coming to me and, in their broken English, suggesting some new idea for saving fuel. When their suggestions are at all reasonable they are carried out at once and their interest is kept alive.

After this experience I firmly believe that this is the only way to "handle" firemen. It is simply a case of deciding whether the money is to be given to the fuel dealer, or divided between the firemen and the company.

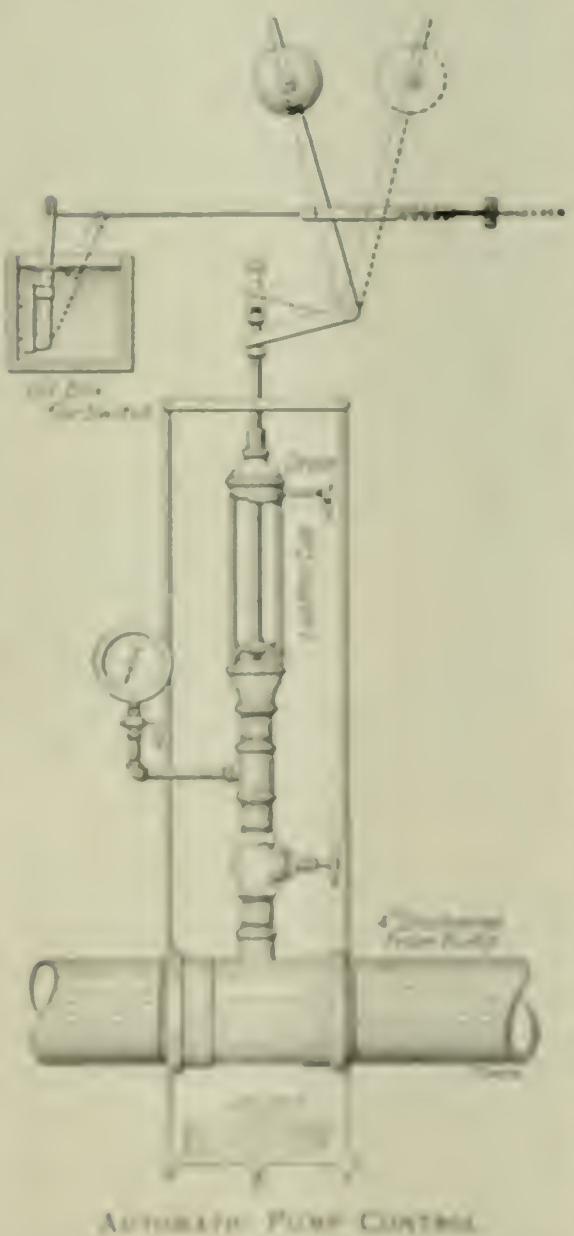
If a man is paid barely enough to keep body and soul together, he will do just as little work as he can and hold his job. If he is getting a good living wage and on top of that is receiving a share in the saving he makes, the chief engineer will soon be saying, "I have the best firemen that I ever saw."

T. P. WILLIAMS.

Brownsville, Texas.

Automatic Pump Control

The accompanying sketch illustrates an automatic pump control I built about one year ago. The motor-driven pump supplied water for a small village and worked against a [illegible]-pound water pressure.



AUTOMATIC PUMP CONTROL

The illustration shows the details of construction.

Glenwood Springs, Colo.

Melting Babbitted Brasses to a Bearing

The main generating unit in a small electric-light plant consisted of a high-speed engine and generator that ran at a speed of 300 revolutions per minute. The plant was operated ordinarily during the night, but at times was started up in the afternoon to furnish light for the opera-house matinée. A request was made for lights one afternoon; the engineer started up, filled the oil cups on the engine and left the plant in charge of the fireman while he went outside to do a job of wiring.

Returning to the plant about the time the show was over, the engineer found the engine room full of smoke, the engine was pounding so badly that it could be heard a block away and the fireman was frantically pouring oil on the crank pin, which had run hot, and the melted babbitt had been thrown out of the brasses.

The crank was oiled by a wiping device which would operate only with thin engine oil in the oil cup. The trouble was caused by the fireman who had made a mistake in filling the oil cup with castor oil. In one hour the engine had to be started for the night's run and it was up to the engineer to make a quick job of babbitting the brasses. They could not be babbitted in position, so a piece of shaft was found that was about the same size as the crank pin on which the brasses were babbitted. After the brasses were replaced it was found that they made a bearing on a few of the high spots only. There was no time to spend in scraping them down, so the engineer decided to try an experiment.

Oil grooves were cut in the brasses, after which they were put in position and keyed up as tight as would allow the engine to be turned with two men pulling on the flywheels. The cylinder was then warmed up, the wiper filled with oil and the oil cup set to run a stream of oil on the pin. The engine was then brought up to speed and the crank watched closely for signs of smoke. As soon as the brasses began to smoke, the throttle was partly closed to bring the engine down to a slow speed so as to prevent the melted babbitt from "freezing" to the crank pin. Oil was poured on the brasses until they stopped smoking, when the throttle was closed. The brasses were then removed and thrown into a pail of water to cool. The babbitt was found to be melted just enough on the surface to give it a good smooth bearing on the pin. After cleaning out the oil grooves the brasses were put in position, the engine started and no trouble whatever was experienced with heating when the load came on. To scrape brasses in this way the engineer must be a good guesser.

Questions Before the House

Comment, criticism, suggestions and debate upon various articles, letters and editorials which have appeared in previous issues

Size of Air Chamber

In the February 21 issue, Mr. Dew describes some trouble he has had with a pump which pounds when he starts it up.

I have had some experience with pumps pounding. Every time that a troublesome pump was started the noise would be something frightful, and it was a great relief when the pump picked up the water.

One engineer told me that the air chamber was not large enough. Another told me to set the steam valves. Every man that came along had a different remedy. But none was of any value. Finally, I repacked the water plungers with fresh packing well saturated with cylinder oil and graphite. I also packed the rods at the same time. I left the packing on the water plungers quite loose. When I turned steam on, I never saw a pump work nicer, and I was surprised to see how quickly it picked up the water.

Pumps have three places in which to look for trouble: the steam valves, the water valves and the packing. Air leaks are usually pipe troubles.

O. L. Sherman.

Duluth, Minn.

In regard to Mr. Dew's air-chamber problem as described in the February 21 issue, it is my opinion that there may be a small leak at the threads in the cap which allows the air to escape and the chamber to fill with water. A threaded cap should not be used on an air chamber as it is difficult to make a tight job. A screwed flange should be put on the end of the air-chamber pipe and the latter well peened. Then, a plate should be bolted to the flange with a rubber gasket between.

A long air chamber has no advantage over a short one; it is capacity that determines adaptability.

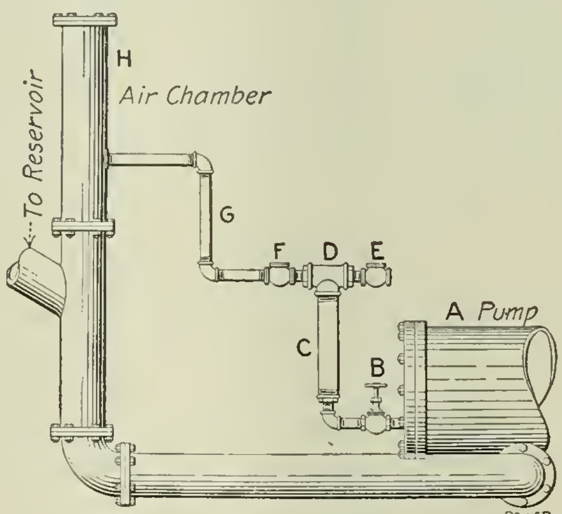
James Johnson.

Hackett, Penn.

In reply to F. A. Dew's question in the February 21 issue regarding air chambers for pumps, I will say that the proper size of the air chamber depends upon the size of the water cylinder and not upon the discharge line, if the pump is properly installed.

For ordinary double-acting pumps working against moderate pressures, and at ordinary speeds, the cubical contents of the air chamber should be not less than three times the piston displacement. For pressures of 100 pounds per square inch or more and for high piston speeds, the capacity of the air chamber should be at least six times the volume of the piston displacement. The effect of a small inlet in the chamber would be to prevent a rapid loss of air.

Under the increased pressure in the air chamber, the air is absorbed by the water and gradually passes off with it. In this way all the air will finally pass off and the chamber will be made useless if no means are provided for renewing the



Arrangement for Replenishing Air Chamber

supply. A simple device for maintaining the supply of air in the air chambers of large pumps is shown in the accompanying illustration. The piece *C* of 2½-inch pipe, about 25 inches long, is connected to the end of the pump cylinder *A* in a vertical position by means of a gate valve or cock *B*. The 2½-inch tee *D* is placed on the upper end of the pipe *C*. The 1¼-inch check valve *E* is placed on a nipple on the side away from the air chamber. This check valve opens inward. The 1¼-inch check valve at *F* opens outward.

This arrangement operates as follows: When the pump is working, the valve *B* is opened. This allows the pipe *C* to fill with water. Then, *B* is partially closed until the check valves *E* and *F* begin to click. Thus, when the valve *B* is opened the pipe *C* will fill with water during the discharge stroke of the pump. As *B* is partially closed when *C* is full, the pump, during the suction stroke, will draw part of the water from *C* and air will flow in through *E* and take its place. During the next discharge stroke more water is forced into *C*, driving the air out through *F* and *G* into *H*.

If the valve *B* is open wide all the water will be drawn out of *C* during the suction stroke and cause a slapping noise in the pump cylinder, but by properly regulating the valve *B*, a column of water is kept in *C* which acts as a piston to pump air into the air chamber *H*.

A. H. Stanfield.

Clarksville, O.

Mr. Duffy Inquires

"I am told," said Duffy, "they have made a book about that Pittsfield biler explosion. Daly says 'tis a fine book, made by the county judge."

"It is," said Doolin, "I've read it. I was over to the sugar house puttin' in tubes in the No. 18 biler an' the insurance inspector was there. He had the book in his grip an' I took it to relieve his mind from the strain of goin' through the evidence in the case. The judge is a fine man, Duffy, an' a good, plain writer. In the end ye find the pipe to the steam gage was choked wid scale an' the poor man didn't know it. With that he goes for the safety valve an' screws it down till the spring was solid an' even the huddle chamber was closed. He keeps on firin' an' chasin' B.t.u.s through the flues, worryin' all the time that he couldn't get steam enough to start. Everybody was wild to go to work an' finally some men started out to be at the ice when the engine would turn. At this instant, Duffy, the biler exploded, an' there ye are."

"Do the judge believe it was overpressure?" asked Duffy.

"There's no other cause," says Doolin, "beyond the poor man losin' his head in guessin' whether 't was the steam gage or the safety valve that wasn't right an' he has paid for that. They found the valve loaded for 225 pounds or so."

"An' I am told," remarked Duffy, "they have the best biler rules in the country up in Massachusetts. Daly says there's no doubt about it; that they have got everybody else's rules in the second division, even the U. S. G."

"Daly is right," says Doolin. "There

isn't a bilermaker but knows the Massachusetts rules is the best. An' what did ye expect else from the land of the sacred codfish an' the home of the Plymouth Rock! Sure, they know beans up there an' bilers too, for that."

"Even so," said Duffy, "the biler blew up."

"True enough," said Doolin, "but why quarrel over the rules? Mind you, those rules are new, merely a beginnin' an' a grand one, at that. Here's a terrible explosion, due to an unlooked for cause, one that had not been counted on. In a short time they will slip in a rule to cover this detail."

"An' how?" asked Duffy.

"Well, now, look at Philadelphia," was the reply. "'Tis the only place in the country where they require two safety valves on each biler. Would you believe, Duffy, if the Pittsfield man had two safety valves on his biler, that he would have took the word of the lyin' steam gage against the two valves? There is the solution of the matter. 'Tis a two to one bet I am right, as ye see. An' further, when the late George Babcock went into the biler business, he had in mind that this might occur an' so he placed two pop valves on each of his bilers. The other water-tube men, of course, did the same an' this accounts in some measure for the safety of the water-tube bilers. The next step, then, Duffy, is to pass a rule providin' for two valves set two pounds apart."

"Why not," said Duffy, "have two steam gages to each biler, one to check the other? True, in most plants ye can check the biler gage by the engine-room gage, but in the small plants, they use but the one gage."

"'Tis a grand thought," said Doolin. "If we can come back in about one hundred years an' see the bilers our gran'sons are runnin', we will see things, Duffy, that, as Bill says, are not yet conceived by mortal man. An' the Boston rules, Duffy, are doin' a great work in hastenin' the day when biler explosions will be confined entirely to the movin'-picture business. Every kicker on present conditions, every crank that takes a whack at lap-seam bilers an' lap-welded water tubes, every dreamer of a nonexplosive biler, is each mother's son a booster for better conditions an' better bilers. An' mind ye, Duffy, that Massachusetts is settin' the pace for the other States. The yeast is working an' the ferment is spreadin'. The engineers are thinkin' an' the bilermakers studyin'. The buyer in Iowa wants Massachusetts standard bilers. When, Duffy, ye get the men from the alfalfa district in line with the lads in the big cities an' then have the various societies devoted to steam engineerin', bilermakin', etc., leave, for the time bein', the discussion of who will be the next President of this bunch, an' get together for laws on biler construction, inspection and operation, ye will see every State with laws matchin' Massachusetts. In the end, Duffy, the bilermaker, the engineer, the owner and society will be benefited financially by the rigid enforcement of such laws. An' the time will come when they will take a visitor from a foreign land to a museum an' show him a lap-seam biler stuck up by a waxwork of Napoleon, Jawn L. an' other curiosities."

"An' when," asked Duffy, "will all this be?"

"I dinnae," said Doolin. "It's up to the readers of POWER."

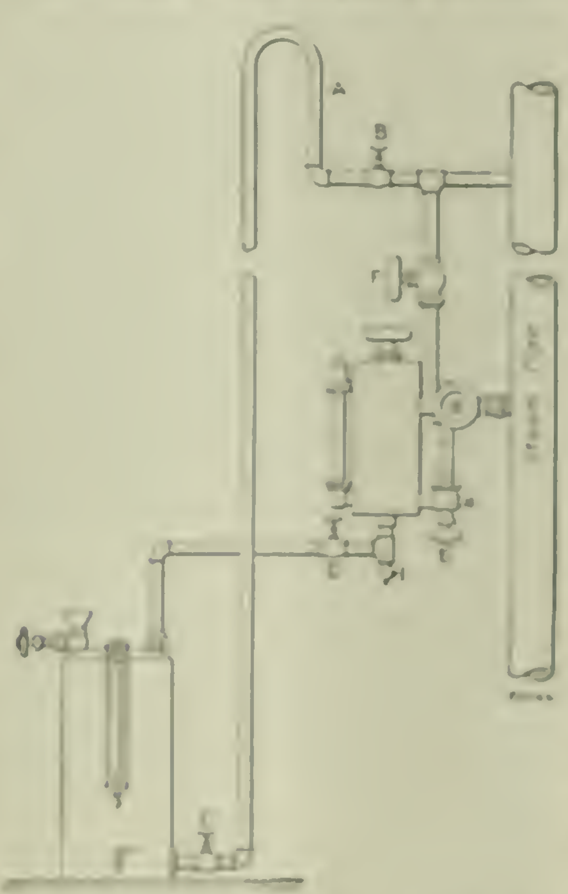
DANNY HOGAN

Punxsutawney, Penn.

Lubricator Piping Layout

In the February 21 issue, Mr. Pierce asks for a method of piping a lubricator to a reservoir. The accompanying figure shows a good method.

The reservoir can be placed anywhere



OIL RESERVOIR AND PIPE CONNECTIONS

that is convenient for filling so long as it is in no danger of freezing. The reservoir must be below the lubricator so that no water or air will be trapped. The steam pipe *A*, leading to the bottom of the reservoir, should be fairly high (20 feet is not any too much). This hight can be gained by forming a loop as shown. This will give the necessary hydrostatic pressure.

The operation is extremely simple. When using the reservoir open valves *B*, *C* and *D* and regulate the oil feed with valve *F*.

When using the lubricator alone simply close valves *B* and *D* and open valve *F*.

When filling the reservoir close valves *C* and *D* and drain off the water through the pet cock on the bottom of tank. When the water is all out close the pet cock and fill the reservoir through the funnel and strainer on top.

GEORGE H. HAMLEY.

Newburgh, N. Y.

Other contributions on this subject were received from James Bennett, Marshfield, Ore.; G. H. Wallace, Racine, Wis., and John A. Wise, Jamestown, O. These letters were much the same as the present contribution and the one published in last week's issue.

Slipping Latch Blocks

In the February 28 issue, I noticed Mr. Greer's account of his experience with latch blocks slipping and his remedy.

I have had considerable trouble myself with latch blocks slipping and wearing off at the edge. Instead of buying Novo steel and paying a dollar per pound for it, I used the common soft steel and case-hardened the plates. This method has proved to be very satisfactory.

I am using such plates on a 20 and 40 by 48-inch engine running at 95 revolutions per minute, sixteen hours per day. One set of plates has been on for eighteen months and when recently they were changed they were but very little worn.

J. R. WAMPLER.

Staunton, Va.

Leakage through a Piston Valve

The tests taken by Mr. Mitchell and published in POWER last October are valuable as they opened up a discussion on a subject which is of the greatest importance to both engine builders and buyers. This discussion seems likely to bring us nearer the truth as to the relative merits of the many types of valve at present in use.

Although these tests did not approach the accuracy of the Callender and Nicolson experiments, the results very approximately conform to the law of leakage which was established by those experimenters.

The suggestions in the letter on this subject in POWER of February 7 are sound and tests taken under these conditions should, without doubt, be readily accepted. One of the great objections to Mr. Mitchell's tests, which was not pointed out, however, is that the valve ran out of its liner, thus leaving only a narrow face for steam to leak past when the valve was at the end of its travel. This objection would be overcome by following the above mentioned suggestions.

The experiments of Messrs. Ide & Sons, described in POWER for November 8, are a striking confirmation of Messrs. Callender and Nicolson's statement that minute differences of fit of a valve do not appear to affect the amount of steam leakage past the valve to any appreciable extent, and are also a confirmation of tests taken by myself to determine the advantage of ring valves over solid valves. The results of the tests which are given by Mr. Allen in POWER for November 29 show that the leakage of a piston valve does not appear to increase much even after several years' running, thus showing that the slight wear which is bound to occur is not sufficient to make any appreciable difference in the amount of the leakage. Mr. Allen champions the piston valve and gives a category of its virtues; however, the results of the tests that he gives are slightly worse than those obtained with slide-valve and rider-valve engines in this country.

Mr. Shoemaker's letter in the January 3 issue calls for much comment. His explanations of the objections to a standing test for leakage, and of the cause of the greater leakage with valves than with pistons are certainly novel and his assertions are surprising.

To test a valve he placed it in its mid-position and turned steam on. Of course, the valve leaked badly as it had very little cover and, hence, the steam had practically no distance to leak through in order to get into the cylinder. Thus, it is not surprising that in not one of more than fifty tests was it possible to open the stop valve fully.

Let him put the valve so that it is neither over the port nor partly out of its liner, then he will obtain a very different result and one which more nearly conforms to the working conditions of the valve.

The arguments that the spectators advanced against the reliability of the tests that they were shown is just the one that is advanced, and is accepted by all engineers who consider the subject, to show why the valve does not leak to any extent when standing, although it leaks considerably when running. As he pointed out, Mr. Mitchell's tests prove that the spectators had got the wrong idea. It is stated that there was no noticeable difference between the leakage with solid valves and that with ring valves; of course there was not, because the steam in all probability had no ring to get past in the latter valves and, therefore, the leakage should be identical. Mr. Shoemaker states, "We have all heard the argument that the rings in a piston do not show excessive leakage; therefore, why should the rings in a piston valve show any more leakage? The answer to this argument is simple." It is, and surely he does not think that the answer he gives is believed by anybody beside himself. From his letter I should judge that he has seen several valves, but has he not come across any that have been working for several years in the same liners?

The information on the reputed test at Cornell University, where the piston-valve rings had to be reëxpanded after three and a half hours' run because the leakage became so great, leaves us wondering how the leakage was discovered and what the mechanical efficiency of the engine was while it was grinding the valve away so rapidly. The statement that the wear on a piston valve after a year's run will be ten thousandths of an inch or more is decidedly inaccurate if the valve has been properly designed, for there are solid valves that have been running several years that have not as much clearance as this. In this country the restrained ring type of valve is largely used, and from personal observation I can say that the wear of the rings is only about four to six thousandths of an inch in a year; in fact, some rings have run a year without wearing down to the diameter of the valve body.

Mr. Shoemaker's observations on the leakage in the slide-valve engine fitted with a pressure plate is in accordance with the results obtained by Messrs. Callender and Nicolson, and it was to be expected that it would be greater than with the piston valve as there is a greater surface over which leakage could occur. I would commend to the attention of Mr. Shoemaker the carefully conducted tests of these experimenters for consideration before he makes such emphatic statements regarding the much greater leakage of the valve after a few weeks' run; apparently he has been anxious to obtain such tests to disprove arguments that have been brought forth that both of the types of valve above mentioned do not leak steam under operating conditions, but whoever brought forward any such arguments plainly showed that he had no knowledge of the subject.

Engineers will agree with Mr. McGahey in his opening remarks upon this subject given in POWER for January 17. Material, workmanship, and care in operation are three most essential considerations in the life and efficiency of a valve, as they are in all engineering work. Engine builders do not, as he suggests, make their piston valves on the expansion principle because they have no faith in their claims that such valves are steam tight, that is, comparatively speaking, but they make them in such a manner because it is realized that some wear must occur and means for taking up this wear should be provided. In the balanced slide-valve engines the wear of the valve has been minimized by the addition of a pressure plate. This plate relieves the working face of the valve from the pressure that would be exerted on it by the steam pressure on the back of the valve and, therefore, the wear is diminished; but this gives more surface for steam leakage, so the attempt to reduce the wear on the valve is not conducive to the attainment of a tighter valve. With a pressure-plate valve it is most essential to the economy of the engine that the wear which occurs should not be allowed to become excessive; because of the greater surface for steam leakage the wear will have a more harmful effect with this valve than with a piston valve.

Mr. McGahey states that he has never been able to see but one advantage that the piston valve possesses; that is, that it runs light and is light on the governor. He overlooks the advantage of not having the piston-rod glands exposed to high-pressure steam and if he had had much experience with superheated steam he would realize the great advantage of using the piston valve instead of the slide valve for high temperatures. He recommends testing the valves for leakage in the same manner as that adopted by Mr. Shoemaker, but I would again point out that this is not representative of the actual conditions of operation and that a fairer test would be to test one end of the valve at a time with its face completely covered by the liner. Mr. Mitchell's tests were conducted on these lines, as also were those of Messrs. Callender and Nicolson.

This discussion has plainly shown the great need of further experiments. The attention which it has attracted shows the interest taken in this important matter. If one or two engineering colleges could carry out a series of tests on different valves it is possible that we should then have definite information regarding the comparative leakage of the valves and this would be of great value to engineers.

JAMES CANNELL.

Stanford le Hope, England.

Water Hammer and Other Phenomena

Of the "Topics for Discussion" in the March 7 issue by John W. Payler the first one, relating to water hammer and its possible causes, has been discussed times innumerable. Two of the theories which receive almost universal acceptance are: Water lying in the steam pipe is picked up by the inrushing steam and hurled violently against the end of the pipe, a bend in the pipe or a stop valve. Second, the steam on coming in contact with the cold water in the pipe condenses, forming a vacuum into which the steam and water are projected with violent force. I accept the former as the correct one. It is beyond dispute that water will condense in a pipe and stay there unless there be an efficient draining system or the steam line be slanted toward the engine to carry it off. If the water is not drained off the steam will throw it against the first obstruction, causing water hammer.

The correctness of this assertion seems to be borne out by various observations. Take the injector, for instance: a jet of steam will pick up a stream of water and force it into a boiler against much higher pressure. If the feed valve be closed suddenly while the injector is in operation or if it be left shut before starting the injector, a water hammer will occur, especially if the feed pipe be a large-sized one or the injector be located at a distance from the boiler.

The vacuum theory does not appeal to me because even if it were possible to create vacuum in a pipe which is presumably full of air, the only result would be an increase in the effective boiler pressure; otherwise the conditions would be the same.

As to whether water hammer is due to the contact of cold air with the inrushing steam, I will relate an experience which I had which bears on this point. I was running an air-compressor plant and dynamo for a constructing company. We ran from 2 a.m. to 6 p.m., excepting Sundays. One Monday morning I arrived at the plant, as usual, in time to warm up the engines, etc. The fireman was supposed to get there about four hours ahead of me to raise steam. On the previous day I had one of the boilers cut out for cleaning, the other one being banked. There was only one steam gage; it was connected to the steam line and there was no way of ascertaining the pressure on the boiler in which steam was being raised. The method which I usually employed was to "crack" the stop valve and give time for the pressure to equalize.

On this particular morning, there was about 75 pounds pressure on the one boiler and a very good fire under the other one. The fireman assured me that he had the fire going for at least four hours. I "cracked" the valve and later on opened it full without its giving a sign that everything was not in order. Then, I started the dynamo. In less than a minute a great rumbling sound issued from the boiler room. The sound was much like thunder and unlike what we call water hammer. Water hammer, judging from personal observation, has a distinct direction of motion. In this case there was no such thing discernible. As I rushed into the boiler room it occurred to me that there must be air confined in the boiler that I had just cut in and, although the boiler did not give a sign while the steam was at rest, it began to grumble as soon as the dynamo engine began to draw steam and the cold air to mix with the steam. I mounted the ladder to shut the stop valve, while the boiler was bucking like an unbroken bronco. As soon as the valve was closed the commotion ceased. Meanwhile, the pressure dropped to 30 pounds. The fireman corroborated my suspicions that he had got there only half an hour ahead of me and had just started the fire; consequently the boiler had just begun to get warm.

After straightening things out, I began to philosophize upon what I had just gone through. Why did not the air assert itself when I connected the boiler on which there was no pressure to the one in which there was 75 pounds pressure? I tried to satisfy this question by the theory that air being a very bad conductor objected to being heated. On second thought, this did not seem satisfactory as, after all, heating anything, no matter how bad a conductor, merely is transferring and not expending energy; the commotion that went on in the boiler required a whole lot of energy. I came to the final conclusion that heat transferred gradually will not cause any rumbling or knocking but when attempted suddenly, it will. For instance, a piece of red-hot iron when immersed in a vessel of water will cause rumbling and the water to shoot in all directions, although, if the number of heat units required to heat the piece of iron be applied to the same amount of water gradually, no disturbance would occur.

As to the second question, "Does air in pipes act as in the air chamber of a high-pressure pump, until equilibrium of temperature is established between it and the steam?" I would reply that it does. I have on several occasions raised steam in boilers without letting the air escape, to try the conductivity of the air. I let the boiler warm up until the gage showed about 15 pounds pressure, kept the pressure there for about 6 hours, then I closed the water valve on the water column and opened the blow-down valve. Air would rush out perfectly cool until the pressure dropped to about one pound and steam began to escape. This showed conclusively that cold air will not mix with steam while at rest and that it will not be heated by conduction; at least, not very quickly. Of course, if circulation be established, it would receive heat quite rapidly.

The third question was: "Is steam formed under or above the surface of the water?" I cannot conceive of steam forming "above" the surface. What is to become of the space between the surface of the water and "above"? The water nearest the heating surface receives heat first. In receiving the heat it expands and rushes to the surface, establishing circulation. This is continued as long as heat is applied. Water, like anything else, is subject to the laws of gravity. The hottest water, being the lightest, always rushes to the surface where, I should say, steam is formed. This seems to be true with the exception of cases where defective circulation exists, when steam is formed at the heating surface. This condition is manifested by priming or a violent motion of the water level in the gage glass.

The fourth question was: "How, and by what means, is a very rapid production of a large volume of steam produced after a violent and destructive boiler explosion?" If in a boiler carrying, say, 100 pounds pressure and containing one ton of water, a sudden reduction of pressure takes place, caused by the opening of a stop valve or a rupture of a defective plate, a corresponding drop in the temperature will result, liberating, per pound of water contained in the boiler, 108 B.t.u. which would instantly be available to turn some of the water into steam. This sudden formation of a large quantity of steam would hurl the water surrounding it against the shell, causing a violent and destructive explosion.

VICTOR BONN.

New York City.

The Benefit of Organization

I read POWER—have read it ever since 1887—and have distributed many copies of it through the State in which I live. I have seen it make many good engineers by a careful study of the experiences of other engineers. But I must differ with Mr. Gotstein in the March 14 issue.

Organization will not secure more salary; the engineer's work is different from any other calling or trade; he is appreciated for just what he is worth. His value is estimated not from the amount of laborious work he does, but from the money he saves in the plant's operation.

His end of the establishment is often the maker or breaker of the firm's financial standing; often either bankrupts or saves money, depending on whether he is what his name and calling indicate or simply a coal passer and oiler—a stopper and starter.

When any man gets the idea in his head, as evinced in Mr. Gotstein's letter, that he is worth more money than his employer pays him, let him get out; if he is competent and muscular enough to perform the work and has the abilities to keep up a better establishment—there are other places. Men of abilities are always wanted, and the pay is proportioned to the abilities displayed.

I know of a man that believed he was worth more than his firm paid him; he said so, he sought another position, he did not seek long; he is drawing $6000 a year today.

I know of many who are drawing good salaries. I have seen men in organizations cut wages more than any other men. It was each for himself and "the devil take the hindmost."

My forty years' of experience has taught me to lead up, look up, help up, to learn all that one can and one will earn more and positions will come his way without depending on organizations. He best helps himself who leads another up.

T. D. WALLACE.

Duluth, Minn.

"What did you do with the steam gage?" asked the superintendent of the lumber mill.

"Oh!" replied the darky engineer. "Do you mean that thar ole clock? I taken it off an' throwed it away. It wasn't keep time no how."

Inquiries of General Interest

Questions are not answered unless accompanied by the name and address of the inquirer. This page is for you when stuck—use it

Split Condenser Tube

If a tube in a surface condenser should split, how could it be temporarily repaired so as to keep on running?

S. C. T.

A surface condenser tube may be cut out of service by stopping the ends with soft-wood plugs. The splitting of a single tube would not have any appreciable effect on the operation of the condenser or on the vacuum.

Bare Tube Sheet

Why can the upper tube sheet of a vertical boiler be left bare without the danger of burning?

B. T. S.

Because the hot gases in passing through the lower part of the tubes give up so much heat that they cannot overheat the upper portion of the tubes and the head to the danger point.

Saturated and Superheated Steam

What is the difference between saturated steam and superheated steam?

D. W. S.

Saturated steam of a given pressure has the temperature at which water will boil under that pressure. It may be moist, may carry unevaporated water along with it as mist in which case its quality is designated by the percentage of the mixture which is steam. Thus steam containing 2 per cent. moisture and having the temperature at which water boils under its pressure is "saturated" steam having the quality 0.98. When the last trace of moisture is dried out the steam is "dry saturated." Further application of heat will raise the temperature of the steam above that due to its pressure when it is said to be "superheated." If moisture is introduced into superheated steam, the superheat (that is to say, the heat above that necessary to make it dry saturated) will be taken up by the water, so that normally superheated steam will be dry.

Temperature and Pressure

Are there other means than the steam gage and safety valve for determining the pressure in a boiler?

F. F. P.

Yes, a thermometer may be used.

Effect of Rocker on Eccentric

What effect has a rocker on the setting of the eccentric?

E. R. E.

It changes the position of the eccentric with regard to the crank. Without a rocker the eccentric leads the crank; with one it follows it.

Effect of Broken Spring

If the spring in a centrifugal governor should break, what effect would it have on the speed of the engine?

E. B. S.

The centrifugal effort of the weight is opposed by the tension of the spring. If this tension is removed by breakage or otherwise the weight will move outward and reduce the speed of the engine.

Location of Lap Crack

Where should search be made for a lap crack in a horizontal tubular boiler?

P. L. C.

A lap crack usually occurs in the outer or overlapping sheet near the row of rivet heads. It is covered by the inside lap and cannot be seen until it extends through the plate. Search will not reveal it as it can be found only by unmaking the joint.

Morrison Flue Collapsing Pressure

What is a Morrison furnace flue? Give the rule for determining the allowable pressure, and the rule for determining allowable pressure on riveted boiler flues.

M. A. D.

A Morrison furnace flue is one with consecutive annular corrugations throughout its length.

For corrugations 1½ inches deep the pressure of collapse is found by the formula

$$\frac{t^2 \times 1200}{D \times \sqrt{L}} = p$$

in which

t = Thickness of tube in thirty-seconds of an inch;
D = Greatest external diameter in inches;
L = Length of tube in inches;
p = Pressure in pounds per square inch.

For the strength of butt-strapped flue joints the English Board of Trade prescribes the formula

$$\frac{90{,}000\, t^2}{(L+1)\, d} = p$$

and for lap-riveted joints

$$\frac{60{,}000\, t^2}{(L+1)\, d} = p$$

in which

p = Collapsing pressure in pounds per square inch;
L = Length in feet;
d = Diameter in inches;
t = Thickness of plate in inches.

Latent Heat

What is latent heat?

L. H. S.

It is heat that is absorbed by a substance when changing from one form to another without any increase in temperature, as when ice changes to water or water to steam.

Boiling Point of Watar

Is it possible to heat water above 212 degrees at atmospheric pressure?

B. P. W.

If water is entirely freed from all dissolved air it may be heated to about 260 degrees before ebullition takes place. It then flashes into steam with an explosive effect, which fact has been used in some instances in attempts to account for certain boiler explosions.

Piston and Cylinder Clearance

What is meant by piston clearance in a steam engine?

C. C. P.

Clearance in a steam-engine cylinder means all of the space not swept through by the piston. With the piston at the end of the stroke, the space between the cylinder head and the face of the piston and the volume of the ports constitutes the clearance. It is reckoned in terms of percentage of the piston displacement. The term piston clearance is sometimes used in reference to the distance between the piston and cylinder head when the engine is on the center.

Full-weight standard pipe should be used for pressures up to 125 pounds, and full-weight extra-heavy pipe for pressures above 125 pounds. Cast-iron standard fittings should be used only for pressures below 100 pounds, medium extra heavy for pressures from 100 pounds to 150 pounds, and extra heavy over 150 pounds.—*Ex.*

POWER

The Control of the Coal Supply

The power-plant owner will sit up nights to figure how he can save ten per cent. in the cost of power production. He will invest money in expensive engines and search for boilers of the maximum efficiency; he will buy indicators and CO_2 recorders and strive to save the last redeemable fraction of a pound of coal per horsepower or kilowatt-hour.

And then he will sit supinely by and see a group of men grab all the coal in sight, and watch its price go up to "what the traffic will bear."

We will not presume to assert that the beneficent storing of the energy radiated to and absorbed by the earth in past ages was designed for the benefit of all mankind, but we think that the fact is sufficiently evident that the many would have profited at the expense of the few if the founders of the Republic had had such a prevision of the coming importance of the coal deposits to the industries of the country as to have kept their ownership and control in the hands of the people.

What has been done is done, and the growing conflict between the rights of property and the rights of man must drag out its slow and tedious course. But we can stop piling error upon error and sacrifice upon sacrifice. All of the coal and oil and mineral wealth has not been ceded, and the people, through the national and State governments, still retain control of much of the undeveloped water power. A few earnest far-seeing men are trying to call a halt upon the wholesale surrender for all eternity of this control and of the rights of the people in their inheritance. Have you attached any more than a political significance to their effort? Have you done anything to hold up their hands? Have you manifested any disapproval when those in high places have blocked their progress, kept alive the hopes and encouraged the machinations of the grabbers?

The far-seeing business man, the educated and thinking engineer, can realize the possibilities of the next half century in this direction as few legislators can. A general attitude of protest upon their part against the continued giving away of the people's property to individuals that they may sell it back to the people at baron-making profits will make their representatives think twice before continuing the process of public depletion and private enrichment. An attitude of openly expressed approval of the efforts of those who are working for new and better ideals and practices in this respect will encourage those who are giving of their time and effort and money for the general good, and discourage those who are reaching after the public property for their individual gain, and the officials who are inclined to help them to get it.

Place the Responsibility

In the matter of boiler explosions, which are rare in England as compared with the United States, a very different course is pursued from that in vogue here. Whenever a power-plant accident occurs the owner is held accountable and primarily responsible until an investigation by the commission of the Board of Trade places the responsibility and fixes the punishment. In this country it seems that the effort on the part of those chosen to fix the responsibility is, if possible, to find someone who was killed on whom the blame can be placed. This, if successful, is usually followed by a "whitewash" of those who may possibly be considered by the public to be even remotely connected with the accident, and the incident is closed.

Last summer a thermal storage tank in a south of England city failed along the head flange, killing two men and doing considerable property damage. The investigation which was conducted by the engineers selected by the commission revealed the fact that the head plate was cracked by the use of a hydraulic riveter in forcing the cold head-plate flange and the shell together. When the evidence was all in, the commission which sat on the case assessed a fine of two thousand dollars against the company that built the tank, a fine of two hundred and fifty dollars against the manager of the company for allowing the tank to go out of the works, two hundred and fifty dollars against the chief engineer of the power plant for allowing the tank to be installed and one hundred and fifty dollars against the operating engineer of the plant for not cutting out the tank when the leak was first noticed.

It would seem that such a glowing handling of a few cases of morally criminal carelessness in this country would have a salutory effect and perhaps tend to reduce the rate at which explosions occur. In 1909 there were five hundred and fifty. The complete reports for 1910 are not yet available but it is thought that the figures for that year will closely approach those of the one before. For the first eighteen days of 1911 there were twenty-four, which rate, if kept up for the rest of the year, will fetch the total to five hundred and forty-seven, a number far beyond the really unavoidable. If the English method had been applied to some of the recent American explosions the beneficial effect would have been felt all over the land, for not a boilermaker, owner, operator or inspector cares to go down in his pocket for funds to pay for the privilege of taking a gambler's chance on the safety of a manifestly unsafe boiler.

Preventing Power Plant Losses

The problem of keeping down the cost of operation confronts every steam-plant owner, and the methods employed in solving this problem are many.

Purchasing cheap supplies is doubtless the means most commonly used. For some reason or other, many operators seem to believe they can get as good an article cheap as they can by paying a higher price. As a result, the repair bills run up to a much higher figure than the sum saved by purchasing cheap supplies.

In other matters men use good business sense. Not one of the purchasers of cheap supplies would think of purchasing a suit of clothes for fifteen dollars and imagine that they would wear as well as a fifty-dollar suit.

Cheap oil is used and journals heat and burn out. Poor coal is put into the furnace and the fireman is blamed because he burns more coal per horsepower developed than the man across the way.

A good engineer working for a low wage can make a good fight to keep things going, but there are conditions that will get the better of him, and one way to bring them about is to supply him with inferior equipment and maintenance supplies.

Is it cheaper to put a packing in the stuffing box of an engine that will last a few weeks or to use a packing costing twice as much that will last years?

Which is the more profitable way of running an establishment: to pay out hundreds of dollars in unnecessary repairs, or to use better and more costly supplies, and avoid frequent repair bills?

How it makes the careful manager squirm to see good coal in the ash pile, yet he has no compunction against running the engine year after year with leaky piston rings and steam valves. He has no idea how much steam is leaking into the exhaust pipe without doing work. The loss is there, although it cannot be seen. And that is the point: the losses that cannot be seen are given scant attention. It is a case of "don't know, don't care." These unseen leaks cost money, however, and these invisible losses eat up profits. The visible losses generally force the management to remove the cause.

In many instances gross neglect can be seen in the management of the power plant. In one instance a steam plant furnishes steam and power for a manufacturing concern, but of all the numerous steam pipes that emit steam hardly one discharges into a trap, although such an arrangement is feasible.

Out in the yard a new Corliss engine has lain all winter exposed to the elements with no pretense of protection and there is seemingly no anxiety on the part of the owners as to its condition or to the extra expense that will doubtless be entailed in getting the engine in proper condition to run when it is finally put on its foundation in the engine room.

On the other hand, a member of this same company reported one of the engine-room attendants because he had been seen eating a portion of his lunch before lunch time—a horrible waste of time and a financial loss to the company.

Why not be consistent regarding these things? If a watch is kept to guard against the company's losses, why not make it thorough and not stop with the man eating a little lunch before time, while out in the yard an engine costing several thousands of dollars is being injured by exposure to the elements? It is better to look after the source of real losses rather than to waste time reporting petty trifles which in a year's time would not save the renowned "thirty cents."

Explosion on the "Delaware"

Elsewhere in this issue appears a summary of the findings of the board which inquired into the cause of the boiler explosion on the battleship "Delaware." There appears to be no question as to the direct cause of the explosion, as all evidence points to a condition of low water. In this type of boiler, the burning of the lower part of the rear headers would indicate that there was no water whatever in the drum; furthermore, as stated in connection with the report, that water which did flow into the boiler probably passed directly into the inboard headers and tubes. Considering the slow rate at which the boiler was steaming, it would have taken at least half an hour for the drum to have been emptied completely and the question immediately arises: What was the water tender doing all this time?

It is possible that the connections to the gage glass may have been obstructed, although an examination after the accident failed to reveal any obstructions. Even if such were the case, the gage cocks would have shown that the water was leaving the drum. We are told that the water tender was an experienced man and, as such, much confidence was placed in him; nevertheless, the boiler exploded and the water tender should have known that there was practically no water in it. Just why he was not aware of it will probably never be known, but the fact remains: Had less dependence been placed upon the human element and a low-water alarm and fusible plugs been used, it is probable that the low water would have been detected before any damage was done.

The effect of vacuum upon the steam consumption of a turbine is strikingly shown by the reports of a recent test on a one thousand-kilowatt machine in which the consumption increased forty per cent. with a decrease in vacuum from twenty-nine to twenty-one inches.

It is conceded that specialization to the exclusion of general knowledge is a bad thing; nevertheless it is always well to know a little more than the other fellow about some particular subject. This knowledge carries with it a certain amount of independence.

The easiest way to find out whether you are right or wrong is to get down to basic principles and work up from them to the question at issue without thinking about preferences, hobbies or personal interests.

The man who uses his fingers to test the possibilities of a dangling piece of insulated wire belongs in the same ward with the idiots who rock boats and point unloaded guns at people.

Gas-engine lubrication by "splash" from the crank case is in the same class with hot tube ignition, the old tallow cup on steam engines and the high-wheel bicycle.

Have you thought of the engineer as a mechanic who must know more, work longer hours, carry more responsibility, and have much more expected of him than of any other ordinary mechanic, and still get a smaller sum on pay day?

The fireman's temper is one of the best indications of the quality of the coal and the condition of the fire.

Oil is purchased by your company to lubricate bearings of various kinds, not to pour on the floor.

It's rash to wish all the fools were dead. Some of our best friends would be missing and lots of us who remained would have to move down several notches in the scale of merit.

An engineer with a chew of tobacco in his mouth and wearing a full-dress suit doesn't synchronize.

Boiler Explosion in Georgetown, S. C.

On March 4, 1911, boiler No. 3 in plant No. 1 of the Atlantic Coast Lumber Corporation at Georgetown, S. C., exploded, killing three persons and injuring four others. The boiler plant consisted of ten horizontal tubular boilers set in one battery, eight of the boilers being in the boiler house proper and the other two boilers immediately adjoining the boiler house. As a result of the explosion, the center sheet of No. 3 boiler was torn bodily from the boiler and several boilers nearby were displaced and damaged to a greater or less extent. The roof of the boiler house, which was made up of structural-iron trusses covered with corrugated iron, was almost a total ruin. Boilers Nos. 3, 4, 5 and 6 were practically ruined. The side walls of the boiler house, which was a building approximately 93x70 feet, were ruined to a greater or less extent, some of the wall being thrown down bodily, and much of the wall that remained standing must be taken down and rebuilt. A number of pumps, heaters, conveyers, engines, belting, etc., together with a very complete supply of operating materials in the engine room, were destroyed.

Fig. 2. Damage to Steelwork and Stacks

The investigation as to the cause of the explosion appeared to show, according to sworn evidence of a number of witnesses, that the stipulated pressure of 100 pounds had not been exceeded. This fact was also corroborated by the record made by the recording steam gage which showed a pressure of [illegible] pounds at the time of the accident. There was no evidence of burned sheets or of low water. Several pieces of the metal in the boiler were tested by being bent double while cold and showed no sign of fracture. The boiler failed at or near one of the longitudinal seams. Practically all of the fracture or break was not (as is usually the case) through rivet holes, but through the solid metal. There was, however, one section about 3 inches long, torn through the rivet holes. It is possible that there may have been a hidden crack at this point, and this appears to be the only reasonable cause of the accident. This boiler having been built in three courses with two sheets to each course, caused the longitudinal seams to be below the top of the tubes; consequently, it was practically impossible for an in-

Fig. 1. Ruins of Georgetown Explosion

spector to discover a hidden crack in the seam from the inside of the boiler and it was equally impossible to discover the crack from the outside on account of the wall being close to the longitudinal seam.

All of the boilers at the plant had been internally inspected during the Christmas holidays of 1910 and inspections were carefully and conscientiously made, according to sworn statements of the chief engineer and foreman boilermaker at the plant, both of whom were with the inspector during the time the inspections were made.

The boilers were insured with the Ocean Accident and Guarantee Corporation, of 59 John street, New York City, who promptly paid $25,000 in settlement of the loss to property caused by the explosion.

Court Findings in Boiler Accident on "Delaware"

Through the courtesy of the Babcock & Wilcox Company, we are enabled to publish the accompanying summary of the finding of the court of inquiry which investigated the accident to one of the boilers of the U. S. S. "Delaware."

From the short note previously published in POWER, it may be remembered that the accident occurred about 9:15 a.m. on January 17, while the "Delaware" was bound for Norfolk, Va. The ship was proceeding under easy steam, but on account of poor draft the fire rooms were closed and working under an air pressure of ¼ inch. This, under the circumstances, was not more than good natural draft, so that the rate of combustion was about 18 pounds of coal per square foot of grate. The boiler is one of the well known Babcock & Wilcox marine type, with 4425 square feet of heating surface and 103 square feet of grate surface, there being 14 boilers in all. On trial, the "Delaware" developed nearly 30,000 horsepower, so that this boiler when worked under forced draft has a capacity of over 2000 horsepower.

The damage was confined to boiler "O" and the extent and nature thereof are set down in the findings in considerable detail. It is also to be noted that the structure of the vessel was not injured at all, thus emphasizing again the fact that an accident to a water-tube boiler involves the minimum of damage. The boiler was repaired while at Norfolk with some headers and new tubes, most of the work being done by the engineering department of the ship.

There is one point in the finding which needs just a word of explanation to make it perfectly clear. The court finds that only the outboard half of the boiler was damaged. It might seem at first glance as though it would be impossible for one-half of the boiler to be injured and the other escape. The explanation, however, is very simple. The feed water enters the boiler in the steam and water drum, which is above the front headers and connected to them by nipples, and is discharged through an internal feed pipe perforated with holes on its lower side. This pipe extends from the check valve at the inboard end of the drum to a short distance past the center of its length. As long as the water in the drum was above the tops of the nipples mentioned, it would not, of course, make any difference where the feed water was introduced, as it would naturally find its level. In case of low water, however, due to inadequate feed, there might be under moderate combustion, just enough water to save the inboard half of the boiler, where the water would go directly down the nipples, while only a few headers and associated tubes on the other side would get any. This appears to be the explanation of the salvation of the inboard side of the boiler.

With this general statement of the surrounding conditions, the finding of the court should be entirely clear, and it would seem that the court is to be congratulated on the very careful analysis which it has made of all the circumstances of the case, so that the reasons for its conclusion that the accident was due to low water are perfectly evident and convincing.

Finding of Court

"In compliance with the request contained in your letter of February 24, and with the approval of the department, the bureau submits for your information the following general statement of the finding and opinion of the court of inquiry appointed to inquire into the accident to boiler 'O' of the 'Delaware':

"(*a*) An explosion occurred in boiler 'O' January 17, 1911, by which three rear headers Nos. 8, 9 and 10 were blown bodily out of the boiler.

"(*b*) These headers were found severely bowed, their tube faces were bulged, and the metal showed signs of overheating. All the back headers of the outboard half of the boiler, 13 in number, were more or less bowed, the degree of distortion diminishing toward the outboard side of the boiler.

"(*c*) The inboard half of the boiler was uninjured, and consequent comment refers only to the outboard half.

"(*d*) The 4-inch tubes next the fire were all more or less bowed near the back ends, and showed signs of having been burned; and the majority of the 2-inch tubes were more or less distorted, while a number showed signs of having been white hot.

"(*e*) The front headers were in good condition.

"(*f*) The superheater tubes and manifolds showed a red color, and the 4-inch tubes through the first and second passes showed the blue color characteristic of overheating.

"(*g*) On two of the headers blown out were found scores and dents made by the headers striking obstructions. The character of the scores and dents, and the blue color of the metal in the scores, indicated that the metal of the blown-out headers was in a softened condition, due to heat, when they struck.

"(*h*) The three headers showed unmistakable signs of having been very hot. They showed the characteristic blue color following overheating, and the tube face of each had been bulged out by internal pressure, possible only when the metal is heated to a condition approaching redness.

"(*i*) The greatest heat appeared to have existed at about the width of the hight of the header, but the effects of overheating were manifest in all the back headers of the outboard half of the boiler, diminishing either way from the zone of greatest intensity of heat, which appeared to exist opposite the headers that were blown out.

"(*j*) A number of 2-inch tubes of the blown-out headers gave evidence of having been white hot. The surface of these tubes, near the back ends, appeared burned, and was covered with a coating of black oxide of iron. Signs of overheating were also in the outboard half of the drum, from which much of the soot had been burned off.

"(*k*) From a consideration of the preceding facts, the court concluded that the explosion was due to the lack of a sufficient quantity of water in the boiler, and that the water tender on watch at the time was responsible for this condition. This opinion was strengthened by the fact that it was possible to enter the fire room with safety a very short time after the explosion occurred, which would not have been possible had the boiler contained the normal quantity of water.

"(*l*) All testimony showed that the boiler was in good condition prior to the accident, and that the regulations regarding the care and preservation of boilers had been carried out; that other boilers which had been subjected to the same use were in good condition; and that the overheating noted in the injured boiler would have produced the results observed by the court after the accident, no matter how perfect the boiler.

"(*m*) From some testimony before the court, the conclusion was reached that the reading of the water gages was misleading, although the gage glass fittings are recognized as simple and reliable; other testimony, however, led to the opinion that the opening of the feed check valve had been increased shortly before the accident occurred.

Very respectfully,

R. S. GRIFFIN,

Acting Chief of Bureau."

New Power House Equipment

What the inventor and the manufacturer are doing to save time and money in the engine room and power house. Engine room news

The Kennicott Water Weigher

A device for automatically recording the weight of water fed to boilers and correctly ascertaining the evaporation, is the Kennicott water weigher, which is manufactured by the Kennicott Company, Chicago Heights, Ill.

As shown in Fig. 1, the Kennicott water weigher consists of a shell, the lower part of which is divided by a partition into two measuring or weighing compartments. A siphon in each compartment discharges the water when the full-unit charge has been received. A tipping box composed of two halves, which alternately fill with water, serves the double purpose of furnishing a sufficient quantity of water to start the siphons and to shift the supply from one compartment to the other. This tipping box is balanced on pivots, is mounted directly above the weighing compartments, and is operated by floats, one in either compartment.

Fig. 1. View Showing Interior of the Kennicott Water Weigher

Water enters the inlet and passes to the tipping box, where a small portion of it is intercepted, the remainder passing directly to the weighing compartment below. When this compartment is nearly filled, the float tilts the tipping box, thereby automatically spilling the water contained in the tipping box into the compartment, thus completing the unit charge and starting the siphon which discharges the unit charge, while the entering water passes to the opposite half of the tipping box and to the opposite compartment which fills and empties in a like manner.

Fig. 2. Weigher Arranged to Discharge into Storage Tank

A counter registers each double unit charge developed by the weigher, and is so arranged that it cannot be tampered with by unauthorized persons.

This weigher has no valves in its mechanism to leak and cause unreliable records and it has no pistons or revolving disks.

The weigher can be placed to receive water from any source and deliver it in unit charges of uniform weight into any available storage tank or hotwell and, when weighing boiler feed water, the feed pumps take the water from the storage tank. This arrangement is shown in Fig. 2.

This weigher is also furnished complete with storage tank and balanced pressure inlet valve, as shown in Fig. 3. The balanced pressure valve is controlled by a ball float in the storage tank which automatically regulates the supply to meet the varying demands of the plant,

Fig. 3. Weigher and Attached Storage Tank

and insures that the storage tank is always full of water.

Each weigher receives an individual test and calibration. The unit charges are accurately weighed on platform scales, and a certificate of accuracy and capacity is sent with each shipment. The weigher is guaranteed to record the correct weight of water to within one-half of one per cent. of absolute accuracy.

Besides weighing boiler feed water, this weigher will accurately weigh or measure any free-flowing liquid, hot or cold.

Automatic Engine Stop

This mechanism has been designed to prevent flywheel accidents due to the engine racing or running away, and also enables the possessor to stop the engine from any desired point in the shop.

It consists of a valve of the Corliss type which is so balanced as to be practically frictionless. Fig. 1 shows a front head of the valve on which is mounted a solenoid, a valve lock or disengaging arm and a valve lever. Fig. 2 shows an interior view of the valve when it is in its open position. The face of the valve is turned on one center and the stem on which it rotates is offset so that the valve does not touch the face of the seat except when it is closed. By means of this eccentric motion of the valve, in relation to its seat, friction between the valve seat and face has been eliminated, and there is no chance of the valve sticking and refusing to operate. Fig. 3 shows the automatic spring-switch trip arrangement, and Fig. 4 is a wiring diagram.

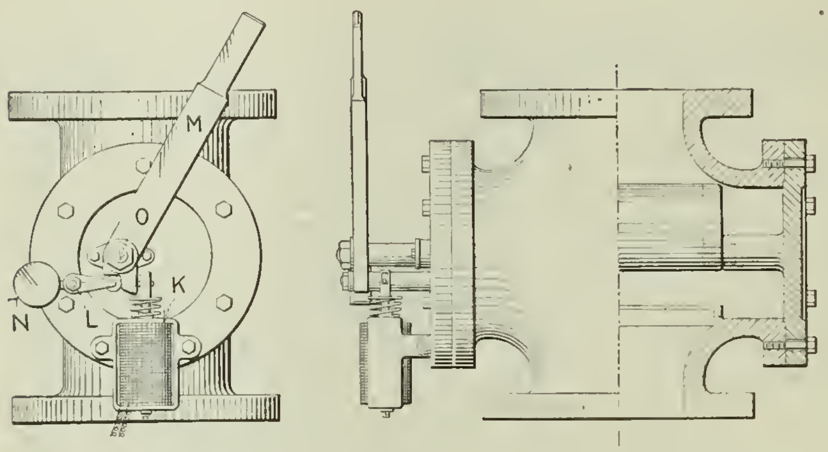

Fig. 1. End and Side View of the Detaching Device

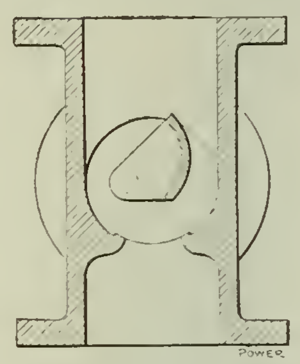

Fig. 2. Sectional View of Valve and Seat

Either batteries or regular line current can be used if desired.

The operation of this mechanism is as follows: *P*, Fig. 4, is the solenoid mounted on the front head of the valve; *R* is the automatic spring switch and *S S S* are shop switches for emergency use.

Referring to Fig. 3, *B* is a bracket fastened to the engine shaft *A* and supports the weight arm *C*, which turns on the pin *D*. The centrifugal force exerted by the shaft turning in the direction indicated by the arrow will throw the arm *C* out and away from the shaft. The distance this force will cause the arm to move out is regulated by the resistance of the spring *E*. At normal speed the spring is set to hold the arm *C* tight against the shaft *A*, but any increase of speed will cause the centrifugal force to overcome the spring resistance and allow the arm to move out so that the point *F* will describe a larger circle until it comes in contact with the pin *G*, forcing it down and thus releasing the spring knife switch *J*. This closes the electric circuit, as will be seen by glancing at the wiring diagram in Fig. 4.

When the circuit is closed, either by the increased speed of the engine or by throwing in one of the shop switches, the solenoid *K* is energized, which causes it to draw the plunger down, hitting the disengaging arm a hammer blow, causing it to turn on the pin *L* and disengaging the roller, shown in Fig. 1, from con-

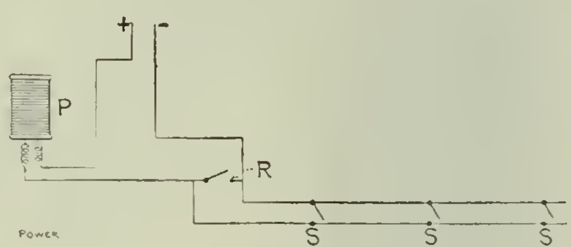

Fig. 4. Diagram of Wiring

tact with the nose of the lever *M*. This disengaging arm is afterward brought back to its normal position by the counterweight *N*. The valve lever *M* is attached to the valve stem *O* and when one of the switches is closed the valve and lever will drop, shutting off the steam and stopping the engine.

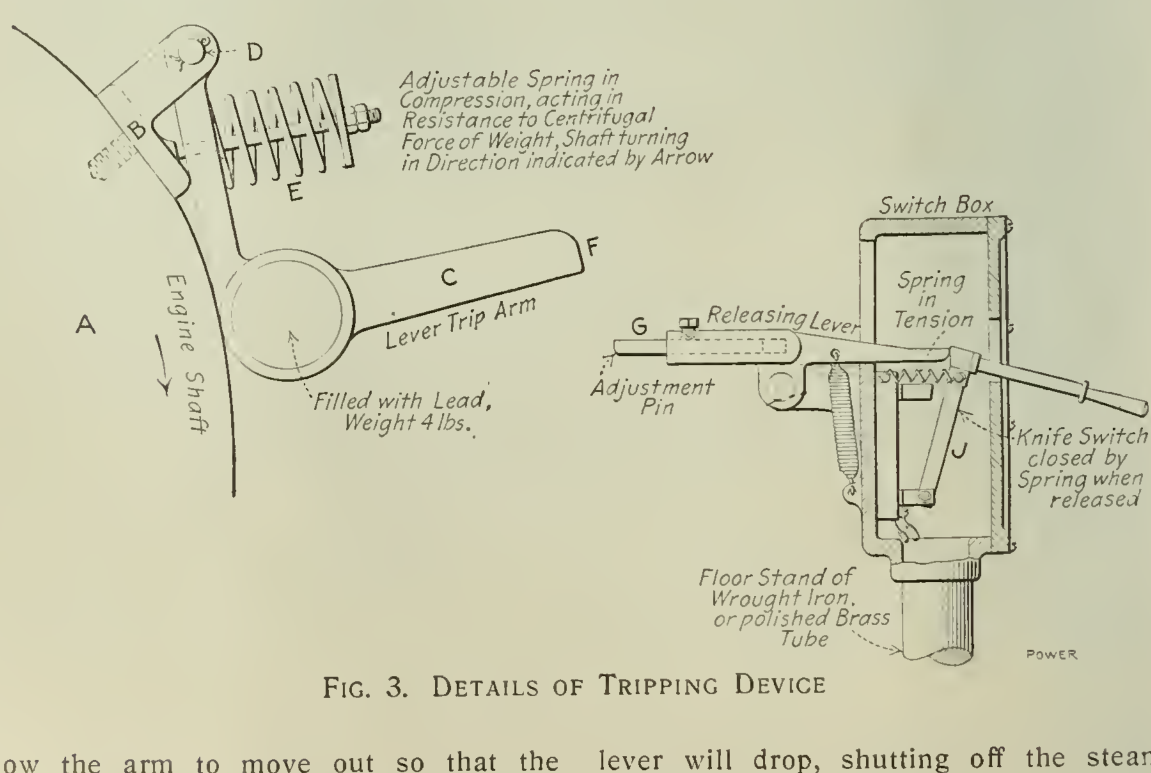

Fig. 3. Details of Tripping Device

This apparatus is made by the Automatic Engine Stop Company, Sheboygan, Wis.

A Vacuum Ventilator

As the name implies, the principle upon which this ventilator operates is due to a vacuum formed in the hollow ball of the ventilator. This ball is placed on the top of a vertical outlet and serves the purpose of drawing out the foul air, gases, etc., from the room to which it is attached.

In operation, the wind strikes the ball, which has an opening as shown in Figs. 1 and 2. As the wind passes over this opening it sucks out the air which is in the ball and causes a partial vacuum. The air in the building or room below, being under normal pressure of the atmosphere, is forced up to take the place of that which has left the ball, the process becoming continuous, and results in a strong, steady updraft as long as there is any movement in the outside atmosphere.

Fig. 1. How it Works

Fig. 1 shows how this is accomplished. The wind velocity is represented by the figure. Air is blown against the ball and the particles shown in the tube between the stand and the ball represent the upward current of the air. Fig. 1 represents a model that has been made for the purpose of demonstration. A person blowing against the ball is able to draw particles of paper, fine cloth or anything that is of a light material up through the tube and out through the opening in the ventilator head.

Fig. 2 shows a sectional view of the ventilator. It will be noted that the head is made in the shape of a sphere and the rounded surface is presented to the wind no matter from what quarter it blows and divides the current of air which passes over the outlet space with the result described.

The hood is provided with a shield which protects the vertical outlets and keeps rain and snow from getting into it and also keeps the ventilator free from downdrafts. It is so situated that the offset is enough to allow free egress of the heated air and free and easy access of the wind to the outlet.

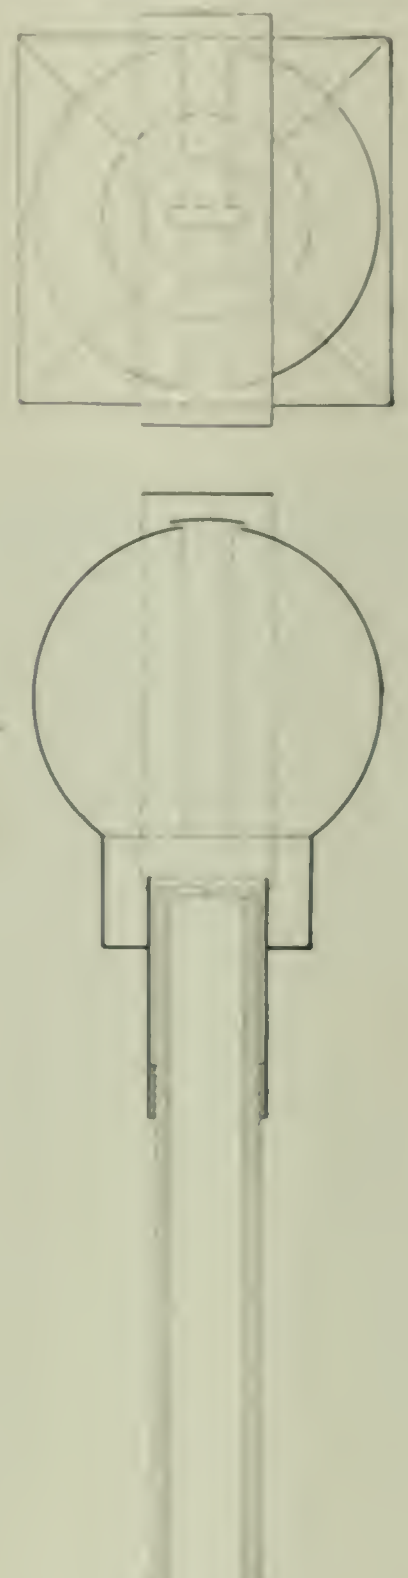

Fig. 2. Details of Construction

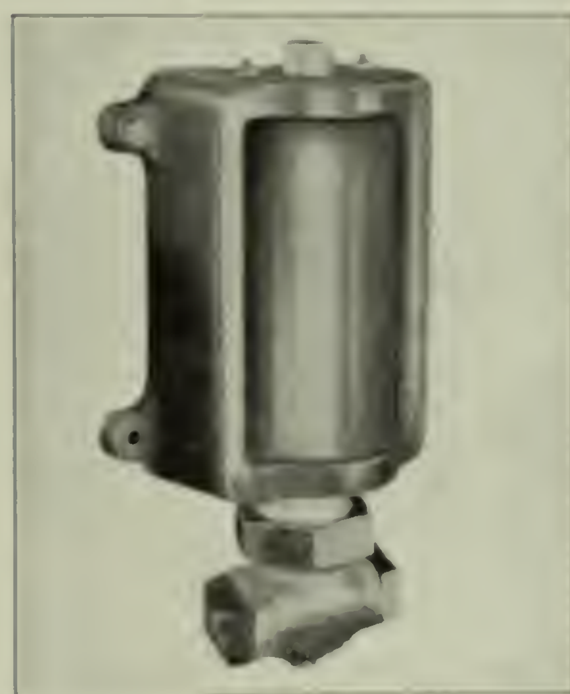
These ventilators can be placed in such position that the wind has full sweep around them, or they may be so located that the wind will come directly down on top of them. Either arrangement will give satisfactory results.

There are only four parts which enter into its construction: the barrel or neck, the diameter of which determines the size of the ventilator, the two hemispherical shells, between which are the vertical outlets and the shield. There are no mechanical parts or movements to get out of order. It is made by the Vacuum Ventilator Company, 84 Purchase street, Boston, Mass.

Solenoid Operated Valve

There is usually considerable difficulty in attempting to start a double-acting compressor because of compression and it is in the function of an unloader that the new solenoid-operated valve recently developed by the Cutler-Hammer Manufacturing Company, of Milwaukee, has found employment. The arrangement consists of a bypass automatically operated by this solenoid valve, which permits the pressure to be released from the compressor cylinder, thereby preventing compression. When the desired speed has been reached the bypass is automatically closed, allowing the loading of the compressor.



Solenoid-operated Valve

It will be noted by referring to the accompanying illustration that the construction is such as to permit placing the solenoid plunger inside the piping system, thus eliminating entirely stuffing-box friction. The energizing of the magnet coil, for which only a small current is required, lifts the solenoid plunger through a short free travel, operating the valve by a hammer blow. After the valve is started the pressure becomes nearly balanced. The coil circuit can be run wherever desired so that the valve can be operated from any location or series of locations, according to the arrangement.

These devices are also applicable for many functions in hydraulic or pneumatic systems; with self-starters, for remote control of valves used for setting the brakes of a pneumatic-brake control set.

tem, etc. When arranged with a thermostat in a heating system they can be made to automatically control the flow of steam as desired. In signal systems where air-operated whistles are used these valves save piping and enable the ready control from a central location.

Four standard sizes of valves are built: ⅜, ½, ¾ and 1 inch, threaded for standard iron pipe and having an area of opening approximately equal to that of pipe of the same rated size. The solenoid coils used are wound for voltages of 115, 230 and 500, being the standard Nos. 3, 5 and 6 Varley coils.

Boiler Explosion at Augusta, Ga.

By S. Kirlin

A 40-horsepower upright boiler used for pumping out a cofferdam and operating a pile driver on the work being done on the Southern Railway bridge at Augusta, Ga., exploded at about 4:30 a.m. on March 23, instantly killing two negroes and fatally injuring two white men.

The body of one of the negroes was blown to atoms and no part of it has been found. The other one was almost completely blown to pieces, but was found later in the cofferdam. W. A. Vowell, the superintendent of the work, from Columbia, S. C., was badly crushed and scalded and is thought to be fatally injured. D. C. White, night foreman, was scalded all over the body and it is not thought that he can recover. He was standing on the platform on which the boiler was set and was blown over into the cofferdam, from which he was removed shortly after the explosion occurred.

All of the men were working around the boiler at the time and it is said that they were trying to get the injector started. It is supposed that the water was low in the boiler and that the explosion occurred when they succeeded in getting the injector to working. Not a trace of the boiler or engine can be found, so that it is impossible to form any correct idea as to the exact cause of the explosion. It is said that a part of the boiler was blown several hundred feet into the air, passing over the top of the bridge and falling into the river below.

The accident seems to have been very similar to the one with the same type of boiler which exploded in the Ideal laundry at Verona, Penn., a description of which was given in the issue of March 14.

A fire in the plant of the Cohannet Silver Company, Taunton, Mass., on March 22 caused considerable damage in the boiler room. The fire started in another part of the building and caused a total loss of about $45,000.

Peat Society Meeting

The New York section of the American Peat Society held its regular quarterly meeting on Tuesday evening, March 21, at the rooms of the Chemists' Club in West Fifty-fifth street, New York City. Dr. Charles F. McKenna, chairman of the section, introduced Prof. Charles A. Davis, peat expert for the United States Bureau of Mines, who gave one paper entitled, "Late Developments in the Peat Industry" and another, entitled, "Drainage of Peat Deposits."

By way of introduction, Professor Davis spoke briefly of the work of the Bureau of Mines in connection with the development of the peat industry. Up to the present time the work has been largely educational. This has been the result of the lack of facility for accomplishing material progress in experimental work.

In his first paper, the Professor described in outline the various processes of digging and preparing peat that so far have been employed.

In his second paper, he told of the ways in which peat bogs are drained, of the difficulties to be contended with and of the difference in drainage requirements of bogs yielding peat for fuel and those yielding peat for filler and other purposes.

National secretary Julius Bordollo announced that the annual convention of the society would be held in Kalamazoo, Mich., late in September. An interesting program is being prepared.

Steam Pipe Explodes in Amoskeag Mills

On March 27 the blowing out of the "dead end" of a 12-inch steam pipe in the new power plant of the Amoskeag Manufacturing Company, of Manchester, N. H., killed two men and seriously injured seven more, according to reports published in the daily press. Full particulars will be given in an early issue.

PERSONAL

David Moffat Myers, consulting engineer, New York City, has moved to larger offices in the New Whitehall building, 17 Battery place.

George Alfred Goodenough, for many years associate professor of mechanical engineering of the University of Illinois, has been promoted to be professor of thermodynamics.

Bernard L. Walsh, chief engineer for the Woonsocket, R. I., Electric Machine and Power Company, has tendered his resignation. He will be succeeded by Everett Read, of East Bridgewater, Mass.

Cornelius T. Myers, formerly assistant secretary and assistant treasurer of the Wisconsin Engine Company, of Corliss, Wis., has now opened consulting-engineering offices at Racine, Wis.

John B. Perkins, president of the John B. Perkins Company, of Boston, and F. P. Sheldon, M. E., of Providence, left on Saturday, March 25, for a visit to Cuba, Jamaica, Porto Rico and the Bermudas.

Prof. W. F. Schaphorst, of the mechanical-engineering department of the New Mexico College of Mechanic Arts, has resigned his position there to become a technical writer on the staff of A. Eugene Michel, advertising engineer, New York City.

Charles Russ Richards, dean of the college of engineering of the University of Nebraska, has been appointed professor of mechanical engineering in charge of the department at the University of Illinois, effective September 1, 1911. Professor Richards has been identified with the University of Nebraska in various capacities for the past 20 years and has been largely instrumental in organizing and equipping this university for mechanical-engineering study.

George A. Orrok, of the New York Edison Company, visited the University of Wisconsin on March 16 and addressed the student section of the American Society of Mechanical Engineers on the subject of "The Utilization of Blast Furnace Gases, with Especial Reference to Gas Engines." Mr. Orrok dealt with the problem of the blast furnace involving the utilization of its waste gases, and showed the historical development of different means of utilizing these gases. The latter part of the lecture included a brief description of the latest types of blast-furnace gas engines, and was very copiously illustrated by lantern slides.

SOCIETY NOTES

The American Institute of Steam Boiler Inspectors annual meeting and election of officers will be held at the Parker house, Boston, Tuesday, April 25, at 8 p.m.

Under the auspices of the power-transmission section of the National Electric Light Association, a public conference will be held in the United Engineering Societies building, New York City, on Saturday, April 8, to consider the important subject of the relation of the National and State governments to the conservation and utilization of water powers. This subject is one, not only of vital concern to the central-station industry, but affects in many ways the conditions of engineering, the employment of labor and capital, and the welfare of the public. Two sessions will be held, afternoon and evening, and papers and addresses will be delivered by several well known men.

On March 16, the New York Electrical

Society celebrated its three hundredth meeting. F. O. Blackwell lectured on "Hydroelectric Development in Mexico." In opening the lecture, Mr. Blackwell gave an interesting sketch of the causes which have led up to the present conditions in Mexico, giving to the enlightened and progressive policy of President Diaz, the credit for the wonderful developments in hydroelectric installation effected in recent years. The society had a short business meeting, at which reports of committees were received. The treasurer reported that the heavy load of debt which the society had incurred during the last few years, in its endeavor to develop its work and increase the advantages of its membership, has been paid off, and the finances are now in a prosperous condition. Twenty-eight members and thirty-two life members were elected. The society now has over eight hundred members.

NEW PUBLICATIONS

Scientific American Cyclopedia of Formulas. Compiled and edited by Albert A. Hopkins. Published by Munn & Co., New York City, 1911. Cloth, 1000 pages, 6½x8¾ inches; 200 illustrations. Price, $6.50 net.

This is the latest and probably by far the most complete work of this kind issued. It was compiled by the query editor of the *Scientific American* and contains some 15,000 recipes, formulas and processes selected from a collection of nearly 150,000. There are chapters treating upon soldering, soap and candles, preserving, painting and photography; lapidary art, leather and lubrication; confectionery, glass making and metal working, beverages, alloys and amalgams, beside some hundreds of other topics, many of which are of the odd, out-of-the-ordinary type, relating to little known technical products. A complete index prepared by professional librarians makes it an easy matter to find any subject desired.

"The Strength of Oxyacetylene Welds in Steel," by Herbert L. Whittemore, has just been issued as Bulletin No. 45 of the engineering experiment station of the University of Illinois. This bulletin gives the results of an extensive series of tests to determine the strength which may be developed in welded joints made by fusing thin steel plates together by means of the flame of an oxyacetylene blowpipe. It was found that with careful manipulation such a welded joint may be expected to have about 85 per cent. of the strength of the plate material. Considerable information as to methods of manipulation of the oxyacetylene blowpipe and the proper regulation of the gases is also given in the bulletin. Copies may be obtained gratis upon application to W. F. M. Goss, director of the engineering experiment station, University of Illinois, Urbana, Ill.

OBITUARY

Charles Wallace Hunt, president of the C. W. Hunt Company, of Staten Island, N. Y., and former president of the American Society of Mechanical Engineers, died at his home on March 27. He was born at Candor, Tioga county, N. Y., in 1841. He studied at Cortland academy, Homer, N. Y., and subsequently received instruction in mechanics and higher mathematics under a private tutor. At the time of the war between the States, he joined the army on the Northern side and served from 1862 to 1865, chiefly in Virginia, undergoing hardships from which his health, for a while, considerably suffered.

The Late C. W. Hunt

Entering readily into mechanical pursuits, he engaged, in 1872, in the manufacture of special machinery on Staten Island, N. Y. His plant has since attained great importance in its province—appliances for handling materials in large quantities. There was such novelty in this branch of mechanics when he took it up that his work partook of a pioneer character. The various special devices he put out were designed to meet actual, definite exigencies. The patents of the business run into hundreds and its ramifications extend to conveying and hoisting machinery for ore, coal, etc., cableways, industrial railways, manila rope and kindred lines.

Mr. Hunt was president of the American Society of Mechanical Engineers, 1897 to 1898, having been for several years before that time chairman of its Committee of Publications. He was also a member of many other societies, such as the American Institute of Mining Engineers; New York Electrical Society; Engineers' Club, of New York; National Science Association, and New York Chamber of Commerce. He had been president of the Staten Island Chamber of Commerce and of several manufacturing companies both auxiliary to his main business, the C. W. Hunt Company, and otherwise.

William Carpenter Woodward, for the past 18 years electrical engineer of the Narragansett Electric Lighting Company of Providence, R. I., died in that city Saturday afternoon, March 25, as a result of cerebral hemorrhage. He had been in poor health since last August and had not worked since that time. Mr. Woodward gained his first experience in electrical work with the General Electric Company, and later with the Standard Electric Company, of Boston. He had entire charge of the electrical-engineering department of the Narragansett company, and it was he who adapted the high-voltage system now in use in Providence. He was born in Roxbury, Mass., about 50 years ago. A son will be graduated from the Naval Academy at Annapolis this year.

The power equipment of the M. S. Novelty Company's factory in Providence, R. I., was destroyed by fire on March 22. The fire started in some chemicals near the engine room, and Engineer B. T. Edwards barely had time to open the injector and fire doors of the boiler and shut off the gage cocks and get out of the building. The equipment included a 35-horsepower Nagle engine and an upright 35-horsepower boiler.

The boiler room of the Woonsocket, R. I., Dye and Bleaching Company's mill was damaged to the extent of about $500 by a fire on Thursday night, March 9.

NEW INVENTIONS

Printed copies of patents are furnished by the Patent Office at 5c. each. Address the Commissioner of Patents, Washington, D. C.

PRIME MOVERS

POWER GENERATOR. William J. Neilson, Elmhurst, N. Y., assignor to himself, and Leland H. Kimball, Salt Lake City, Utah. 987,158.

CONSTANT-PRESSURE INTERNAL COMBUSTION APPARATUS. Edward P. Noyes, Winchester, Mass. 275,861.

ENGINE. Daniel R. Scholes, Chicago, Ill., assignor to Aermotor Company, Chicago, Ill., a Corporation of Illinois. 987,177.

OIL ENGINE. Hermann Bowyer Leech, Halifax, England. 987,246.

COMPOUND ROTARY ENGINE. Lucas K. Sivertson, Carrington, N. D. 987,264.

ELASTIC-FLUID TURBINE. Berthold Wolff, Berlin, Germany. 987,336.

ROTARY EXPLOSIVE ENGINE. James C. Peterson and Robert T. Peterson, Gleichen, Alberta, Canada. 987,486.

WINDMILL. John O'Toole, Colegrove, Cal. 987,645.

WINDMILL. William P. Bennett, Woodstock, Ohio. 985,131.

POWER WHEEL. Walter H. Fierce, Atlantic City, N. J. 985,152.

ROTARY ENGINE. Stephen E. McGann, Cleveland, Ohio. 985,192.

INTERNAL COMBUSTION ENGINE. Alden E. Osborn, New York, N. Y. 985,198.

INTERNAL COMBUSTION ENGINE. Andrew Betts Brown, London, England, assignor to William Albert Hickman, Pictou, Canada. 985,507.

ROTARY ENGINE. Reece Williams, Albany, Western Australia, Australia. 985,562.

ROTARY ENGINE. David N. Green, Sunbury, Ohio. 985,584.

ROTARY ENGINE. David Newton Green, Sunbury, Ohio. 985,669.

INTERNAL COMBUSTION ENGINE. Henry Joseph Podlesak, Chicago, Ill. 985,703.

BOILERS, FURNACES AND GAS PRODUCERS

MECHANICAL STOKER. Wilfred Rothery Wood, London, England, assignor to the American Stoker Company, Erie, Penn., a Corporation of New York. 987,661.

BLACK-OIL BURNER. James Warren Elder, Visalia, Cal. 987,617.

BOILER. George Peterson, Duluth, Minn. 985,281.

LIQUID-FUEL BURNER. Henry W. Schoff, River Forest, Ill. 985,291.

FURNACE. Henry E. Wallis, Terre Haute, Ind. 985,480.

LIQUID-FUEL BURNER. John Jay Vallier, Oakland, Cal. 985,644.

POWER PLANT AUXILIARIES AND APPLIANCES

FLUE PLUG. Silas Adams, Cleveland, Ohio. 987,099.

COMBINED WATER, VACUUM AND PRESSURE GAGE, AUTOMATIC REGULATOR AND SAFETY DEVICE. William T. Fowden, Chester, Penn. 987,125.

VALVE MECHANISM FOR INTERNAL COMBUSTION ENGINES. Alden E. Osborn, New York, N. Y. 987,164.

STUFFING BOX. John Hahn, Los Angeles, Cal. 987,296.

VALVE. William J. Theis, Chicago, Ill., assignor to Manufacturers Equipment Company, a Corporation of Illinois. 987,334.

STAY BOLT FOR STEAM BOILERS. Patrick J. Connors, Greenville, Penn., assignor of one-half to Frank Disler, Greenville, Penn. 987,431.

BOILER-FLUE CLEANER. William Eichelberger and De Los E. Hibner, Dubois, Penn., assignors to the Vulcan Soot Cleaner Company, of Pittsburg, Penn., Dubois, Penn., a Corporation of New Jersey. 987,450.

VALVE. Edward Dwyer, Clymer, Penn. 987,447.

VALVE. Robert Charles Green, Winchester, England. 987,571.

PRESSURE AND DAMPER REGULATOR. John B. Bischoff, Mount Clemens, Mich. 987,610.

AIR-LIFT DISPLACEMENT PUMP. Frank S. Miller, Indianapolis, Ind. 987,679.

VALVE. Vincent F. Bernesser and Joseph J. Crotty, New York, N. Y. 985,134.

VALVE. Axel Valdemar Clorius, Copenhagen, Denmark. 985,146.

SAFETY VALVE. Nelson Goodyear, New York, N. Y., assignor to Maine Development Corporation, a Corporation of Maine. 985,160.

VALVE. Willard A. Speakman, Wilmington, Del. 985,220.

STEAM TRAP. Joseph B. McKeown, Union Hill, N. J. 985,362.

VALVE. Franklin M. Patterson, Philadelphia, Penn., assignor, by direct and mesne assignments, to Patterson-Allen Engineering Company, a Corporation of New York. 985,444.

VALVE. George W. Hammond, Philadelphia, Penn., assignor of one-half to John H. Michener, Jr., New York, N. Y. 985,526.

PACKING FOR VALVES. Caspar W. Miller, Wallingford, Penn. 985,618.

ELECTRICAL INVENTIONS AND APPLICATIONS

ALTERNATING - CURRENT ELECTROMAGNET. David L. Lindquist, Yonkers, N. Y., assignors to Otis Elevator Company, Jersey City, N. J., a Corporation of New Jersey. 987,146.

ELECTRIC IGNITION SYSTEM FOR EXPLOSION ENGINES. Oliver B. Thompson and Carl R. Moeller, Buffalo, N. Y. 987,188.

ELECTRIC SWITCH. Oliver B. Whipple, Saginaw, Mich. 987,200.

ELECTRICAL SYSTEM OF DISTRIBUTION. Albert S. Hubbard, Belleville, N. J., assignor to Gould Storage Battery Company, a Corporation of New York. 987,301.

ELECTRIC INDUCTION FURNACE. Wilhelm Rodenhauser, Volklingen-on-Saar, Germany, assignor to the Grondal Kjellin Company, Ltd., London, England. 987,404.

ELECTRIC WATER HEATER. Herbert N. Riche and William Ruth Ray, San Francisco, Cal., assignors to Thomas B. Gray, San Francisco, Cal. 987,493.

SNAP SWITCH. Samuel Korf, Chicago, Ill., assignor to the Wi-Ko Electric Company, Chicago, Ill., a Corporation of Illinois. 987,581.

ELECTROLYTIC CELL. Victor E. Goodwin, Schenectady, N. Y., assignor to General Electric Company, a Corporation of New York. 987,622.

PRIMARY BATTERY. Charles B. Schoenmehl, Waterbury, Conn. 987,647.

TUNGSTEN INCANDESCENT LAMP. John J. O'Brien, Shamokin, Penn. 987,483.

ELECTRIC HEATER AND STERILIZER. Johann G. Wallmann, Oakland, Cal. 987,658.

ENGINEERING SOCIETIES

AMERICAN SOCIETY OF MECHANICAL ENGINEERS

Pres., Col. E. D. Meier; sec., Calvin W. Rice, Engineering Societies building, 29 West 39th St., New York. Monthly meetings in New York City. Spring meeting in Pittsburg, May 30 to June 2.

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS

Pres., Dugald C. Jackson; sec., Ralph W. Pope, 33 W. Thirty-ninth St., New York. Meetings monthly.

NATIONAL ELECTRIC LIGHT ASSOCIATION

Pres., Frank W. Frueauff; sec., T. C. Martin, 31 West Thirty-ninth St., New York. Next meeting in New York City, May 29 to June 2.

AMERICAN SOCIETY OF NAVAL ENGINEERS

Pres., Engineer-in-Chief Hutch I. Cone, U. S. N.; sec. and treas., Lieutenant Commander U. T. Holmes, U. S. N., Bureau of Steam Engineering, Navy Department, Washington, D. C.

AMERICAN BOILER MANUFACTURERS' ASSOCIATION

Pres., E. D. Meier, 11 Broadway, New York; sec., J. D. Farasey, cor. 37th St. and Erie Railroad, Cleveland, O. Next meeting to be held September, 1911, in Boston, Mass.

WESTERN SOCIETY OF ENGINEERS

Pres., O. P. Chamberlain; sec., J. H. Warder, 1735 Monadnock Block, Chicago, Ill. Meeting first Wednesday of each month.

ENGINEERS' SOCIETY OF WESTERN PENNSYLVANIA

Pres., Walter Riddle; sec., E. K. Hiles, Oliver building, Pittsburg, Penn. Meetings 1st and 3d Tuesdays.

AMERICAN SOCIETY OF HEATING AND VENTILATING ENGINEERS

Pres., R. P. Bolton; sec., W. W. Macon, 29 West Thirty-ninth street, New York City.

NATIONAL ASSOCIATION OF STATIONARY ENGINEERS

Pres., Carl S. Pearse, Denver, Colo.; sec., F. W. Raven, 325 Dearborn street, Chicago, Ill. Next convention, Cincinnati, Ohio, September 12-15, 1911.

AMERICAN ORDER OF STEAM ENGINEERS

Supr. Chief Engr., Frederick Markoe, Philadelphia, Pa.; Supr. Cor. Engr., William S. Wetzler, 753 N. Forty-fourth St., Philadelphia, Pa. Next meeting at Philadelphia, June 5-10, 1911.

NATIONAL MARINE ENGINEERS BENEFICIAL ASSOCIATIONS

Pres., William F. Yates, New York, N. Y.; sec., George A. Grubb, 1040 Dakin street, Chicago, Ill. Next meeting at Detroit, Mich., January 15-19, 1912.

INTERNAL COMBUSTION ENGINEERS' ASSOCIATION.

Pres., Arthur J. Frith; sec., Charles Kratsch, 416 W. Indiana St., Chicago. Meetings the second Friday in each month at Fraternity Halls, Chicago.

UNIVERSAL CRAFTSMEN COUNCIL OF ENGINEERS

Grand Worthy Chief, John Cope; sec., J. U. Bunce, Hotel Statler, Buffalo, N. Y. Next annual meeting in Philadelphia, Penn., week commencing Monday, August 7, 1911.

OHIO SOCIETY OF MECHANICAL ELECTRICAL AND STEAM ENGINEERS

Pres., O. F. Rabbe; acting sec., Charles P. Crowe, Ohio State University, Columbus, Ohio. Next meeting, Youngstown, Ohio, May 18 and 19, 1911.

INTERNATIONAL MASTER BOILER MAKERS' ASSOCIATION

Pres., A. N. Lucas; sec., Harry D. Vaught, 95 Liberty street, New York. Next meeting at Omaha, Neb., May 23-26, 1911.

INTERNATIONAL UNION OF STEAM ENGINEERS

Pres., Matt. Comerford; sec., J. G. Hannahan, Chicago, Ill. Next meeting at St. Paul, Minn., September, 1911.

NATIONAL DISTRICT HEATING ASSOCIATION

Pres., G. W. Wright, Baltimore, Md.; sec. and treas., D. L. Gaskill, Greenville, O.

POWER

NEW YORK, APRIL 11, 1911

THERE are many kinds of pessimist (which is the parlor substitute for such terms as "croaker," "calamity howler," "grouch," etc.)

First, there is the amateur. His case is seldom hopeless if treated properly in the early stages. The primary cause is usually a languid liver or some other temporary physical failing. When a person is troubled in this way, even a slight run of hard luck may serve to put him in the dumps of despair. But, a liver pill or a spring tonic soon re-establishes his mental equilibrium and he gets safely over his distemper.

Then, there is the professional—the chronic kicker. You can depend upon him to ferret out an excuse for complaint every time and to make the best possible use of it when he does. To express it mildly, the habitual howler is a nuisance and sometimes even a positive danger.

The amateur pessimist usually thinks that the trouble is with himself; the professional is positive that it is with the world.

If you tell old "Steady Grouch" of some pet project you have in mind or of some ambition you hope to be able to realize by dint of hard work, he will see instantly a thousand things to thwart you and will knock a lot of enjoyment out of telling you how impossible it is for you to realize your "dreams" as he probably would call them.

Optimism is an asset. Perhaps faith is a better name for what we mean—faith in ourselves, in our own ability, in our friends, in our assistants and in the man "higher up."

During the late lamentable "financial stringency" one of the "foolish" papers "did" the cleverest thing. Just at the time when all of us were dragging our weary selves around with the fear of rank ruin written in every wrinkle of our faces, *Judge* came out with a full-page cartoon which "hit off" the condition of the business world to the "queen's taste." The picture showed a group of men standing about looking at a cake—a circular doughnut, to be perfectly frank with you. One member, rotund and jovial, was urging the others to keep their eyes on the doughnut and not to mind about the hole. Good, wholesome advice, that, and well worth practising right along.

It doesn't do anyone a bit of good to think so hard about the hole in his cake that he forgets to eat and enjoy the cake itself. Not only is such practice bad for the man himself but it also has a bad effect upon those with whom he comes in contact. Deny it though you may, the fact remains that all of us are strongly influenced by our companions and our environment.

By the same token, then, each of us has his influence on his companions. Keeping this in mind, is it not more profitable to be a "booster" than a "knocker"? We guess yes.

After all, this is a good old world and right down in our hearts we're glad we're here. This being so, why not mention the fact now and then to someone who seems to have forgotten it temporarily?

Gas Engine Waste Heat to Turbine

By Edwin D. Dreyfus*

> *The economies to be effected by running low-pressure steam turbines in connection with gas engines are considered, as influenced by investment as well as by heat recovered. The turbine may be designed to use steam of two pressures, a primary supply at from one to three atmospheres generated by the heat of the gases and a secondary lower pressure supply derived from the jacket water and introduced at later stages.*

Composite power plants containing independent sections of steam turbine and gas-engine generating equipment have heretofore been shown to establish a very economical arrangement for the production of electrical energy from stores of latent heat. As observed, this plan would prove of advantage for swinging loads and low load factors—the gas-power division to be operated constantly near normal capacity and the fluctuation and peaks absorbed by the steam installation.

It is patent that gas engines rapidly decline in efficiency on loads less than 50 per cent. of their rating and, moreover, their greater first cost generally demands a large output to reap commensurate returns on the investment.

The high thermal efficiency of the gas engine is well known, but the large steam turbine has also developed remarkable economies so that the internal-combustion motor only excels in the moderate and small units.

When the combining of turbines and gas engines in a single station was first proposed, it was with the intention of using high-pressure steam, requiring the installation of boilers, stokers and additional coal-handling machinery, which entails greater labor expense and standby losses. It was suggested at that time, however, that the gas-engine waste heat be applied to the feed water of the steam section.

Since the advent of the low-pressure turbine, it has become feasible to economize the waste heat of the gas engine in exhaust heaters and utilize the energy directly in the turbine without the introduction of high-pressure boilers and coal-burning furnaces in the plant. Furthermore, the heat so conserved may be stored in large tanks, analogous to the system outlined by A. M. Hunt in the April, 1910, *Proceedings* of the American Institute of Electrical Engineers, for high-pressure operation in emergency stations, and used in bulk for peak demands.

Based upon the actual performance of the component elements of such an amalgamated plant, the following results may be readily achieved:

For Continuous Operation

(*a*) Employing the exhaust heat only, 6 to 8 per cent. heat saving over the existing economy of the gas engine.

(*b*) Abstracting heat from both the engine exhaust and jackets, 10 to 14 per cent.

For Peak Load Operation

(*a*) Storing heat from the exhaust over periods several times the duration of the peak, enables heavy overloads to be sustained, resulting in appreciable reduction in investment for the maximum demand, 15 to 30 per cent. normally, in addition to the fuel saving.

(*b*) Operating with intermittent storage, the variable swings may be loaded on the turbine and the engine and producers operated under the most favorable conditions. Ultimate improvement about 15 per cent. in heat consumption and a reduction of 12 per cent. in investment. Moreover, the auxiliary low-pressure turbine would act as a reserve unit to relieve, partially or fully, any temporary embarrassment of the engine.

*Commercial engineer of the Westinghouse Machine Company.

Heat Storage

If a widely changing load should be experienced, providing a *low loading factor*, the installation of the auxiliary plant for continuous operation may likely prove inadvisable, as the fuel expense may bear only a small relation to the total cost. But by accumulating the primary waste heat in a storage system and utilizing it in a simple and comparatively inexpensive low-pressure turbine auxiliary, this arrangement will lend itself to reducing the burdensome capital charges.

The conditions where the auxiliary low-pressure turbine may be profitably installed, may be divided mainly into two classes:

Case I. Low-pressure turbines operating continuously with uniform load on the plant, as exists in most industrial works.

Case II. Widely varying load on the plant, with the low-pressure turbine in conjunction with a heat-storage system, serving only the peak swings of the load. (a) Fixed peaks, as in central lighting stations; (b) irregular peaks, such as occur on an interurban railway with infrequent service.

Uniform Plant Load

The value of a waste-heat power installation for steady service may be readily appreciated; and the accompanying general layout, Fig. 1, shows the principal elements of the plant.

From a practical standpoint, it would not be warrantable to employ for *continuous operation* a smaller low-pressure turbine auxiliary system than 150 kilowatts, which would serve a 1400-kilowatt normally rated engine plant.

The low-pressure turbine system will cost $45 to $60 per kilowatt installed, the smaller size naturally being the larger in unit cost. A four-unit gas plant would represent an investment of $130 to $140 per kilowatt with units 300 to 500 kilowatts in size. The entire plant unit cost will be reduced about 6¾ per cent., which will, in itself, not greatly affect the cost of a kilowatt-hour generated.

Where the price of fuel is a serious factor in a plant, such an installation as that outlined may commend itself.

Peak-load Operation

Gas engines have very limited overload capacity in addition to suffering greatly in economy on the light loads. Their initial costs also produce high fixed charges on low load factors. This auxiliary system, using heat storage, should prove decidedly beneficial if not a complete panacea for these ills. A tank is provided as indicated by dotted lines in the lower left-hand corner of Fig. 1 and as no use would ordinarily be made of the jacket heat in this case the low-pressure boiler *D* of the first case would be eliminated. Obviously, the size of the low-pressure turbine unit would be affected by the extent and duration of the station peak.

On the basis of employing the exhaust heat only, and figuring storage efficiency at 85 per cent., the loss being due to radiation, the percentage of overload that may be obtained above the normal rating of the plant, is plotted in Fig. 3 a. For example, if a three-fourths hour peak is to follow six hours full-load operation, the overload capacity the plant would be capable of sustaining would be 60 per cent.

As it is unusual in commercial operation for full load to obtain for a period of six hours preceding the time of maximum demand on the plant, Fig. 3 b has been included so the approximate entire overload capacity for varying average fractional-load operation may be

readily derived graphically from Fig. 3 a. For illustration, if the plant had been running at three-quarters load for six hours and was to sustain a three-fourths hour peak, it will be found from Fig. 3 a that 60 per cent. overload could be sustained by the turbine. Taking, then, the 60 per cent. vertical ordinate and extending it horizontally to the 75 per cent. load diagonal, Fig. 3 b, 55 per cent. is obtained—this value including the 10 per cent. overload capacity of the gas engines. For other conditions, manifestly the same course is to be pursued. It is to be observed that the percentage of peak to be determined in each case represents the average of the period over which the low-pressure turbine operates. The maximum will therefore undoubtedly exceed the values given, especially if the maximum swing occurs during the first half of the time so that the tank temperatures will not be too low to operate the turbine on overloads. For peak-load conditions, plants as small as 500 kilowatts in engine capacity, may well include the byproduct power system.

These charts, therefore, facilitate the predicting of possibilities for any combination of conditions, but each individual case should be treated specially to definitely prove its merits.

The actual gain in fuel economy in this system will depend upon the true nature of the load curve. Where a peak of steep character and of very short duration occurs frequently and at indefinite times, the improvement in operation may be 15 to 25 per cent., as the engines will not have to be run underloaded normally so as to sustain the heaviest swing. With a widely changing load, as in some interurban railway systems, sufficient time may not elapse for adequate heat storage between peaks.

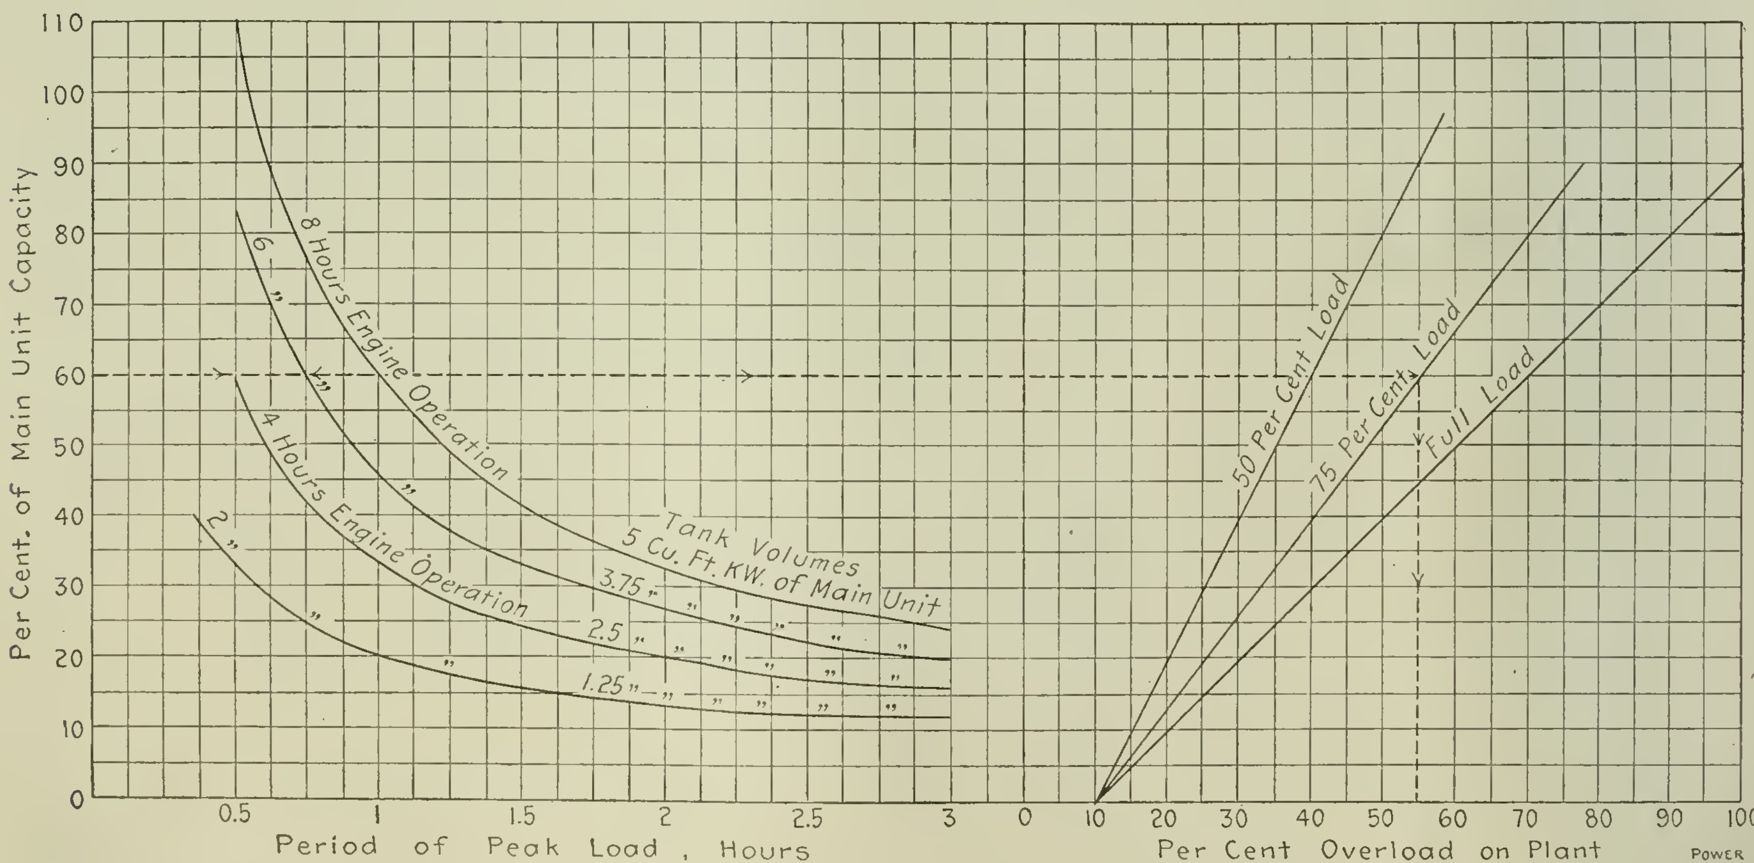

Fig. 3a. Percentage of Main Unit Capacity Available from Low-pressure Turbine Operating on Gas-engine Waste-heat Storage System. For Full-load Operation Preceding Peak

Fig. 3b. Chart for Obtaining the Percentage Overload Capacity of Gas Plant and Low-pressure Turbine from Fig. 3a for Fractional-load Operation Preceding Peak

The influence on costs works out in an interesting way. A four-unit gas plant, aggregating 1200 kilowatts, or more, will require an investment of approximately $135 per kilowatt, including buildings and plat. An installation of a low-pressure turbine system with condenser, tanks and piping, would approximate $45 per kilowatt. Therefore, if the station is to carry a 50 per cent. peak, of which 40 per cent.

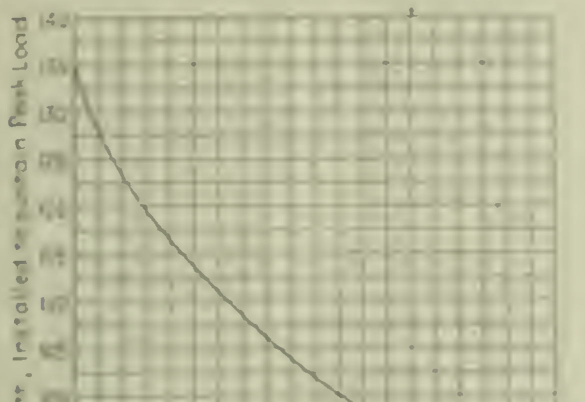

FIG. 4. DECREASED COST PER KILOWATT, DUE TO INSTALLATION OF LOW-PRESSURE TURBINE

is taken by the low-pressure turbine and 10 per cent. by the engines, the average cost becomes,

$$\frac{135^*}{1.10} \times \frac{110}{150} = 90$$

$$45 \times \frac{40}{150} = 12$$

$$\$102$$

This average corresponds to a reduction of $20.75 per kilowatt, or 16.9 per cent. For convenience, a number of values for other ratios have been determined and are given in Fig. 4.

If the low-pressure turbine is to be operated to supply peak loads only, but must be in operation continuously to absorb any sudden load increase, it will probably be warrantable to utilize the jacket heat to supply the no-load losses, as well as pump and condenser auxiliary power. The no-load steam consumption of a turbine is from one-fifth to one-sixth that of full load. As one-third of the work is obtained with the jacket heat, as brought out in the first case, the installation of a secondary system will contribute materially toward decreasing the power losses of the turbine running idle. In this manner, the low-pressure turbine system would be analogous to a storage battery floating on the line. The plant arrangement would be one which would combine the features of Cases I and II.

POSSIBLE SAVING

To demonstrate the value of this combination of gas engines and low-pressure turbines, studies of specific cases are included. For one example, a typical central lighting station load has been considered. Where central-station development is properly conducted, the character of the load curve should be more or less similar for the average city, and a form of load curve as given in Fig. 5 has been chosen. As previously shown, at least 7 per cent. of the gas-engine output may be obtained in the low-pressure turbine. To cover all contingencies, 6 per cent. has been used for this particular example.

Integrating the entire load chart and determining a peak-load area (6 per cent. of the area representing the gas-engine output) the portion of the load that the turbine may carry is indicated by the cross-hatched area. This shows that three 500-kilowatt gas engines and one 500-kilowatt low-pressure turbine may be installed in place of four straight gas-engine equipments. The gas plant, including building and real estate, would cost, at $135 per kilowatt, $270,000. A low-pressure turbine and auxiliaries, including low-temperature boiler, may be added without increasing the building or land cost and may be set up at about $50 per kilowatt, or, with the three gas engines, the entire plant would represent only $227,500 investment, a difference of $42,500. At 11 per cent. fixed charges* (5 per cent. interest, 4.5 per cent. depreciation—18 years' annuity—and 1½ per cent. insurance and taxes), the decreased yearly capital expense would be $4675.

As regards fuel saving, 6 per cent. would be conserved from the exhaust heat. The engine load factor must be improved, saving fully 4 per cent. additional. There would obviously be few producers standing by for peak load, and it may be safely estimated that a further saving of 5 per cent. may be secured from the elimination of a greater part of the standby losses. Thus the total improvement in fuel economy should equal 15 per cent. For such a plant-load curve as that shown in Fig. 5, the load factor for the winter months is 50 per cent., and for the summer months 30 per cent. The average should be over 40 per cent. where the winter months predominate. Therefore, the 2000-kilowatt plant at 40 per cent. load factor would generate (2000* × 8760 × 40 per cent.) 7,008,000 kilowatts per annum. The approximate coal curve for a four-unit plant, where the units would be placed in and taken out of service to correspond as closely as possible with the load variations, and including auxiliary-power losses, is given in Fig. 6. At 40 per cent. load factor, the average coal consumption per kilowatt-hour becomes about 2.8 pounds. This represents

$$\left(\frac{7{,}008{,}000 \times 2.8}{2000}\right) = 9{,}811$$

tons per annum, which, at $2.50 per ton, delivered, amounts to $24,528. By reducing the fuel consumption 15 per cent., the saving would be $3679. The total decrease in annual expense would be $4675 plus $3679, or $8354, regardless of labor. Capitalized at 11 per cent., this represents a decrease in investment of $75,900, which is about three times the cost of the turbine equipment. Or it might be stated that the low-pressure turbine system, if adopted for the fourth unit, would pay for itself in three years by the saving produced over and above the investment and operating cost of a fourth gas-engine unit.

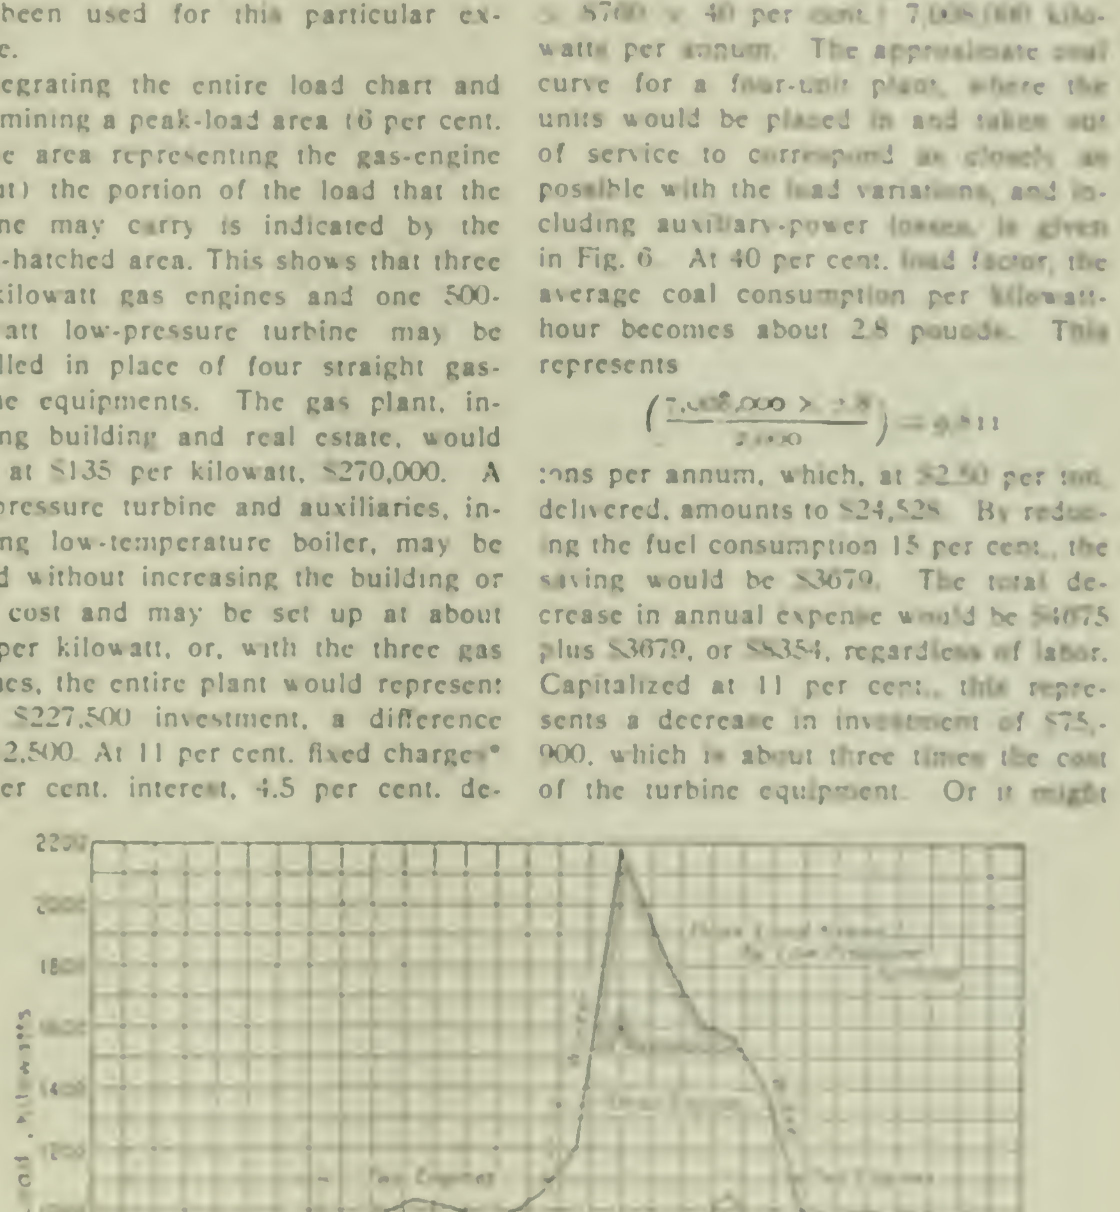

FIG. 5. TYPICAL CENTRAL-STATION LOAD CURVE. EXHAUST HEAT ONLY UTILIZED

Fig. 7 is an illustration of what may be accomplished with a swinging load, as in interurban-railway service, the curve being an actual one taken from a

*Reducing to cost per kilowatt, maximum rating, $122.75.

*This would be greater if allowance were made for depreciation.

*The classification, load factor is based on the normal rating of the plant.

station log. Engines would be improved 10 per cent. in economy, 9 per cent. would be saved by using the exhaust and jacket heat, and probably 3½ per cent. in the producer, totaling 22½ per cent. By carrying a 35 per cent. overload, the investment cost would also be lowered about 12 per cent. A curve of temperatures is plotted in this figure, showing the variation in the storage tank with load throughout the day.

It is understood that in Germany, particular activity has been displayed in this direction, and the possible gains which have been herein portrayed, have there become a matter of fact in actual installations.

Operating Conditions

In the preceding calculation, ample supply of condensing water at an average temperature of 70 degrees is assumed. With lower water temperatures, the results would obviously improve. On the other hand, if either the natural water supply is warmer or cooling towers are demanded, the attractiveness of this type of plant rapidly diminishes, which is emphasized by the theoretical water-rate curves, Fig. 8, for varying vacuum. This is essentially true for Case I, while Case II may show warrant for existence even under this condition.

All estimates are purposely made conservative in order that the advantages assumed may be realized in practice. Improvements in the detail apparatus may follow and refinements be introduced which will produce greater benefits than have been indicated.

The application of an amalgamated generating equipment of this nature will, it is believed, be confined to stations of 10,000 kilowatts aggregate capacity and less, due to the low fuel, labor and investment costs of the large turbine plant.

To facilitate a working understanding of the details involved in developing a combined gas-engine and low-pressure turbine equipment, the fundamental factors have been discussed at length below.

Power Developed in the Low-pressure Turbine

For all practical purposes, the heat distribution in the internal-combustion engine may be considered evenly divided between mechanical conversion (and radiation), the exhaust and the jackets. With an engine consuming about 10,000 B.t.u. per brake horsepower-hour at full load, the exhaust heat (33⅓ per cent. of the total) applied in a low-pressure boiler, with 70 per cent. efficiency, will produce, roughly, two pounds of atmospheric-pressure steam.

To facilitate a ready understanding of the accompanying deductions, the ideal water rates of steam motors, based on the Rankine cycle for different initial temperatures and vacua, are given in Fig. 8.

Expanding from atmospheric pressure to a 28-inch vacuum, the theoretical steam consumption is 15.2 pounds per horsepower-hour. A small steam turbine may be designed with a conversion efficiency of 65 per cent., hence would actually require 23.4 pounds per brake horsepower-hour at its normal rating. Consequently, the two pounds of steam generated from the engine exhaust may be applied in the turbine to develop $\frac{2}{23.4}$ or 8.54 per cent. of the power produced

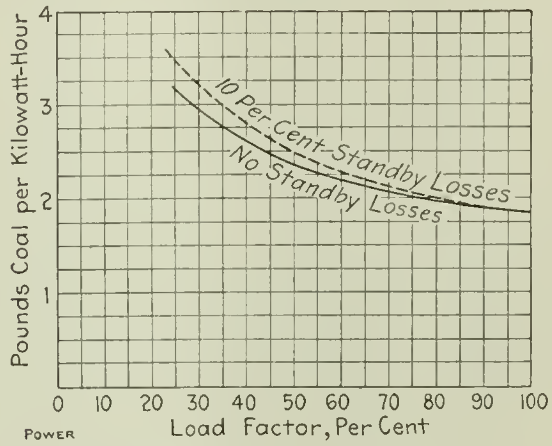

Fig. 6. Effect of Load Factor on Coal Consumption of Four-unit Gas-engine Plant

in the main engine. This percentage would be practically correct where a turbine of 500 kilowatts capacity may be used, and obviously smaller and greater, respectively, for corresponding sizes of turbines.

There is an equal amount of heat available in the jacket at a lower temperature head, and with consequently less potential energy above the condenser pressure.

The problem of utilizing this low-tension steam and obtaining it conveniently from the jacket water is not a difficult one. It is entirely feasible to extract the heat from the jacket water in the form of steam by circulating the discharge through a vessel in which a pressure is maintained lower than the steam tension corresponding to final jacket-water temperatures. The water, in passing through the low-temperature boiler, will be partly evaporated until the whole body is chilled to the low temperature. There would even be a tendency for this action to take place violently in the boiler. This can be obviated by a proper design in which the water passing through is divided into sheets, or sprays, so that steam may be released with the minimum amount of resistance.

In ordinary practice, the jacket- and piston-water temperature averages about 150 degrees. Allowing a working range of 20 degrees for the jacket water, secondary steam may be supplied to the final turbine stages or rows, at 130 degrees. Between 130 degrees (4½ pounds absolute) and 102 degrees (28 inches vacuum), the ideal water rate is approximately 50 pounds, and with a Rankine cycle efficiency of practically 65 per cent. in the lower last row of blades, the actual water rate becomes 77 pounds per brake horsepower-hour. With 33 per cent. of the heat being absorbed by the jackets, 3300 B.t.u. become available when the engine is at full load; 1018.7 B.t.u. are required to evaporate one pound of steam from and at 130 degrees and hence $\frac{3300}{1018.7} = 3.24$ pounds of steam available per engine brake horsepower-hour at 4½ pounds absolute pressure. This is then equivalent to producing $\frac{3.24}{77} = 4.21$ per

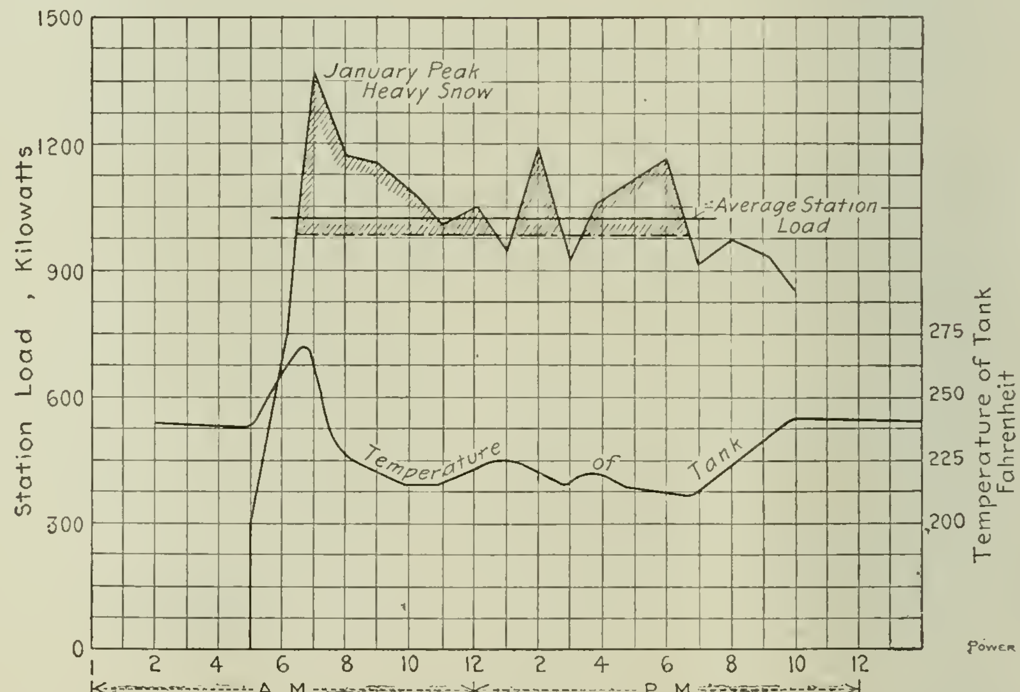

Fig. 7. Load Curve of Interurban Railway System. Jacket and Exhaust Heat Utilized

cent.* of the gas-engine output, which, added to the power from the exhaust heat, amounts to 12.75 per cent. In the smaller plants, this may not be greater than 11.75 per cent. Evidently these quantities represent the gross gain by

*Temperatures of 150 degrees Fahrenheit have been considered for the jacket and piston water. Should the temperature be raised to 200 degrees Fahrenheit as found in some foreign plants, the power that may be developed from the jacket heat would be doubled. The advantage will probably inspire this practice.

the operation of a low-pressure turbine; and to determine the net benefit that may be obtained, the power consumption of the auxiliary condenser and pumps must be deducted. As a close approximation, it may be assumed to be 1 per cent. for every 6 pounds of steam consumption of the main unit; in other words, 2½ per

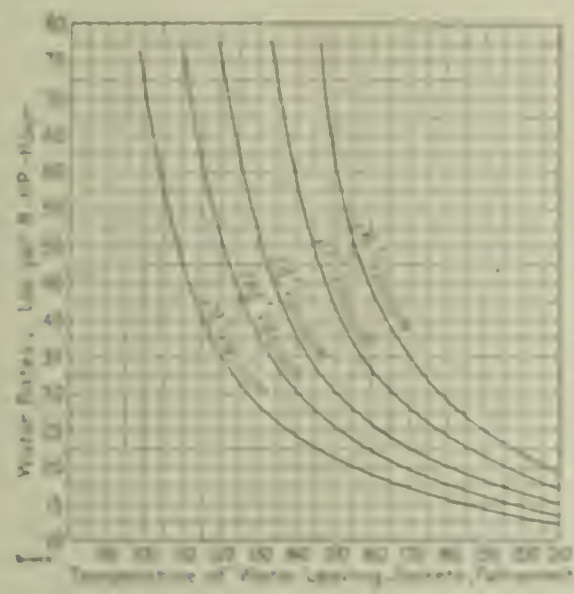

FIG. 8. IDEAL WATER RATES

cent. for 15 pounds steam consumption per brake horsepower-hour, 5 per cent. for 30 pounds, 12½ per cent. for 75 pounds, etc.

Furthermore, a small allowance must be included for radiation and friction, say 2 per cent. The following establishes a fair estimate of the true improvement:

$$8.54 \times (1 - 0.04) \times 0.98 = 8.04\%$$
$$4.21 \times (1 - 0.1283) \times 0.98 = 3.595\%$$
$$11.635\%$$

The smaller plant would, in proportion, be about 10.5 per cent. The coal consumption of the plant would be lowered 10½ to 11½ per cent. by the installation of the low-pressure turbine using both exhaust and jacket water. If operating only on exhaust heat, the reduction would be but 7 to 7½ per cent.

For the purpose of designation, the steam obtained from the exhaust-gas heat, being predominant in available energy, may be correctly termed the "primary" steam, and that obtained from jackets the "secondary" steam. While the percentages expressed above were for full-load conditions, they may be safely applied, to an extent, to fractional loads, it being noted that the engine declines in efficiency at somewhat greater rate than the turbine and auxiliaries, and thus a fairly uniform percentage should obtain over a wide range in load.

In addition to the saving above shown, the sensible heat of the gas leaving the producer may be absorbed in an economizer placed between the producer and the scrubber, and the steam thus generated consumed in the low-pressure turbine. This item has been neglected, however, as it represents but a small percentage of the heat which may be conserved, and as a producer with an integral vaporizer has been considered, this extra apparatus seems unwarranted.

Some brief data on turbines and exhaust boilers may be appropriate for reference.

DISTRIBUTION OF HEAT AT AVERAGE LOAD

The characteristic performance of the gas engine is exemplified in the Norton tests which form a part of volume No. 29 of the American Society of Mechanical Engineers *Proceedings*. Based on brake-horsepower output, the items divide as follows:

Useful work	24.86
Electrical losses	[illegible]
Friction and pump work	4.38
Jacket absorption	34.22
Exhaust and radiation* (by balance)	36.54
Loss in producer	[illegible]

TURBINES

Results of series of tests under conditions of varying vacuum, conducted two years ago on one of the first double-flow, reaction, low-pressure turbines, are presented in Fig. 9. While it is to be understood that they are not typical of the improved economies secured with later designs, they are very complete and are to be found instructive in this study.

The efficiency obtained then was 65 per cent. on a 2000-brake horsepower turbine. A like efficiency is probable in a turbine such as that discussed in this paper.

In some research work undertaken by The Westinghouse Machine Company, a low-pressure turbine designed for an initial pressure of 2½ pounds absolute and 1 pound absolute back pressure produced the results plotted in Fig. 10. The experience that was gained from the operation of this very small machine justifies the assumptions made above for the large units, which would also benefit from more recent knowledge of the requirements.

EXHAUST BOILER

A countercurrent, cast-iron exhaust boiler under test exhibited the amount of steam that could be practically generated from the engine exhaust. Fig. 11 shows that, regardless of rating, 30 per cent. of the heat input to the engine may be converted into steam.

It is important that the exhaust heater be placed close to the engines to reduce the length of the exhaust piping and consequently the radiating surface. As it is impracticable to lag the exhaust piping with nonconducting material owing to the heating and trouble at the engine that would result, it becomes desirable to water-jacket this piping, either as shown in Figs. 1 and 2, with special cast pipe or perhaps with a less expensive method of small coils wrapped around the pipe. The primary steam mains pass through the exhaust header, which secures a small superheating effect.

LOW-TEMPERATURE BOILER

Recovering heat from the jacket water in the form of steam is almost ideally accomplished. The apparatus consists merely of an elevated cylinder, shown in Fig. 2, through which the jacket water is allowed to flow. Water entering the drum or cylinder will be approximately at the temperature at which it leaves the engine jackets. It is thus only necessary that a pressure be maintained in the chamber corresponding to the temperature of the water leaving the boiler, and that the water travel at a sufficiently low rate to

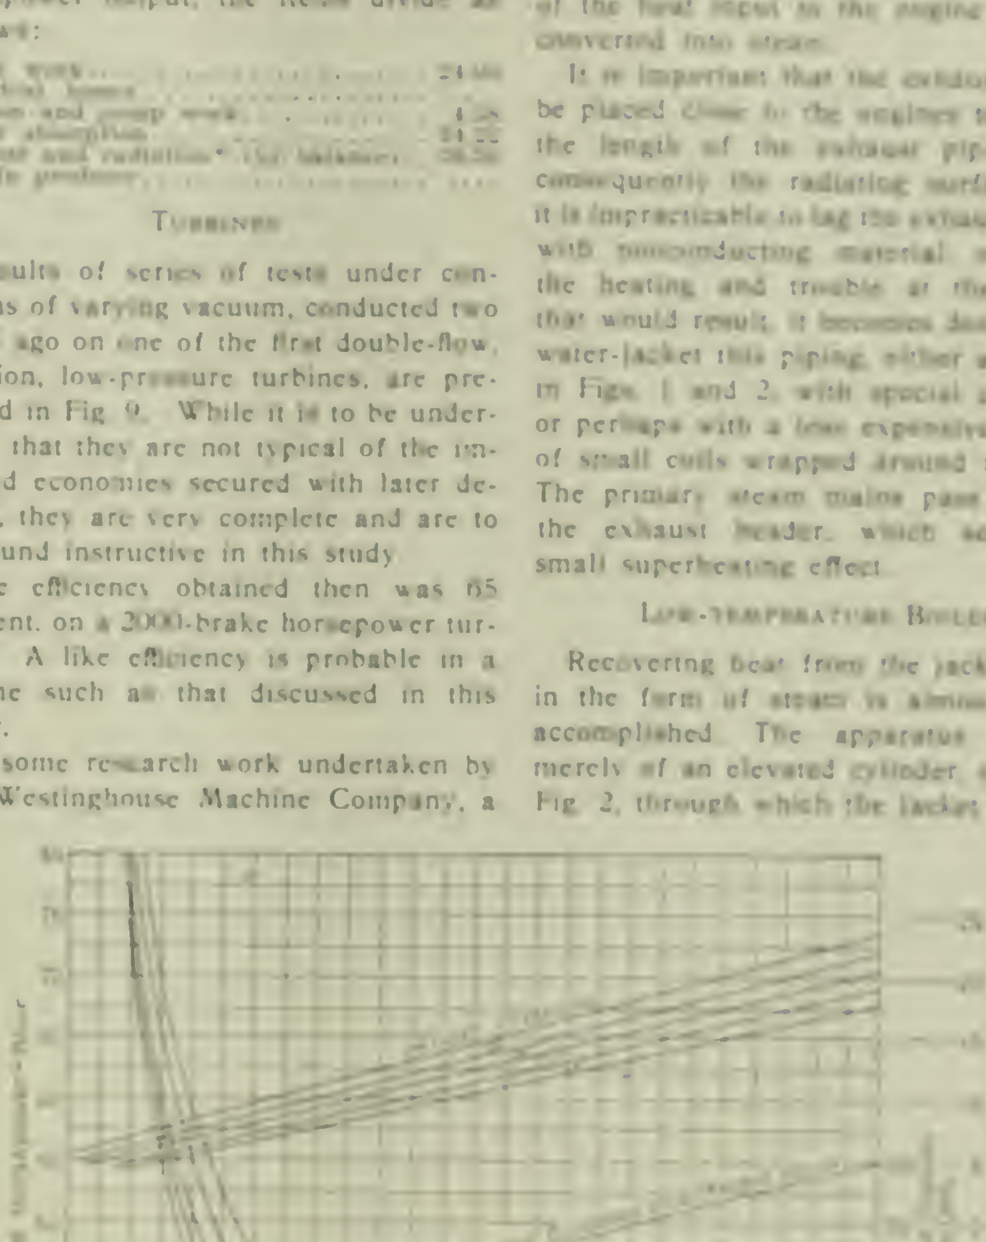

FIG. 9. RESULTS OF ECONOMY TEST OF 2000 BRAKE HORSEPOWER LOW-PRESSURE TURBINE

*Radiation, which is included with the exhaust by balance, should be credited the remaining the available heat for economy.

allow proper disengagement of the steam. The boiler is elevated to avoid operating the jackets and water lines under vacuum and to prevent the formation of steam pockets which otherwise would be liable to be injurious to the cylinders. Regardless of the fact that all the heat is transferred from the jacket to the steam, the boiler cannot be considered 100 per cent. efficient. To effect the interchange, the temperature must be lowered, which reduces the available energy in the steam. Thus its efficiency may be only from 60 to 80 per cent.

Storage Tanks and Insulation

Guide or baffle plates may be used in the tank to facilitate circulation, which will manifestly depend upon the rate at which the energy may be withdrawn from the tank.

Owing to the large tanks that are essential, it is advisable to maintain the working temperature and pressure above atmosphere. This obviates the expense of providing tanks to resist the collapsing tendency under a vacuum and prevents air leakage. On the other hand, while it is desirable to have as high a temperature elevation as practical to confine the heat storage to a small body of water, there are obviously natural limitations in the exhaust heater. Present calculations show that from 45 pounds absolute (274 degrees) to 15 pounds absolute (a range of about 64 degrees Fahrenheit) best suits the conditions. The amount of water necessary to absorb the heat available from the gas engine is a definite quantity, depending upon the temperature range worked through and the time during which the heat is supplied; in other words, the hours of engine operation preceding the peak load.

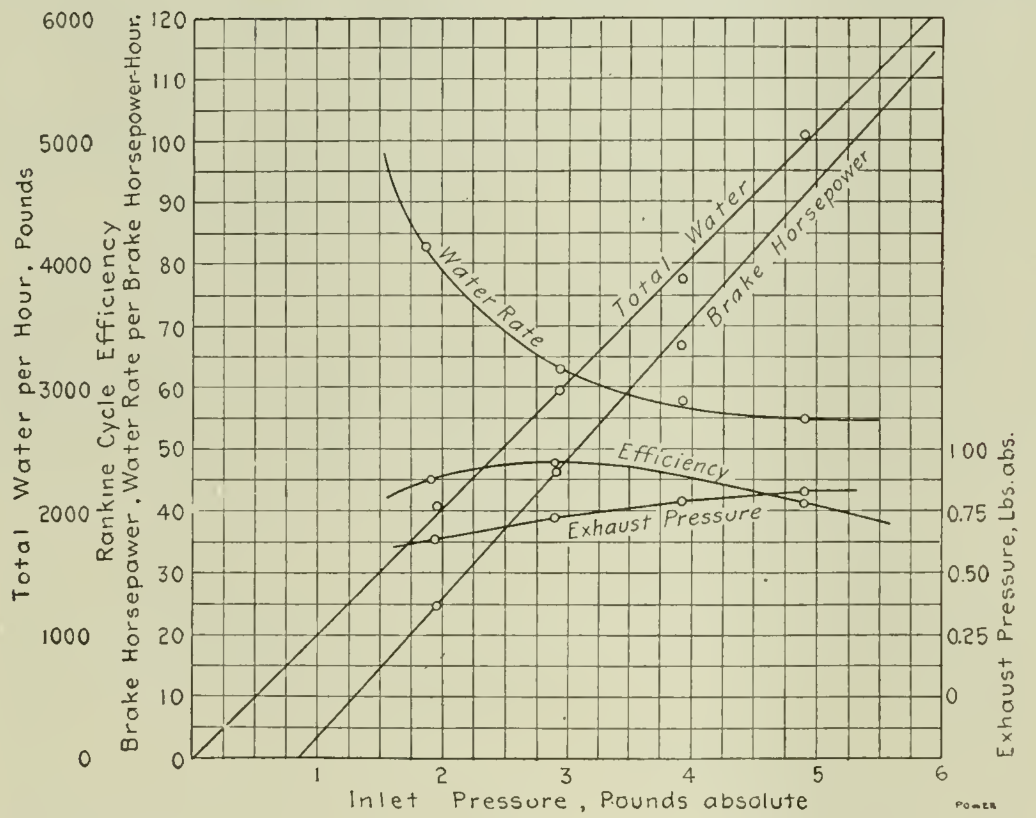

Fig. 10. Results from Test of 20-horsepower Low-pressure Steam Turbine

The curves, Fig. 3, have all been plotted on the basis of 64 degrees Fahrenheit temperature drop, and it therefore follows that the curves of constant period of engine operation preceding the peaks are also lines of constant tank volume. Thus for a period of four hours engine operation at full load previous to the peak, 2.5 cubic feet per kilowatt of gas-engine capacity are necessary; for 6 hours, 3.75 cubic feet; 8 hours, 5 cubic feet, etc. For a 2000-kilowatt plant, this corresponds to a tank volume of 5000 cubic feet. If the peak is to last three-quarters of an hour after four hours storage, 840 kilowatts, or 42 per cent. of 2000 kilowatts, are available from the low-pressure turbine. Proportioning the tank allows considerable latitude. The area of the surface of the water, or disengagement of the steam, may be determined by employing a disengaging velocity of the steam varying from 1½ to 5 feet per second. Thus the dimensions of the tank may be accommodated in a large measure to the plant layout. The tank should be equipped with burners or grates and fire tubes, at relatively low cost, such that a byproduct plant could be made self-contained in an emergency.

Losses from radiation and conduction may be made very small items. Low temperatures are used, and consequently the rate of transfer, depending upon the temperature difference, will be correspondingly low.

Radiation loss from the heat-storage system is an extremely low percentage of the low-pressure power available. Authorities on the subject of "Conduction and Transmission of Heat" differ somewhat in opinion as to the rate of heat dissipation from cast-iron and sheet-steel surfaces; 2.5 B.t.u. per hour per degree difference in temperature per square foot of bare surface is about the accepted average.* With 85 per cent. covering efficiency, the actual loss per square foot is 0.375, or ⅜ of a B.t.u. With approximately 180 degrees average temperature difference, the hourly loss per square foot would be 67.5 B.t.u. As 37,500 B.t.u. are, roughly, required to develop a kilowatt-hour in a low-pressure turbine,

$$37{,}500 \div 67.5 = 556$$

square feet of exposed surface would

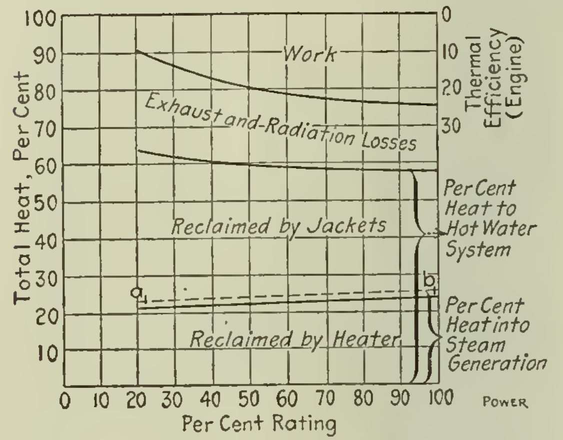

Fig. 11. Heat Balance from Test of 200-horsepower Gas Engine and Heater with 134 Square Feet of Heating Surface

represent a loss of one kilowatt in an hour. In case of the 2000-kilowatt plant results, a tank 15 feet in hight and 28 feet in length, would be required, providing 20 per cent. steam space. Together with the connecting pipe, the radiating area would be in the neighborhood of 2500 square feet and the loss per hour would be

$$2500 \div 556 = 4.5$$

kilowatts. For four hours operation preceding the one-half hour peak of 840 kilowatt,

$$4.5 \times 4 = 18$$

kilowatts would be lost. This amounts to only $\frac{18}{840}$, 2.15 per cent. of the power required. These radiation losses have been more than conservatively covered in the accompanying results.

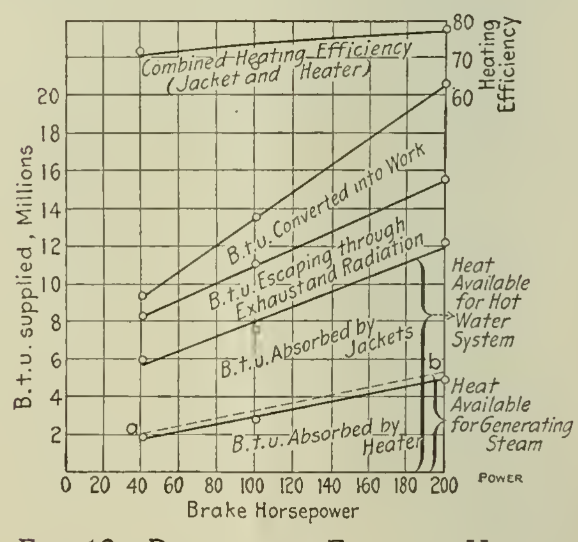

Fig. 12. Results of Exhaust Heater Test

Addendum on Heating Systems

The utilization of gas-engine waste heat was attempted very soon after the gas engine assumed commercial importance, over twenty-five years ago, effort

*Steam-heating engineers use a lower value.

being applied to divert as much of this heat for steaming and industrial purposes as possible.

The amount of heat to be obtained in the form of steam or hot water is given in Figs. 11 and 12. Two facts have operated against a more general adoption of gas-engine waste-heat systems. First, the steel boilers that were employed at the outset were very seriously corroded by the sulphurous-acid gas and the moisture present at the low temperatures. The introduction of cast-iron heaters should revive the use of waste gases. Only 1½ per cent. of the jacket water* may be evaporated by the exhaust heat, and the use of the jacket water in a hot-water system involves several disadvantages, and more complicated and costly installation. Secondly, where the ratio of heating requirements to the power demanded in isolated industries or buildings is large, the noncondensing steam motor is obviously superior. Probably in a southern latitude, or where the power consumption is large in comparison with the heating to be done, sufficient heat may be obtained from the gas engine.

ACKNOWLEDGMENTS

The author is indebted to the Westinghouse Machine Company for permission to use these data, and to A. T. Kasley for fruitful suggestions in the arrangement of details of the installation.

*Equal to 16½ pounds jacket water per brake horsepower hour.

Safety Valves and Their Application

By John S. Leese

The limitations and uses of the different types of safety valves and the necessary computations for setting one of the ball and lever type.

All steam boilers should be fitted with two safety valves, one of these valves to blow off for high steam pressure, and the other for both high steam pressure and low water. The former is generally of the dead-weight or direct spring-loaded type. Where springs and weighted levers are used, the lever and the weight should be such that the valve will open at blowing-off pressure when the weight is at the extreme end of the lever. This prevents overloading, due to slipping of the weight, although unscrupulous attendants may adopt the dangerous and often criminal practice of hanging more weights on the lever. There are other points to be noted in connection with the choice of a lever-type safety valve; for instance, if guide forks are fitted to the lever, they must be open at the top so that the lever cannot become wedged; also, iron to iron contact should not be permitted for the lever pins on account of rust. If the valve is of the closed type the "iron to iron" remark applies also to the valve spindle passing through the cover. Dead-weight valves are not permissible on marine, portable or locomotive boilers, owing to the vibration and swaying, but the direct spring-loaded type is not affected in this way.

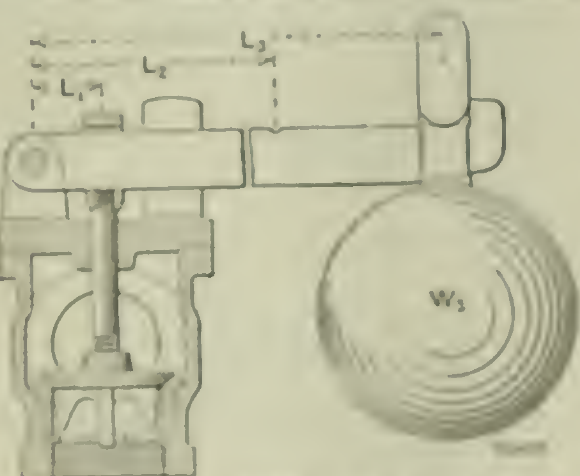
The second safety valve is often connected to a float in such a way that it will open when the water sinks to a certain level; this type is known as the "low-water safety valve." Preferably it should open for high steam pressure as well.

On many portable boilers, especially those that have been in service for many years, lever safety valves, loaded by spring balances, are used. It should be made impossible to lock these by screwing up the thumb nut on the balance, as an unskilled attendant may ignorantly cause disastrous results. The readings on the spring-balance scale should indicate "pounds per square inch" by a suitable proportioning of the valve area and the length of the lever to the pressures. Neglect of these precautions has led to many explosions, owing to the attendant being ignorant of the existing pressure.

Where the use of dead-weight safety valves is prohibited, there appears to be no reason why direct spring-loaded valves should not be used. They are much preferable to the lever-spring-balance type.

Safety valves should never have a diameter less than two inches, the relation of diameter to lift being a much debated point. In the writer's opinion neither extreme, that is, high lift and small diameter or small lift and large diameter, is desirable, but rather a mean might be reached between the two.

In many cases the valve is so formed



BALL AND LEVER SAFETY VALVE

that the reaction of the steam blowing through it increases the lift, thus insuring the full area of opening. The use of a lifting gear arranged so that the safety valves may be operated by hand from the floor of the engine or boiler room, may be decidedly advantageous in cases of emergency.

Referring to the sketch, let

W_1 = Weight of valve;

W_2 = Weight of lever;

W_3 = Weight on end of lever;

L_1 = Distance from fulcrum pin to center of valve;

L_2 = Distance from fulcrum pin to center of gravity of the lever;

L_3 = Distance from fulcrum pin to center of weight;

A = Area of safety valve, in square inches;

P = Steam pressure at which valve will blow off, in pounds per square inch.

Then,

$$P \times A \times L_1 = W_1 \times L_1 + W_2 \times L_2 + W_3 \times L_3$$

and,

$$P = \frac{W_1 \times L_1 + W_2 \times L_2 + W_3 \times L_3}{A \times L_1}$$

The miter of a safety valve should not exceed one inch.

Electrical Engineering Exhibition

The third triennial exhibition of electrical engineering and machinery is to be held at Olympia, London, this year, from September 23 to October 21. It is to be international in character and is a manufacturers' exhibition, promoted by the large electrical manufacturers of England, through their association, the National Electrical Manufacturers' Association. All the exhibiting firms will participate in the profits, if any, arising from the exhibition, although their liability is limited to their space rental, which is advertised not to be in excess of those of any similar exhibition.

The forthcoming exhibition, it is stated, will be the largest event of the kind which has ever been held in England, and perhaps in any other country. The fact that this event will take place in the coronation year, it is urged, is also strongly in its favor, as there will be a large number of colonial buyers visiting in London, who will embrace the opportunity of visiting such an important undertaking, in which many of them will be keenly interested.

It is suggested that if any manufacturers of the United States contemplate participating in this exhibition, it is important that they make inquiry early as to space, because a large percentage of the ground floor and a very large proportion of the galleries have already been engaged.—*Daily Consular and Trade Reports.*

Friction Clutches and Their Use

By H. A. Jahnke

Reasons why the use of clutch pulleys and cutoff couplings makes for economy. Suggestions in regard to the selection of suitable clutches. General description of some clutches of well known make.

In most manufacturing plants changes and improvements are constantly being made in the machinery for the sake of effecting greater economy. But, strangely enough, in many plants, although they are equipped with modern machinery, there exist inefficient means of stopping and starting line and countershafting. Aside from the independent, electric-motor drive, there is nothing better for this purpose than the friction clutch. The use of clutches permits the shafting to be so divided that it is only necessary to run the machinery, countershaft and line shaft which are actually in use. Thus a machine, countershaft, line shaft or whole department may be shut down without interfering in any way with other departments or equipment. This results in a saving of power and time and should be appreciated by every engineer and

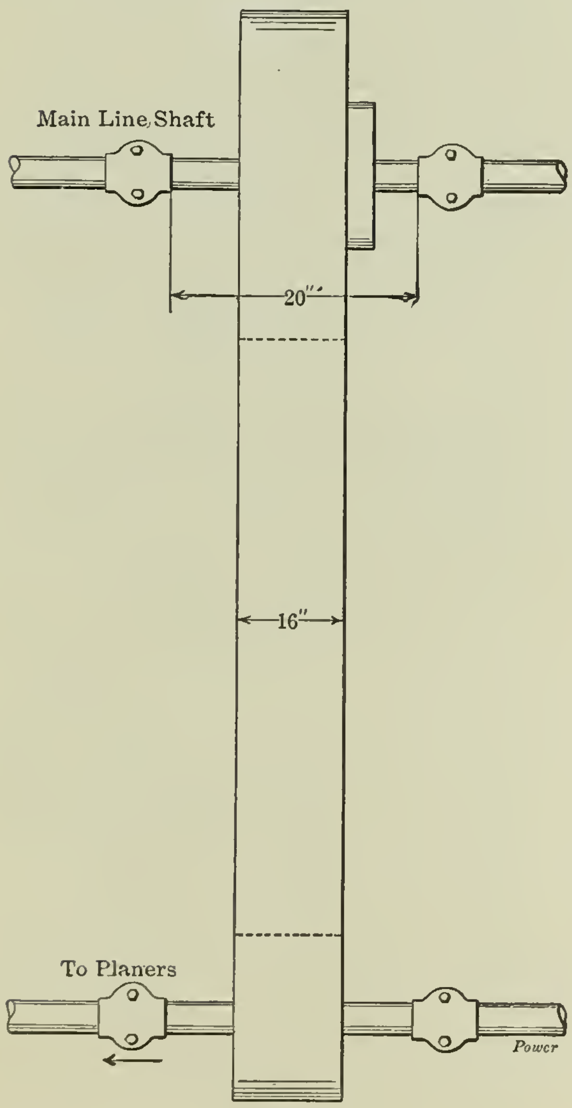


Fig. 1. Use of Friction Clutch to Economize Space

power-plant owner who perhaps has seen a whole plant shut down, the men standing idle and production stopped, all due to the breaking of a belt, rope or pulley. Where friction clutches are in use this trouble can be overcome. Of course, to equip a whole power-transmission system with friction clutches is quite expensive, but it should prove to be cheaper and more efficient, in the long run, than the use of tight and loose pulleys. With friction clutches, the loads may be picked up slowly while the driving shaft is running at full speed. Further, clutches act as safety devices and eliminate strains upon machinery and belting. The slippage in starting and stopping is taken up by the clutch instead of the belt.

If it is desired to place friction clutches in line of shafting so as to make parts of the shaft independent units, this can easily be done by removing shaft couplings at convenient points and in their place putting friction-clutch cutoff couplings. By the use of a split type of friction-clutch cutoff coupling such a change can be made without much expense or trouble.

A large percentage of the unnecessary cost of running line shafts and countershafts can be saved by arranging the shafting and machinery so that parts can be stopped by means of friction clutches when not in use.

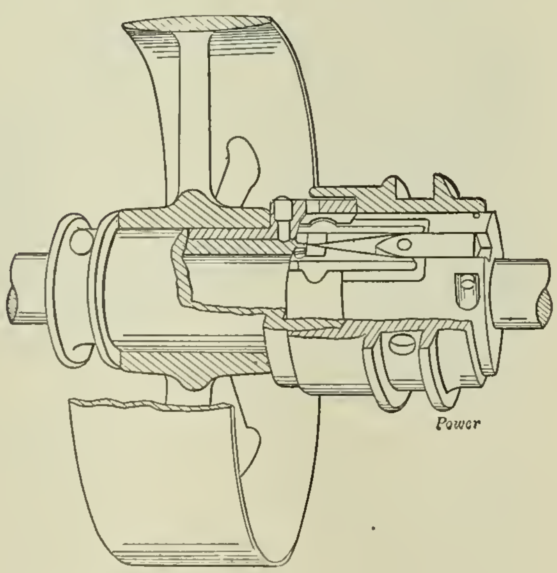

Fig. 2. Johnson Clutch, Engaged

Often, slight changes in transmission conditions save a great loss of time. Take, for example, the following case of a machine which is driven direct from the line shaft by means of a 4-inch belt. In order to start or stop this machine the belt has to be shifted from tight to loose pulley or *vice versa*. Should the belt tear or need tightening during the time when the machine is in operation, the line shaft has to be stopped before adjustment can be made. Often, this results in shutting down other departments. This would not be the case if there was a friction clutch on the line shaft; all that would be necessary would be to disengage the clutch and any repairs could be made without interfering with other parts of the transmission equipment. Friction clutches save wear and tear on the belts. With a tight- and loose-pulley arrangement, when the belt is shifted from one to the other, the stress in the edge of the belt is considerable. This results in the burning of the belt and the opening of the laps at the edges.

In a certain plant, a line shaft, used for driving planers, had been driven for many years by a 10-inch double leather

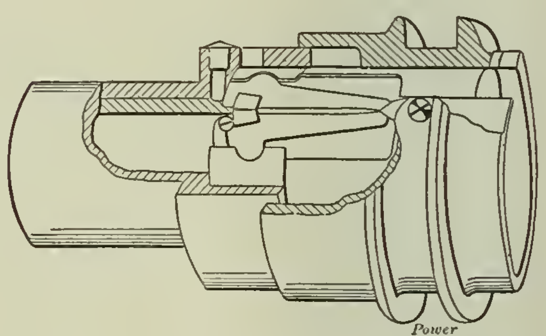

Fig. 3. Johnson Clutch Disengaged

belt from the main line shaft. The planer line shaft was arranged with a tight and loose pulley to permit the stopping of this shaft during the noon hour and at night when machinery in other parts of the factory was worked overtime. A few years ago it became necessary to install a larger belt to drive the planer line shaft, due to the installation of more machinery. A 16-inch belt was necessary. Had it been necessary to use the tight- and loose-pulley system with the larger belt, considerable work would have been required, for the new pulleys would have required 32 inches and this would have necessitated the shifting of the bearings. By the use of a clutch, however, this was obviated, as shown in Fig. 1.

For economy of space and convenience in subdividing transmission systems into separate parts, any of which may be taken out of service without disturbing the others, friction clutches find extensive use. It may be well, therefore, to consider the design and operation of some clutches in general use.

Clutches may be divided into two general types, the ring type and the disk type. In the former, the friction surfaces bear on a ring which is concentric with the shaft. In the latter, the surfaces bear on a disk which is normal to the shaft.

In most clutches one contact surface

is composed of wood while the other is made of cast iron. The advantages consequent to the use of these materials are: High coefficient of friction; uniform contact due to the wearing of the wood shoes; low cost of renewing wood shoes; negligible amount of wear of cast iron in contact with the wooden sur-

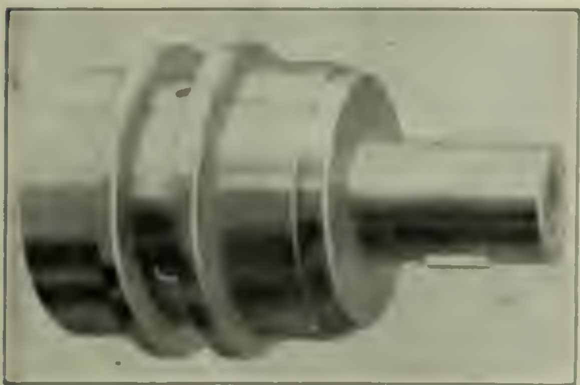

FIG. 4. EXTERIOR VIEW OF JOHNSON CLUTCH

faces; the fact that wood can be used without lubrication, and freedom from danger of the surfaces seizing.

In purchasing a friction clutch great care should be taken to select the right size of clutch to transmit a given horsepower and due consideration should be given to the character of the work which is to be performed. Especially is this so if the clutch is to be used in connection with an electric motor. Where the motor is capable of carrying perhaps 50 per cent. or more overload that clutch should be selected which has a horsepower rating at least 50 per cent. in excess of that of the motor.

A clutch which is frequently thrown in and out will be subjected to more wear and tear than a clutch which is operated infrequently. A clutch will carry a uniform load more easily than a variable load. Greater satisfaction will be secured if a clutch is selected with a capacity in excess of the work required of it. Overloaded clutches are the source of much of the difficulty that users of friction clutches usually experience.

In placing a friction clutch on a line shaft it is advisable to put it as close to a bearing as is possible, because when the clutch is thrown in there is a heavy strain on the shaft. Friction-clutch pulley service, with its frequent stopping and starting, picking up and dropping a full load, is very hard on pulleys and it is advisable to use a substantial pulley for this service.

A friction clutch must receive good care if it is to do its work right. The bearings should be well lubricated and all friction surfaces kept free from dirt, oil and grease. Never allow a clutch to slip, for, ultimately, slipping will ruin a clutch.

THE JOHNSON CLUTCH

Figs. 2, 3, 4, 5 and 6 show the Johnson clutch. This clutch has few parts and is very compact. A body fastened to the shaft carries a split ring in which are inserted a pair of levers. A curved-shaped wedge which is made a part of the slipper sleeve, forces the levers apart, extending the ring and thus bringing its outer surface into frictional contact with the inner surface of the friction cup, the hub of which is made to suit requirements. The leverage is so compounded that it requires but slight pressure to operate the clutch.

This type of clutch is used in many plants in place of a countershaft for driving machines direct from the line shaft, as shown in Fig. 5, as they operate smoothly at any speed without bang or clatter and have no projections to catch anything. By using the double clutch, Fig. 5, on a countershaft with two pulleys, one carrying an open belt and the other a crossed belt, the machine can be run either in the forward or in the reverse direction. This form of clutch is especially convenient for running machines which require a reverse motion.

To adjust this clutch, all that is necessary is to give a single screw a fraction of a turn, or more if necessary, to

FIG. 5. JOHNSON DOUBLE CLUTCH

the right or left. This screw can be reached through the hole in the friction cup. The Johnson clutch is manufactured by the Carlyle Johnson Machine Company, Manchester, Conn.

THE HILLIARD CLUTCH

Figs. 7 and 8 show the Hilliard clutch. In this clutch all toggle mechanisms have been avoided, as will be seen in the part sectional view, Fig. 7. Two friction plates are drawn against a friction ring, which contains a number of hardwood inserts, by means of screws operated by spiral gears which are turned by the spiral racks attached to the sliding collar. Ball thrust bearings are provided for the spiral gears so as to reduce the effort necessary to engage the clutch. It will be seen that as long as there is space between the hub, or body, of the clutch and the sliding collar, the clutch can always be thrown in tighter, and readjustment is not necessary until these parts come together.

This clutch is particularly valuable for controlling delicate machinery, especially

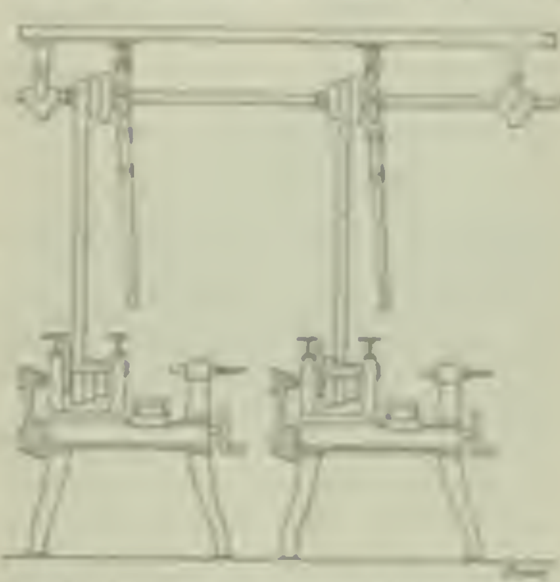

FIG. 6. DRIVING MACHINERY DIRECT FROM LINE SHAFT WITH JOHNSON CLUTCH

in textile mills where a sudden shock in starting may cause much damage, as the screws can be turned slowly, thus applying the friction gradually and picking up the load smoothly.

When the clutch needs adjustment this can be done by removing a nut which allows the sliding collar to be drawn out, taking the spiral racks out of mesh with the gears. By turning each gear the same number of teeth to the right the friction plates are drawn up the same amount on all sides. This clutch is especially free from bolts, nuts and fastenings and cannot easily get out of adjustment. The Hilliard Clutch and Machinery Company, Elmira, N. Y., manufactures this clutch.

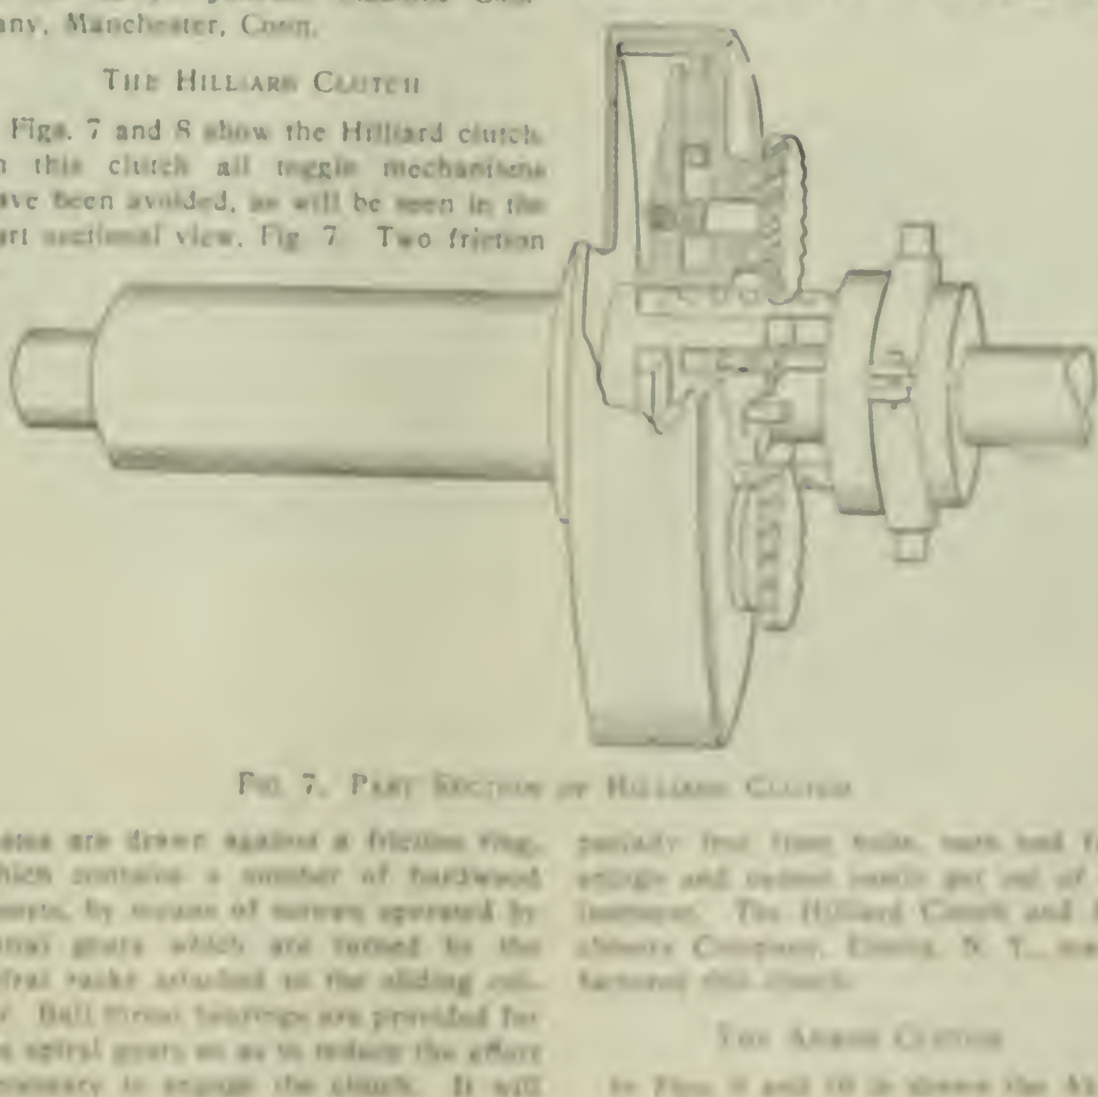

FIG. 7. PART SECTION OF HILLIARD CLUTCH

THE [illegible] CLUTCH

In Figs. 9 and 10 is shown the [illegible] clutch, which is of the disk type. The construction of the Akron clutch is extremely simple, as a little study of the sectional view in Fig. 9 will show. The

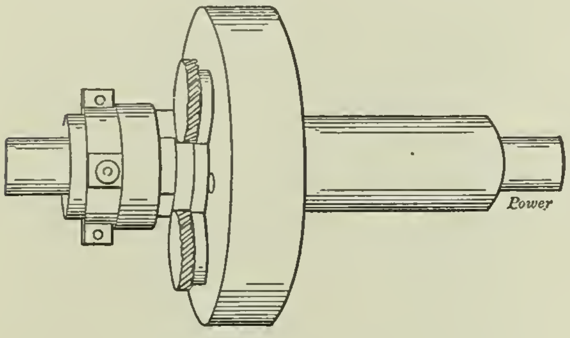

Fig. 8. Outline of Hilliard Clutch

drum *A* carries a hub or sleeve to which a pulley, gear or sprocket wheel may be keyed. The head *T* of the drum is separate. Within the drum are arranged two cast-iron friction plates *C* which the keys *H*, sunk into the fixed, or driving, member *B*, force to rotate with the shaft. The disks *C* are free to move laterally on the keys *H*. The clutch depends for its power-transmitting capacity upon the friction between the disks *C* and the corresponding friction surfaces of the drum *A* and

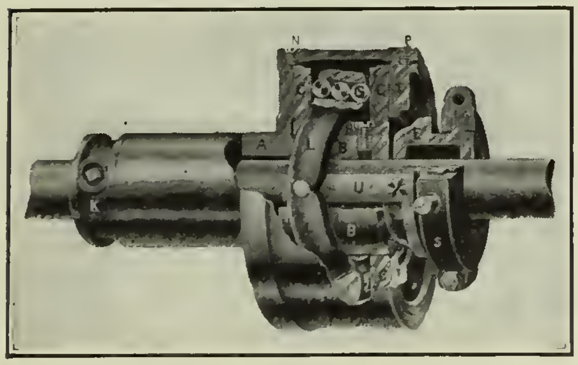

Fig. 9. Sectional View of the Akron Clutch Coupling

the cover *T*. The clutch is engaged by forcing apart the friction disks *C* into contact with the drum heads by means of the toggle mechanism, the latter being connected by steel links *U* to the sliding sleeve *E*. Regular shifter forks attached

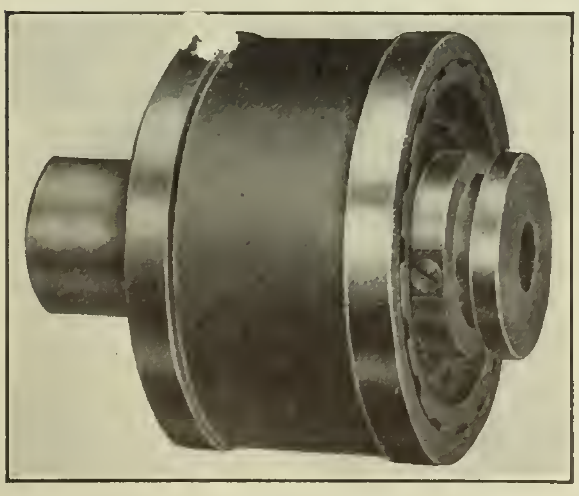

Fig. 10. Exterior of Akron Clutch Coupling

to the yoke *S* are used to disengage and engage the clutch. The roller toggle is a novel feature of this clutch; it consists of two forked liners *L* with chilled holes through them in which are lodged three hardened tool-steel rollers. When the levers *L* are perpendicular to the shaft, the center line of the three rollers is perpendicular to the faces of the friction disks, and the latter are pressed apart into contact with the friction surfaces. The design of the improved shifter ring *S* is such that the oil is retained while dust and dirt are excluded. The ring is made of cast iron and lined with babbitt.

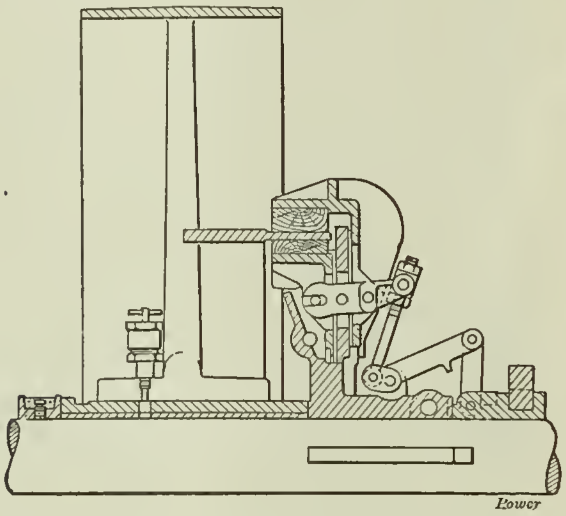

Fig. 11. Section of One-half of Hill "Smith Type" Clutch

The Akron clutch requires no attention other than the occasional renewal of oil in the case through the oil hole *N*. The cover *T* serves to retain the oil.

The clutch is adjusted by means of the head *T* which is screwed into the drum *A* and provided with notches in

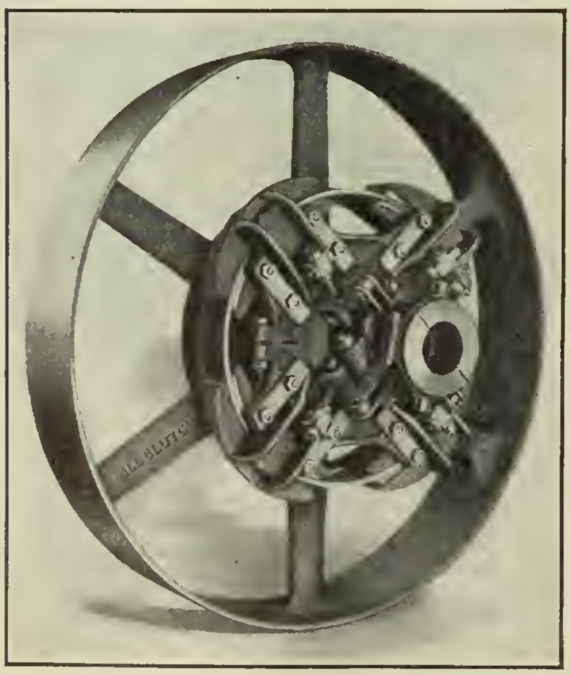

Fig. 12. Hill "Smith Type" Clutch

which the point of the locking screw *P* engages. The pitch of the screw and number of the notches are so proportioned that one adjustment of one notch corresponds to a lateral movement of 1/200 of an inch between the friction surfaces. The Akron clutch is made by the Williams Foundry and Machine Company at Akron, O.

The Hill "Smith Type" Clutch

The new Hill "Smith type" friction clutch is shown in Figs. 11 and 12. In this clutch the positive release feature is new, and eliminates the use of springs formerly used for disengaging the fric-

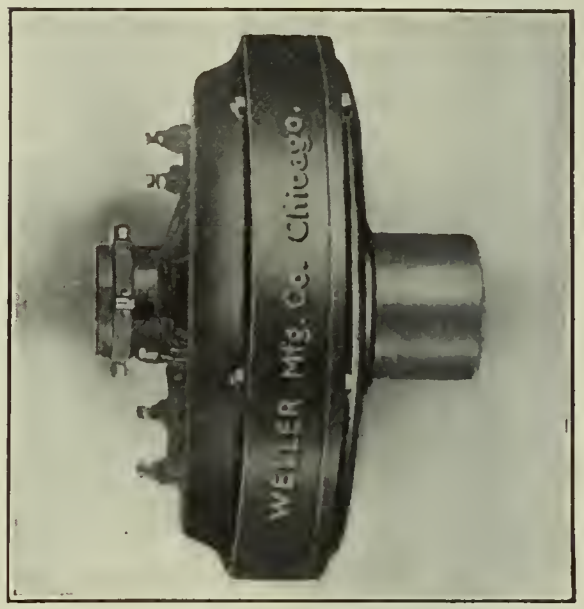

Fig. 13. The Weller Compound Clutch

tion jaws. As an examination of Fig. 11 will serve to show, the continuous toggle connection from the cone to the jaws positively releases the ring when the clutch

Fig. 14. Side View of Weller Compound Clutch

is thrown out. This new clutch is distinguished by improvements in the design which allow any working part to be removed parallel to the shaft from the

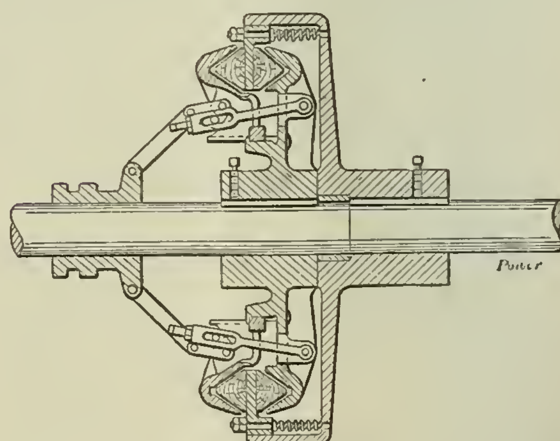

Fig. 15. Details of the Weller Clutch

mechanism side without removing the main spider casting. On account of the rigidity of the construction, the clutch is self-protective; if the clutch is loaded beyond the limit set by the jaw adjustment, slippage ensues instead of breakage.

This clutch is manufactured by the Hill Clutch Company, Cleveland, O.

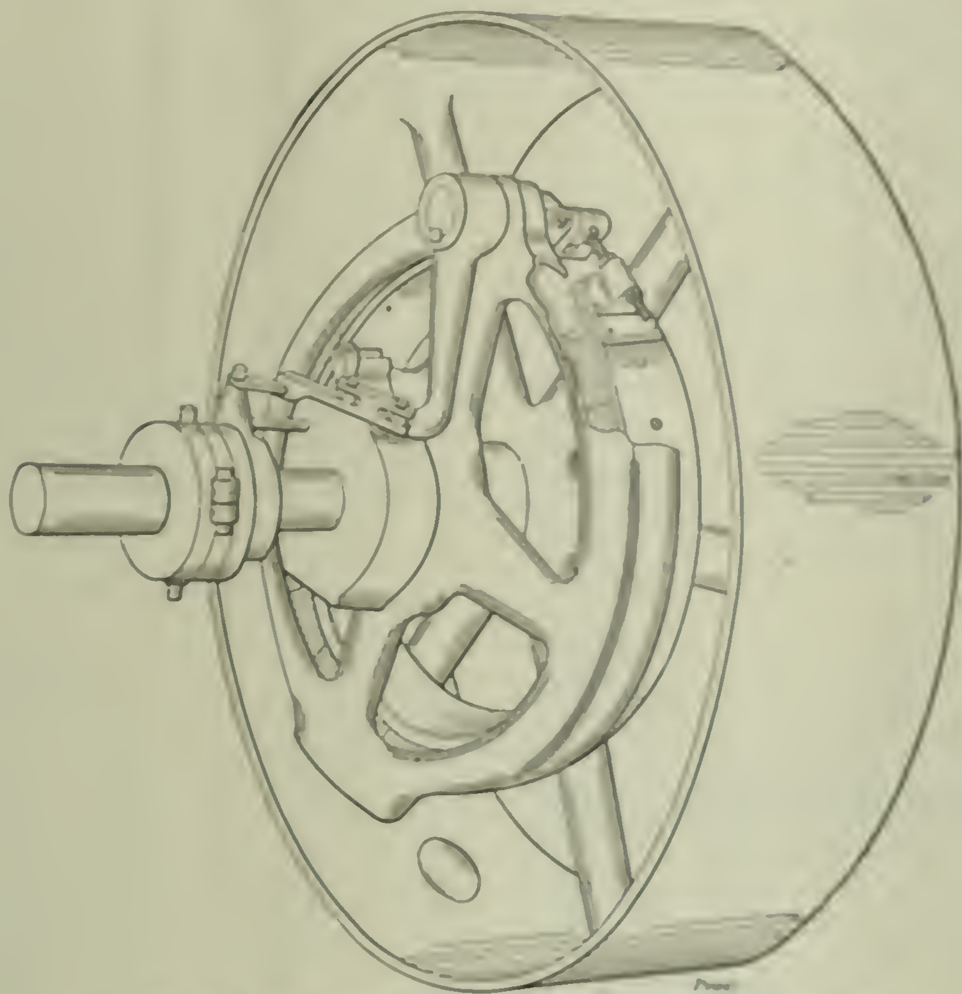

Fig. 16. Caldwell Clutch Attached to Pulley

The Weller Compound Clutch

Figs. 13, 14 and 15 show the Weller compound clutch, designed for high speeds and large powers. The clutch is made with two sets of wedge- or V-shaped wooden shoes extending around its entire circumference. When used as a cutoff coupling, the V-shaped construction of the wooden shoes and iron friction ring or grips which engage the latter helps to keep the shaft in line. The ring or plate to which the wooden shoes are attached is dovetailed into the drum of the clutch and acts as a universal joint when the shafts are out of alinement.

The Weller Manufacturing Company, Chicago, makes this clutch.

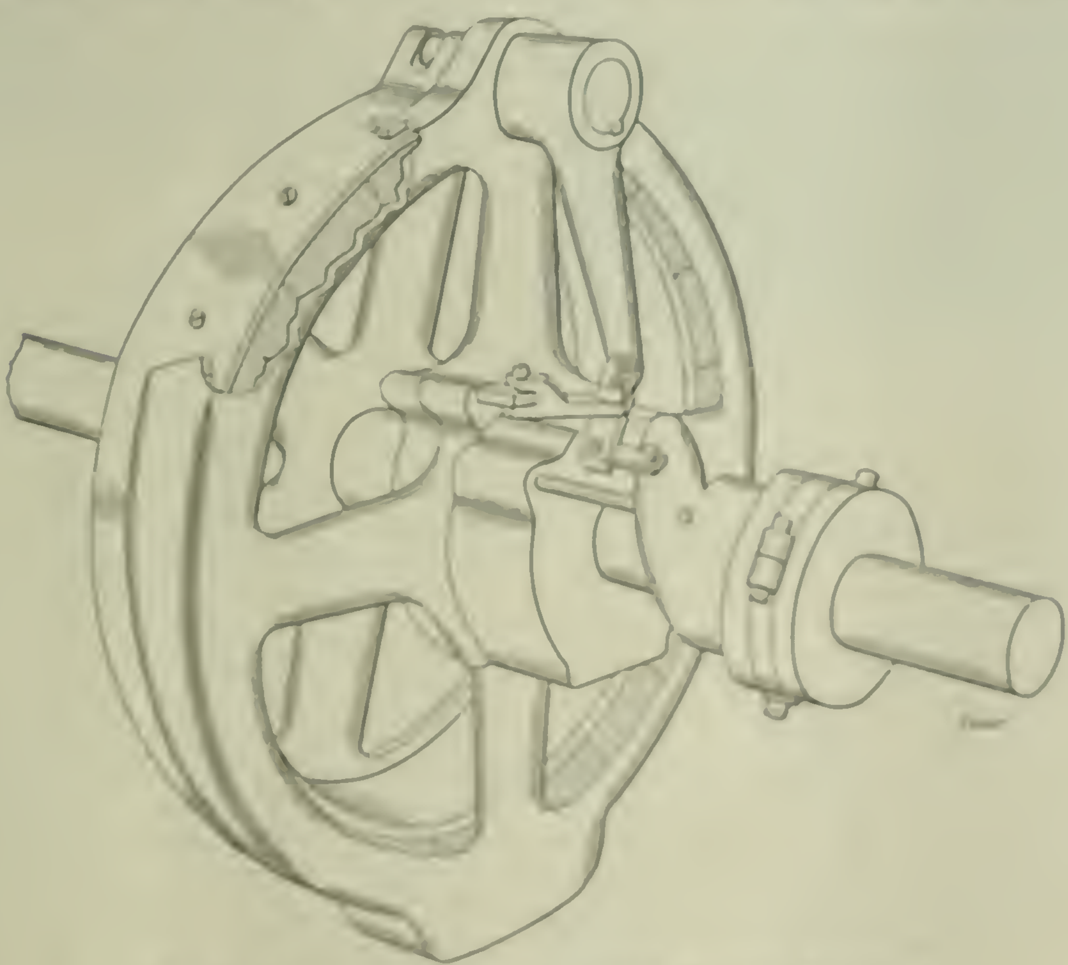

Fig. 17. Caldwell Friction Clutch Cutoff Coupling

The Caldwell Clutch

The Caldwell clutch, shown in Figs. 16 and 17, can be attached to a pulley or used as a friction-clutch coupling. The principal features of the Caldwell clutch are large friction surface, simplicity and small number of parts. A steel friction band is lined with hardwood friction blocks and when the clutch is engaged contact is obtained entirely around the friction surface, distributing the strains equally on all parts of the friction mechanism.

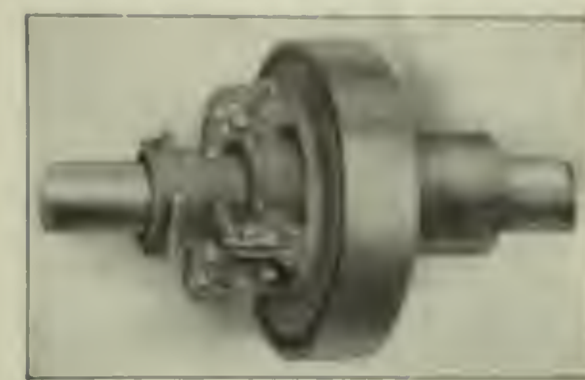

Fig. 18. Universal Giant Friction Clutch Cutoff Coupling

This clutch is manufactured by the W. E. Caldwell Company, Louisville, Ky.

The Universal Giant Clutch

Figs. 18 and 19 show the Universal Giant clutch. This clutch is of compact design, strongly built, easy to apply and readily adjusted. It is designed so that the outer rim covers and protects the friction disks from dust and dirt. The friction surfaces, which have a large area, are wood and iron. Selected hardwood blocks are fitted into the friction disk so as to present two end-grain surfaces which come in contact with the two iron surfaces of the friction plates when thrown into or out of engagement. The friction disk and follower plates adjust themselves with the clutch.

Fig. 19. Universal Giant Clutch Attached to Pulley

The Universal Giant clutch is made by the T. B. Wood's Sons Company, Chambersburg, Penn.

Other clutches will be described in an early issue.

Underground Pipe Covering

By Charles H. Herter

The modern tendency to distribute heat from central points makes it necessary to lay steam pipes underground more frequently than ever; consequently, information on this subject should be appreciated by those who are expected to do underground pipe work in an uptodate manner and at moderate cost.

The essential features of a successful underground conduit conveying steam, hot water, cold brine, ammonia, etc., are now recognized to be perfect insulation and protection. These can only be obtained when the outside of the pipe is always dry. The importance of dryness is only realized fully when it is remembered that the transmission of heat from a steam pipe to surrounding quiet air is from 2.1 to 2.8 B.t.u. per degree Fahrenheit temperature difference per square foot of pipe surface per hour and that proportionately greater losses result when the best possible conditions are not maintained.

Any type of wooden inclosure is subject to decay, sooner or later, and should, therefore, be avoided, for there is available now material which is proof against water, fire, acid and time. A conduit which has been used in many important installations within the past fifteen years is one which is specially prepared for underground service. It is made from stoneware and fireclay, passed through hydraulic presses, vitrified and glazed inside and out. This pipe in form is similar to ordinary bell and spigot sewer pipe, except that, after burning in the kiln, it is split into duplicate numbered halves, for which purpose two downward diagonal grooves are cut along the interior wall, leaving at least one-half of the thickness rough for cementing. Care is taken to cement the same halves together on the job as when mending a broken plate. The conduit comes in 3-foot lengths and in diameters ranging from 6 to 30 inches. There should always be a distance of not less than 3 inches between the wall of the conduit and the nearest steam pipe. One or more and different sized pipes can be inclosed in the same conduit.

About every 15 feet a special supporting tee with the branch set downward and inclosing pipe supports concreted in this base is provided. These supports are provided with rollers, permitting the pipes to expand and contract freely without imposing the least strain upon the conduit. Clamps with anchor bolts embedded in concrete in a blind pit or a manhole are used for anchoring the steam pipes at suitable points, especially where the direction or elevation of the line changes. Expansion is provided for by expansion joints, arranged in water-tight manholes at proper intervals. Where the line enters a building or a manhole, or inside building walls, a shutter is built of 4 inches of concrete on lattice work spread over the opening of the conduit to prevent the passage of vermin from one building to another, and to seal the conduit. Sleeves of suitable pipe covering about a foot long and wired with a waterproof jacket or of the next larger size pipe, are put on each pipe to act as a stuffing box allowing pipes to slide without injury.

For brine and ammonia pipes the conduit can be packed with fine, regranulated cork, say 8 pounds for each cubic foot of space filled. For steam, hot-water pipes, etc., H. W. Johns-Manville Asbesto-Sponge filling has proved to be very efficient, 7½ pounds being required per cubic foot. Its insulating value is exceptionally high and the material does not deteriorate under the heat and moisture met with in practice.

The approved method of laying this conduit is to dig a trench about 20 inches wider than the conduit and of proper depth and grade. As in any first-class work, it is essential to first of all lay an underdrain of sewer pipe in a narrow subtrench, the joints being laid open and not cemented. This underdrain, which is surrounded with broken stone, serves to lead away any water which might otherwise remain in contact with the conduit, absorbing heat much faster than dry material would. Connection to this underdrain can be made with the manhole pits, draining them of any drippings from valves or expansion joints. A clean gravel should ultimately extend up above the side joint of the conduit. Next, the lower halves of the various tile sections, unions and supporting tees, are assembled and cemented, and roll frames to carry the pipes concreted into bases of supporting tees. An opportunity is now presented to thoroughly test the whole pipe line for leaks, after which the upper halves of all conduit sections are cemented exactly in place, one by one, and packed with insulating material. Then the hub joints of the top halves are cemented up.

This type of conduit has been tested in the field by George H. Barrus and others, and found in the case of steam pipes to reduce the loss of heat to the extent of from 89 to over 94 per cent. of that suffered with bare dry pipe. Very few pipe coverings approach and retain this high insulating quality. The cost is little more than for wooden covering and much less than for a pipe tunnel.

Test of Zoelly Turbines

The accompanying table, taken from a recent issue of the *Zeitschrift für das Gesamte Turbinenwesen,* shows the results of a series of tests at different loads on four turbines of the Zoelly type, built by the firm of Escher, Wyss & Co., of Zurich. These turbines are extremely short and show especially good results.

Central Station Will Have to Show 'Em

No. 2, of Missouri, National Association of Stationary Engineers, St. Louis, is sending out to its members a very complete power-plant report blank. This is being done to encourage the engineers to keep a system of records.

The report is a four-page leaflet. On the first page, blank forms are to be filled which call for power-plant investment, total output, capacity of plant, cost per kilowatt-hour, total costs and credits for each month of the year, and other data of a leading character.

The second and third pages are devoted to daily, weekly and monthly costs, including fixed charges, wages, materials, repairs, service of plant, service outside of plant, lamps furnished and credit and bills under control. The fourth page is the daily log.

The report is one of the most completed of its kind that has come under our inspection, and if given the attention it deserves, the members will be better engineers and in addition they will have data that should forestall any encroachment of the central station.

Methods of Testing Boiler Steel

By Guy Wise

A description of the machine used in testing specimens of boiler plate with directions for preparing the test piece and conducting the test.

The formula for calculating the safe working pressure of a steam boiler is

$$\text{Safe working pressure} = \frac{\left(\begin{matrix}\text{Ultimate}\\\text{tensile}\\\text{strength}\end{matrix}\right) \times \left(\begin{matrix}\text{thickness}\\\text{of plate}\end{matrix}\right) \times \left(\begin{matrix}\text{efficiency}\\\text{of joint}\end{matrix}\right)}{\text{Radius of boiler} \times \text{factor of safety}}$$

Before this formula can be used, however, it is necessary to know what value to assign as the ultimate tensile strength of the plate.

It is almost universal practice for large users of steel plate to inspect and test all material bought, in order to make sure that it conforms to the specifications; also, this information, in connection with the results given by the material in actual service, is of great value in determining the requisites that are essential to good service so that these qualities may be specified and secured in future orders. Furthermore, it is common practice for the manufacturers of steel plate to make tests of samples of their entire output so as to know at all times the qualities of their product.

The machine generally used in this work is shown in Figs. 1 and 2. The specimen to be tested is represented by *A*, one end of which is held by the jaws in the upper or fixed head *B*, while the other end is similarly gripped in the lower or movable head *C*. The load is applied to the specimen by the downward movement of the head *C*, at the rate of about one inch per minute, trains of gears being used to drive the screws which draw the head downward. The load to which the specimen is subjected is sustained by the head *B* which, in turn, transfers it through the columns *D D* to the weighing table *E*. Inserted in the lugs on the lower side of the weighing table are hardened-steel pins which rest on the hardened-steel knife-edges of the main weighing levers *F*, which are fulcrumed on the base of the machine. The load is transmitted through the intermediate lever *J* to the graduated weighing beam *G* which carries the screw-driven poise *H*.

The specimens to be tested are sheared from the plate, trimmed to the overall size and then milled to the standard form

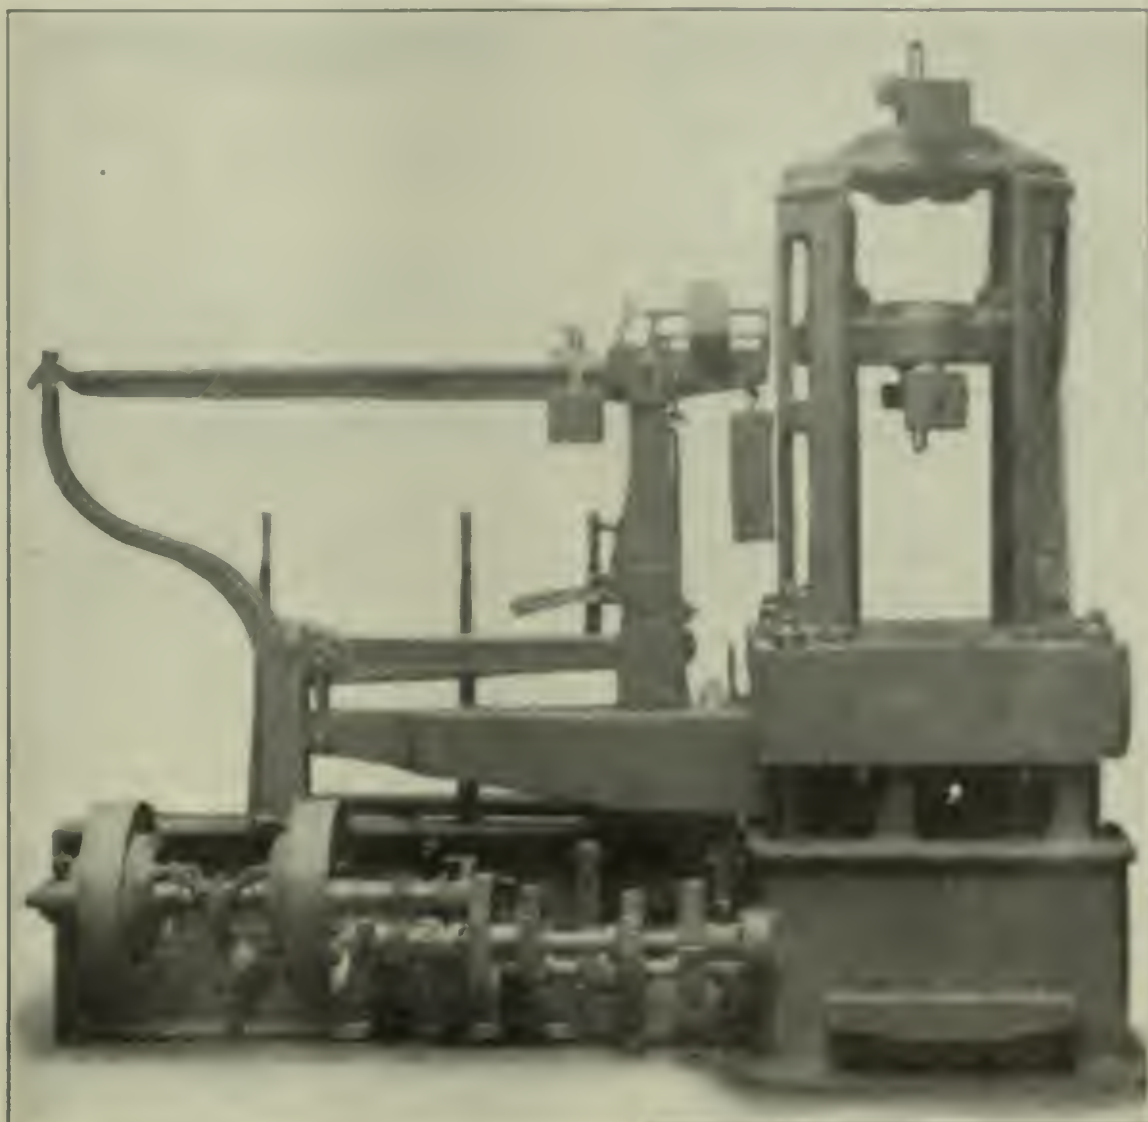

Fig. 1. Testing Machine Showing Driving Gears

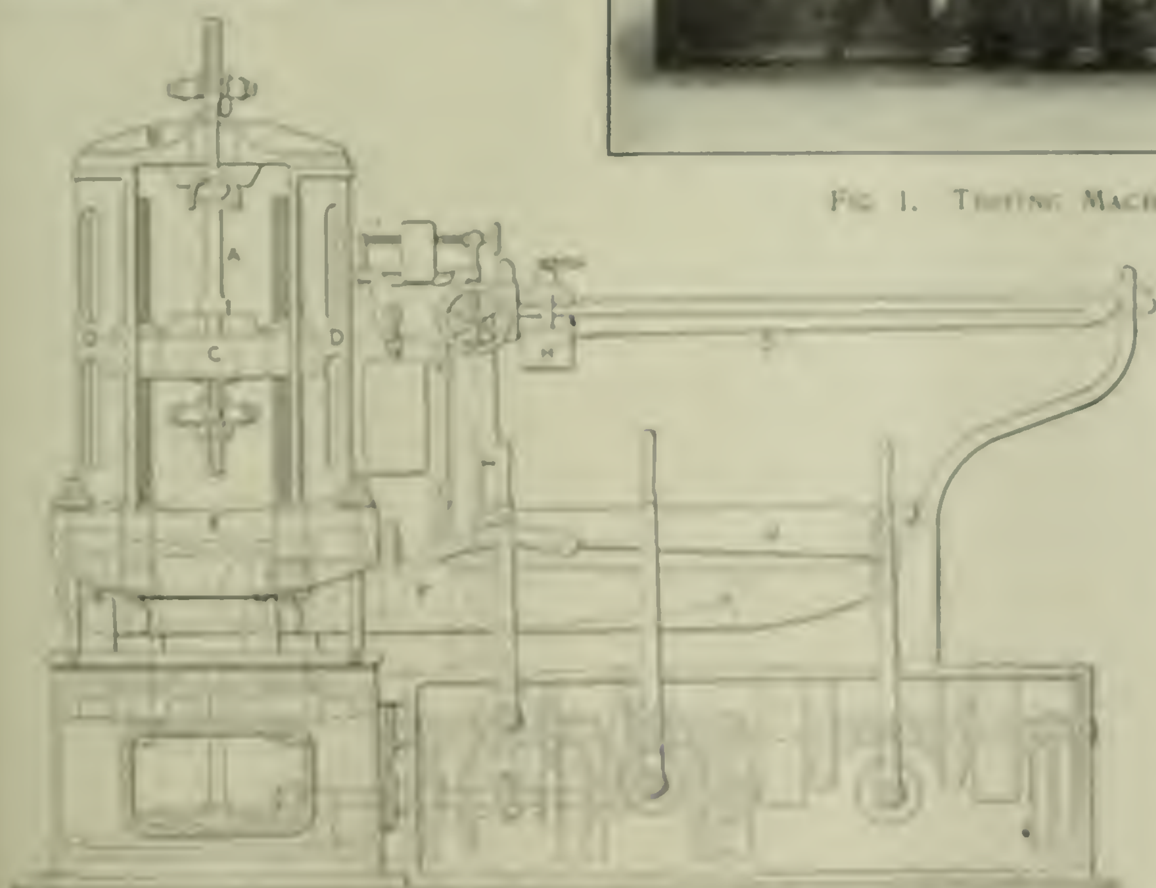

Fig. 2. Sketch of Testing Machine with Test Piece in Place

shown in Fig. 3. Taking one of the specimens thus prepared, two punch marks are placed on it 8 inches apart, the width and thickness are carefully measured and the readings recorded, after which it is placed in the grips of the testing machine. The machine is started and the observer then operates the poise so that the weighing beam is kept floating; it is necessary to maintain this condition in order that the load on the specimen at any instant may be known. For a short time the load rises rapidly until a point is reached at which the beam drops suddenly. Noting the load on the beam at this point and recording it as the elastic limit, the test is continued, generally at a higher speed, and the beam maintained in the floating position as before.

After passing the elastic limit the load increases steadily but slowly, even with an increase of speed, until the maximum load that the specimen can sustain is reached, when the beam drops and remains down. The load indicated on the beam at this point is recorded as the ultimate tensile strength. Also, the test piece is seen to be growing thinner at the place where rupture later occurs. From now on until the specimen breaks it is necessary to run the poise of the weighing beam backward if it is desired to keep the beam floating; this is practically never done as load readings beyond the maximum are not desired.

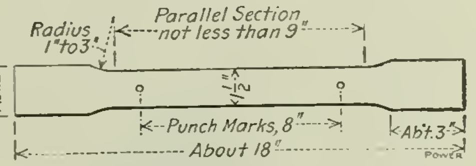

FIG. 3. STANDARD SIZE OF TEST PIECE

Immediately after rupture has taken place the machine is stopped and the specimen is removed. The shape of the fracture and the character of the steel are carefully examined and noted. The pieces are fitted together in their original position and the distance between the punch marks is measured. This dimension shows how much the specimen has been stretched.

Assume, for instance, the data taken during the test to be as follows: Final size, 1.48x0.52 inches; final area, 0.77 square inch; elastic limit, 25,680 pounds; ultimate strength, 46,820 pounds; elongation in 8 inches, 2.32 inches.

In order to be able to compare the results derived from the tensile tests of

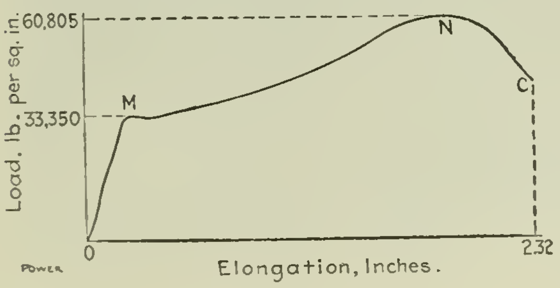

FIG. 4. CHARACTERISTIC CURVE

specimens of different thicknesses and widths, the data must be reduced in each case to the same basis. The necessary calculations are made so as to show the elastic limit in pounds per square inch of original area, the ultimate strength in pounds per square inch of original area and the percentage of elongation in 8 inches. Therefore, the final results of the test are recorded as: Elastic limit, 33,350 pounds per square inch; ultimate strength, 60,805 pounds per square inch; elongation, 29 per cent.

During the test, as described, no attention is paid to the elongation of the specimen other than to measure the distance between the punch marks after rupture. If, however, a number of readings of the elongation are taken and these results are plotted in connection with the loads which produced them, a characteristic curve similar to that shown in Fig. 4 will result. This diagram shows plainly the rapid increase in load for the small elongation which takes place up to the time the elastic limit at *M* is reached; here the load is seen to remain stationary for a time and then increase slowly while the specimen is stretching rapidly. This condition continues until the point *N*, representing the ultimate tensile strength, is reached, after which the load decreases, the specimen now stretching rapidly until rupture occurs at *O*.

The ultimate tensile strength of boiler steel varies from 55,000 to 65,000 pounds per square inch so that in the calculation for the safe working pressure of a boiler the average value of 60,000 pounds per square inch is generally used.

Writing for the Technical Paper

By E. Dixon

Havin' ben afflict'd with "writer's itch," almost since berth, sum pain, plesure an' profit hav' kum mi way from usin' a pencil. Mi furst experience, wuz with mi mother, after I'd dek'erat'd a newly paper'd wall with a few chaste records of mi thoughts. She chas'd me an caught me an I need'd a cushin real bad for the next few days. Gee, but she stung me proper. When I went to the skool, the teacher an' I got in wrong with each other an I us'd the blackboard to express my opinion. The illustrations were rather raw but I had a fair opinion of the writin' until the teacher convinced me that it was impolite.

When I got into the shop, I commenced to fin' out where a lot of the "dope" I'd side stepped wuz useful. Well, there were induc'ments. I saw the foreman knew more nor I did an' wuz not a hull lot delited to supply informashun. It didn't seem squar' to me an' I kep' mi eyes wide opun a lookin' fur things. One day I caught on to the fac' that the way Jim figgered out the change gears fur a screw I wuz to cut had a sorter familiar look, an' that nite to hum I dug up mi rithmetic. I found a part of it call'd "proportion" an' I set down to study it out. I'd made a list of the change gears fur the lathe an' the number of threads in the lead screw an' the number of teeth on the spindle gear. I dugged 'till I got the thing strait in mi noddle an' the nex' time I had a thread to cut I made bluff an' figgered out the gears. Jim nearly scart me stiff after figgering them for he changed the two intermediates, but I didn't hold mi breth none. I jus' counted their teeth an foun' out I'd been right an' Jim 'd chang'd them to keep me frum gettin' wise. I'd foun' out I wasn't the only one an that week I foun' a copy of the *American Machinist* at the library. It looked good to me, an' I saw a notiz that they pade fur things sent in wich they used. I knew sum of the other boys didn't know how to figger out the gears an' to get it fast in mi nut I made a try tu put it down on paper so I could understan' it. When I got it in shape I'd near swet blood, an', thinkin' of the others who didn't know, I puts 'er in an envelop an' mails 'er. Well, I got a notiz sayin' my contribushun had been receipted an' I waited, an' I waited. Then one day I saw mi piece, at least they had mi name to it. I wuz sore. After all the time I tuk to get that thing done good the editur hadn't left much to it but mi name. I wuz mad, but aftur I'd cooled down a bit I read 'er again, an tuk mi time to it. The editur'd done sum things which made me take notiz. Sum of the things had ben a bit muddy when I wrote them out but now they'd ben made clear. I got tu thinkin' to miself that they'd never think mi stuff woth payin' for, they way they'd treat'd it, an' when I got the check frum the papur it seem'd like sumthin' fur nothin'. I need'd the mun' an tuk the check tu the cashier.

Say, I must 'a spent that "V" 'steen times, ther' wer' so many things I want'd, but Old John, the engineer, waz a teachin' me tu run the engine an' I sent fur a "Tulley." I'd had longin's fur that book but I'd never had the coin tu get it. The rest uv the "fortune" tuk me an' mi steady tu the "Lake" an' we had a boat ride an' sum ice-creme soda. Mebbe I didn't feel that "brain money" burn mi pockit. When Old John quit they gave me the engine an' after I'd run 'er awhile I'd got a better job to the power house. By this time I'd seen mi name in print several times an' I kep' right on a writin' an' a sendin' it in. The more I writ, the easier it becum an' the goods seem'd to stick to me. I studied to write an' I writ'd what I studied. Then I got a raise, not the toe kind.

Onc't I learn'd sumthin' not in the books or the plant. I'd been a visitin' an I told about a place I saw. The man that run it was heftier nor me by 50 pounds an' sum kin' fren' show'd him what I'd said. He came over tu see me an' after he'd gone I bo't sum beef steak. Then I'd foun' sum of mi frens'd argue 'bout what I'd said an' get real personal. An' I fin'lly conclud'd that I'd use a nomme due plum like sum of the big ones. The editur didn't object an' gradu'ly cut out writin' in my own name, an' it 'sav'd a heap of argument. Sum of the boys as't me 'bout it an' I 'splained the writin' took too much time an' they want'd to know who the guy wuz who seemed to kno' so much about the lokul doin's. I didn't tell but I kep' right on a writin' an w'ile I'll never get rich quick at the game, there's a big lot more in it than the checks I get. I'm helpin' the other feller an' am a charter member of the league of self-risers, no dues, no admission fees, the only qualifications bein' a bit of grit an' stic'-to-it-iv'ness.

Electrical Department

Especially conducted to be of interest and service to the men in charge of the electrical equipment

Some Features of Induction Motor Operation

By W. A. Hill

When the Willys-Overland Company took over the plant of the Pope Motor Car Company, of Toledo, O., to manufacture automobiles, the factory machinery was group-driven by direct-current motors ranging from 1 to 50 horsepower, the total connected load being about 650 horsepower. In most cases the motors were mounted on the floor in the corners of the rooms; in some instances, however, one motor was used to drive three floors. Upon extending and rearranging the plant it was found expedient to change over to alternating current, the increased load being large enough to justify the central station in putting a transformer substation right on the factory premises.

Three-phase currents at 4000 volts and 25 cycles are transmitted from the central station, about three miles distant, through one-half mile of underground and 2½ miles of overhead feeders consisting of three No. 0000 solid copper wire and a neutral of No. 4 copper wire which is grounded at the power house. The high-tension feeders are brought over the property on poles to a transformer station located at the center of distribution, and there stepped down to 440 volts for power purposes and 115 volts for lighting service. Separate transformers are provided, of course, for the lighting and power services.

Notwithstanding the separation of the secondary circuits, however, the fact that the lighting transformers are supplied with current from the same primary circuit which supplies the motor transformers has caused some difficulty in maintaining constant voltage at the lamps. This is occasioned by the fall and rise of the primary voltage when motors are thrown on and off the circuits, the trouble is worse, of course, when a large number of motors is stopped at one time, as at noon and evening each day. In fact, it is so objectionable that special provision has been made for correcting the voltage variation.

The 115-volt incandescent lamp circuits are supplied from transformers connected star or Y-fashion at the primary terminals. The primary winding of each of these transformers is provided with a 5 per cent. tap and these taps are connected to one pole of a single-pole double-throw knife-blade switch. The primary terminal nearest the 5 per cent. tap is carried to the other pole of the corresponding switch. The blades of the three switches are connected together, forming the neutral for the star connection. This arrangement is illustrated diagrammatically in Fig. 1.

Normally, when the motors are in operation the primary voltage is pulled down to approximately 3800 volts, which would reduce the secondary voltage of the lighting transformers to about 110 volts if the full primary windings of the lighting transformers were in circuit, and this, of course, would dim the lamps to a very objectionable degree. When the motors are started, the switches are set to supply the lighting transformers through the 5 per cent. taps, thereby reducing the transformer ratio and consequently raising the secondary voltage. Under these conditions the 5 per cent. drop in primary voltage is offset by a 5 per cent. reduction in the turns of each primary winding, giving practically the same voltage to the secondary circuits that the full primary windings would give with the full primary voltage.

After the motors have been stopped the voltage comes back to normal and with the lighting transformers connected as described an excessive voltage would be impressed on secondaries; to prevent this the automatic arrangement shown in the diagram is provided. The operation of the apparatus is as follows:

When the motors are thrown on, pulling down the primary voltage, the switch blades *A*, *B* and *C* are pulled to the right by means of the rope with a handle at *H*, connecting the neutral point to the 5 per cent. taps instead of the main terminals. The weight *E* is lifted until caught by the latch *F* and the switch *D* is closed, completing a circuit through the voltmeter relay *R*. This voltmeter is so adjusted that when the secondary voltage rises to 125 it closes the circuit through the solenoid *M* which trips the latch *F* and allows the weight *E* to fall. The weight pulls the switches *A*, *B* and *C* to the left, cutting in the whole of the primary winding, as shown here, and preventing the secondary voltage from remaining too high. At the same time the switch *D* breaks the solenoid circuit; consequently the windings of the meter and the solenoid are not kept in circuit unnecessarily.

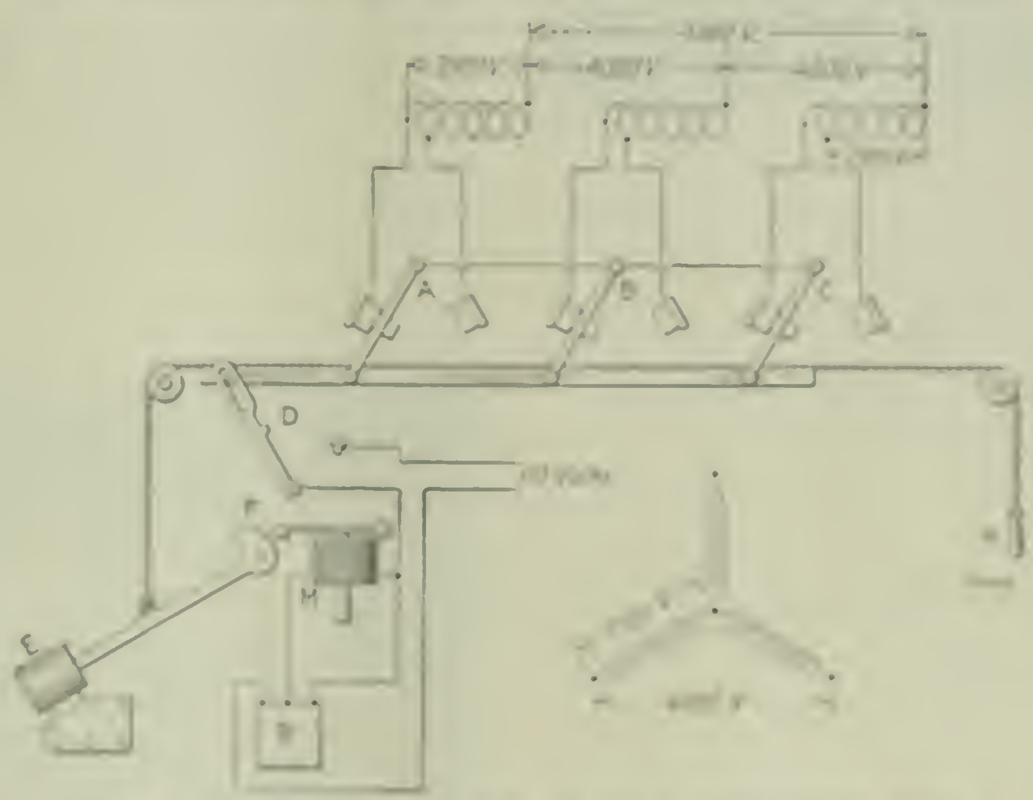

Fig. 1. Diagram of Device for Changing Transformer Ratio

A single stick connects the switch blades and is pulled back and forth by ordinary sash cord running over pulleys. The weight *E* drops on a rubber buffer and, therefore, the switch contacts are not subjected to any extra shock when the weight falls.

Owing to the character of manufacture and plant arrangement, group drive was retained except in a very few cases. The direct-current motors which have been displaced were set on the floor and belted to the line shafts at about 45 degrees. Owing to the amount of space required for the motor and belt, which necessarily

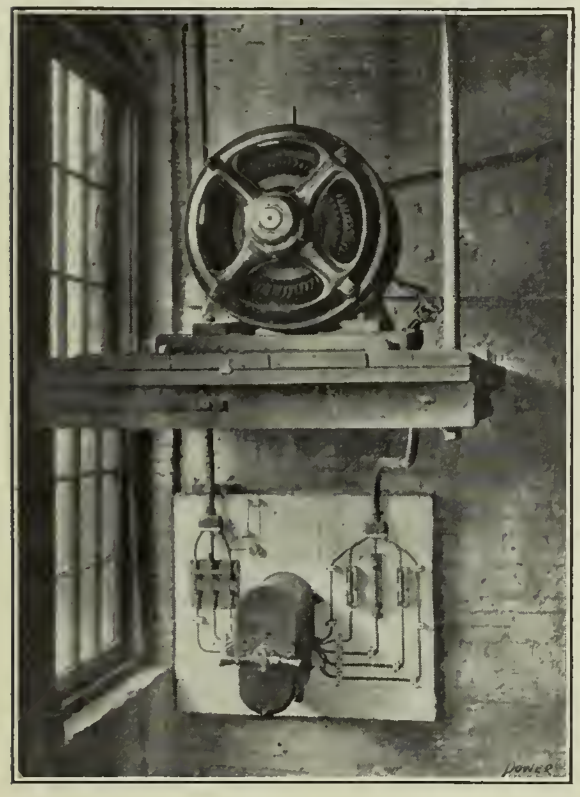

FIG. 2. A PLATFORM EQUIPMENT

had to be boxed in so as to eliminate the possibility of employees coming in contact with it, it was found advisable to either suspend the new motors from the ceiling or mount them on platforms. Most of the motors are of 20 to 50 horsepower, and motors of such sizes are not so accessible when suspended from the ceiling; moreover, the ordinary ceiling will not stand such an arrangement without reinforcement; consequently, the platform installation was adopted. Fig. 2 illustrates one of these. The ceilings average about 16 feet from the floor, and the motor platform clears the floor 8 feet.

In some instances the platform is placed in the corners of rooms, as in Fig. 3, and in others it is located in a convenient space and suspended by 1-inch round-steel rods in 2-inch pipe spacers. The platform frame is of 6x6-inch pine timbers and floored with a double layer of 2-inch planking. The platform is large enough to allow the removal of the rotor without lowering any parts to the floor below. Where the platform is located in a corner the walls carry a portion of the weight of the frame through a projection of the frame timbers mortised into the brickwork. The frame is further tied to the wall by means of lagged straps which pass through the brickwork. Those platforms located away from side walls are suspended by four bolts and steadied by ⅝-inch tie rods and turnbuckles which extend from each corner to the ceiling at an angle of 45 degrees to the edges and surface of the platform. Beneath every platform is a cluster of four incandescent lamps, the function of which is not merely to give light at this particular location but also to indicate whether the power is off or on.

In starting an induction motor one of the running fuses may blow and leave the motor running single-phase; if left in this condition very long, the active winding may be burned out. To detect burnedout fuses, an arrangement is used which consists of a fuse-block with a 2-ampere fuse connected to about six feet of lamp cord equipped with terminals similar to those on a portable voltmeter. Upon connecting this to the terminals of a fuse to be tested, if the fuse has blown the fact will be indicated by the blowing of the 2-ampere test fuse. This is a cheap device and can be used while the motor is running.

Some difficulty was experienced due to the static electricity generated by the slipping of the belt on the iron line-shaft pulley. Various brush devices were tried to take the static charge from the belt, but these soon become deranged and rendered useless from various causes. All motor frames are now grounded through resistors of about 200,000 ohms resistance, made up of two ¼x12-inch round graphite rods; this effectively removes the static charge.

The motors are blown out with compressed air once a week. Compressed air is piped to most departments to op-

FIG. 3. A SIDE-WALL PLATFORM

erate portable tools or to keep machine tables free from chips. Taps are taken from this general distribution system and a ⅜-inch pipe is carried close to each motor, terminating in a valve and the male portion of a hose coupling to receive a hose for blowing out the motor (note the air tap at the left of the motor in Fig. 2).

The oil is changed in the bearings and the bearings washed out with gasolene at least every six months; those located in dirty places are cleaned more frequently. Current readings are taken from the motors at frequent intervals, or whenever a motor appears to be overloaded, a portable ammeter being provided especially for that purpose. As nearly as possible the motors are given full load; by changing motors to suit the load, the power factor and load factor are maintained reasonably high. At present the load factor is 75 per cent. and the power factor 82 per cent.

Telephones in the Power Plant

By W. H. RADCLIFFE

Amongst the minor devices that have contributed largely toward facilitating the supervision and executive control of power plants is the telephone. In the average power plant, telephones can be advantageously used for communication between the boiler room, the engine or dynamo room, the switchboard gallery, the storage-battery room, the repair shop, the stock room and the offices of the various officials of the company.

Ordinarily, the telephone requirements of a power plant come well within the range of capacity for which intercommunicating telephones are manufactured; the maximum capacity is about thirty stations or telephones. On the front of each telephone set is a button or key for each of the stations in the system. If there are ten stations in the plant there are ten buttons on each telephone; if, in addition, there is one trunk line to a central exchange, there are eleven buttons on each telephone. The buttons are labeled "Boiler Room," "Dynamo Room," "Switchboard Gallery," "Battery Room," etc., and pressing a button automatically connects the caller with the telephone corresponding to the button pressed, and signals the called station by ringing the bell there.

One of the principal advantages of the intercommunicating telephone system for a power plant is its low operating cost as compared with other telephone systems. It is entirely automatic in action; that is, no telephone operator is required to complete the connections, this being done by pressing the proper button, as just explained. There is therefore no operating expense except the renewal of a few dry cells once or twice a year.

Another advantage of the intercommunicating telephone system for power plants is the fact that the service is available at all hours of every day and night. Furthermore, no separate switchboard is needed, the buttons and keys on the telephone sets serving in place of this expensive and rather complicated piece of apparatus.

If more than thirty telephones or thereabouts are required, and if connections with outside parties through a central exchange are of frequent occurrence, the private exchange system is necessary. A separate switchboard is required in the private exchange system, as well as an operator to attend it, connections between stations within the plant being made by the switchboard operator instead of by the party who uses the telephone.

Whichever system is used, the benefits derived from the prompt giving and receiving of orders and the transmission of information without leaving one's work, the quick adjustment of matters in emergencies and the coöperation among the employees result in a saving of time and an efficiency of operation that are out of all proportion to the expense of the telephone system.

Connecting a New Compound Wound Dynamo

By G. J. Reynolds

While employed as construction foreman for a large factory, I was sent out

Fig. 1. First Connections

to wire up and start a 100-kilowatt railway generator. This machine was to operate in parallel with two others that were already in service. Before beginning to wire up the new generator the switchboard was looked over but the connections to the old generators were not

Fig. 2. Second Connections

checked. The positive and negative busbars were easily identified by the connections to the outgoing feeder circuits.

Assuming that the old machines equalized on the positive side, the new generator *C* was wired as shown in Fig. 1 and started, but it refused to generate. In order to restore its residual magnetism, all of the brushes on the machine were raised from the commutator and its main switch thrown in; instantly, the circuit-breakers on the old machines went out. The condition that really existed is easily seen by observing the arrows showing the direction of the current. A short-circuit was thrown on the machines *A* and *B* through the series field winding of the new machine. If all the connections had been normal, the shunt field winding of the generator *C* would have been energized by current from the bus-

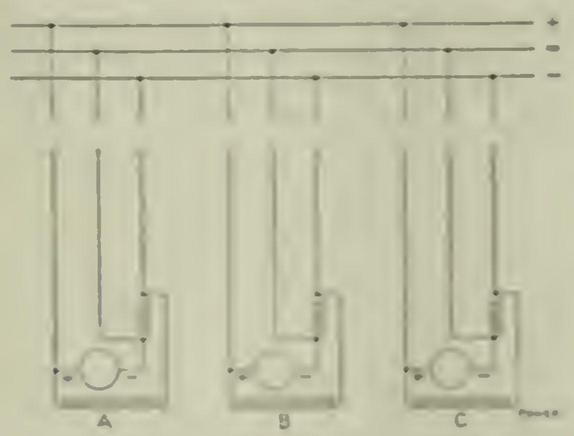

Fig. 3. Final and Correct Connections

bars without interfering with the operation of *A* and *B*.

In endeavoring to locate the trouble we found that *A* and *B* were connected to equalize on the negative side. When making changes in the wiring, the equalizers were connected to the busbar side of the series field windings, as shown in Fig. 2; the machines would not run in parallel satisfactorily when connected in this manner, for the reason that the series field windings were not equalized, as the diagram disclosed. For fear that a mistake had been made in testing for polarity, a portable voltmeter was used to check the one on the switchboard. As an additional but very simple proof, we connected wires to the machine terminals and stuck them into a bucket of water. Bubbles arose from the negative terminal.

After many unsuccessful attempts to parallel the generators, we finally connected them as in Fig. 3 and no further trouble was experienced.

Sparking Brushes Cured by Paraffin

Some time since, the brushes on two motors in our plant began sparking very badly. One was a 15-horsepower machine running at about two-thirds its full load, and the other was rated at 5 horsepower; both ran continuously from sixteen to eighteen hours per day. The brushes sparked so badly that it was necessary to sandpaper the commutators and brushes two or three times a day. The ammeter showed that the motors were not overloaded, and shifting the brushes did no good.

As an experiment we took the brushes from the 15-horsepower motor and boiled them in paraffin. They worked "like a charm," and we lost little time in "experimenting" with the other motor, which is now doing as well as the smaller one.

E. D. Nitchals.

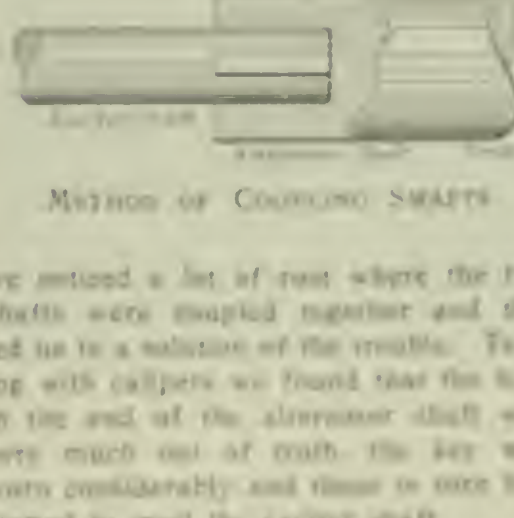
Kansas City, Mo.

[This remedy frequently, but not always, produces the result described. The explanation seems to be that the paraffin increases the electrical resistance of the brush face, which merely increases the difference between the "commutating ability" of a carbon brush and that of a copper brush. The paraffin also lubricates the surfaces and thereby reduces chattering and abrasion.—Editor.]

An Unusual Cause of Commutator Trouble

Some time ago we began to have brush trouble with the exciter of a belt-driven alternator. The commutator became so rapidly and badly injured by sparking that it had to be turned off every two weeks. Our efforts to remedy the trouble were somewhat instructive as we began to make various adjustments which resulted in a better knowledge of the machine and smoother running.

However, we ordered an extra armature and installed it and as everything started off all right we thought our troubles were over. But after two months we had to turn down the commutator of the new armature. On taking out the armature



Method of Coupling Shafts

we noticed a lot of rust where the two shafts were coupled together and this led us to a solution of the trouble. Testing with calipers we found that the hole in the end of the alternator shaft was very much out of truth, the key was worn considerably and these in turn had started to spoil the exciter shaft.

At week-end I had a slide rest taken from a 24-inch lathe and having taken the exciter off the base I blocked up with wood until the tool lined up true with the hole. I then plugged up the keyway with hard wood and started to bore by running the engine as slowly as possible and feeding the tool very gradually. In two hours we succeeded in getting a perfectly round hole [illegible] inch larger than the original one. Then we chipped the keyway deeper and [illegible] it up. The end of the exciter shaft was turned true and a phosphor-bronze bushing was fitted to the new diameter, and a keyway cut along its length.

The exciter was again put in operation and up to the present time we have had no trouble, although we have run it ten months, during four of which the machine has run 24 hours a day.

Newburgh, N. Y.

Effect of Impaired Rotor Insulation and Contacts

In a recent number of POWER I noticed a letter relative to an induction motor that refused to carry its rated load. This calls to mind an experience I had some time ago with a 50-horsepower two-phase motor that I rewound after a primary burn-out. The insulating material around the bars of the rotor was carbonized and the bars had been hot enough to oxidize them. As the bolts which held the bars to the end rings were battered over the nuts it was almost impossible to remove the nuts with the tools at hand, so I let the rotor go as it was.

After rewinding the stator and putting the motor in place it ran up to speed when tested with no load. It is direct-connected to a centrifugal pump and as water was not needed at the time I heard nothing of it for some time after. When they began to pump, however, I was notified that the pump was not lifting its usual amount of water. Investigation showed that the motor ran 100 revolutions per minute slower with the load than when it was free. I could attribute this to nothing but extra resistance in the rotor circuit. We made suitable socket wrenches and took out the rotor bars, cleaned the contact surfaces to bright metal with emery cloth, cleaned out the slots and put in new cells of paraffined paper and reassembled the rotor. This remedied the trouble. I think Mr. Blue will find his trouble to be like mine.

Mesa, Ariz.

The Simplest Current and Polarity Indicator

During the past few weeks this department has contained letters from various correspondents describing different methods of testing electric circuits in order to determine whether the current was alternating or direct; and also in some cases of detecting the polarity of direct-current circuits. All of the methods described were very interesting, and of various degrees of utility and convenience.

I have used for many years a method which might prove interesting to those of your readers who have need for it, and one which I believe has not been mentioned by any other correspondent. Simply tear a small piece off a blueprint, wet it and place the two ends of a pair of wires connected to the circuit to be tested in contact with the blue side of the print. The wire ends should be placed from a half inch to two inches apart, depending on the voltage. If the current is alternating, practically no effect will be produced, but if the current is direct, a white spot will appear under the *negative* wire. Any piece of blueprint paper will do provided it has been exposed.

I. SAWFORD.

Sydney, Nova Scotia.

Can These Alternators Be Operated in Parallel?

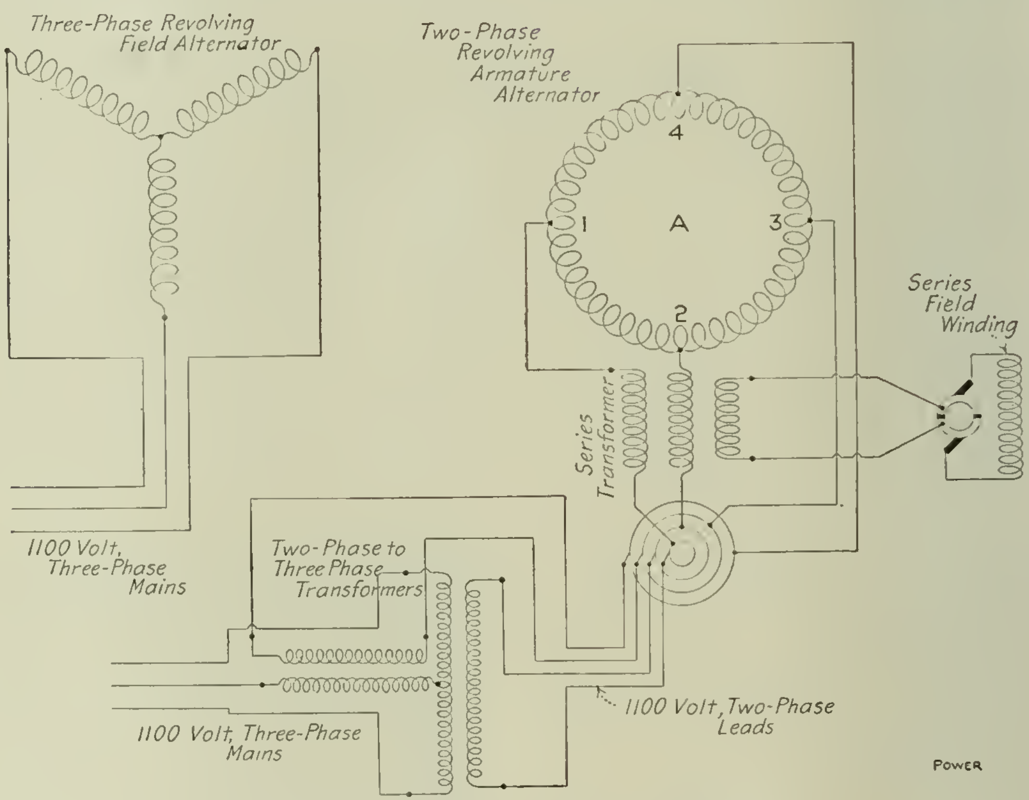
In our plant are two alternators which we wish to operate in parallel through transformers if possible. One is a three-phase 150-kilowatt revolving-field generator and the other is a 120-kilowatt two-phase revolving-armature machine equipped with a rectifier and a compensating winding. Both generate 1100 volts and 60 cycles.

Will some of the other readers express their opinions as to whether the two-phase machine, delivering through a two-phase three-phase transformer, as indicated in the sketch, can be worked in parallel with the three-phase machine? Furthermore, if the two machines can be operated in parallel, would the compensating winding of the two-phase machine have to be discarded altogether and new field-magnet coils installed in order that the field magnet may be energized entirely by the exciter, or could the winding be left as it is and the machine connected as shown in the sketch?

As the load supplied by these alternators is made up principally of incandescent lamps, the power factor may be considered relatively high. There are a few motors, all of them small, and only ten arc lamps; the rest of the load is in incandescent lamps.

D. M. GROVE.

Covington, Va.



CAN THESE ALTERNATORS BE PARALLELED?

Side Stepping Crane Troubles

It is not always the highly educated man but rather the practical man threatened with intelligence and natural resourceful ideas who gets results without looking up his card system—which, however, is of great value.

A short time ago the hoist armature of a 50-ton electric crane became badly grounded, with a load of 60 tons hanging about ten feet in the air and in the middle of a large machine shop. The electrical expert was called up on the jump and decided the armature must be changed; as the load hung in the middle of the shop too low to be bridged to one end and the two other cranes tied up one side, the delay meant dollars and cents to the firm. The idea occurred to the repairman to place heavy paper on the rails of the bridge, rack the trolley onto the paper, thereby insulating the trolley from ground, and lower the load to the wood floor. This was done, the block hoisted up and the crane run to one end of the shop for repairs, with about fifteen minutes' delay all told.

In another instance a hoist controller was burned out with an important job hanging on. The wires to the hoist motor were tapped onto the bridge controller, the job handled, the wires transferred back again and the crane run to one end of the shop for repairs without serious delay to the work.

In another instance one field-magnet coil of a hoist motor burned out with the load on; the coil was cut out and the motor run without it until the job was finished. The repair was made at a more convenient time. A little ingenuity will often save a whole lot of time and trouble in cases of this kind.

Engine and Piping Changes

A tandem compound high-speed engine gave trouble from the time it was installed about ten years ago. In spite of all that could be done by the engineer in charge, local machinists, or even the man sent by the makers, the engine still pounded and made so much noise that it could be heard for blocks at times. Finally, the crosshead shoe came off, the crosshead dropped down, bending the piston rod, and that broke off the stuffing box which was screwed into the cylinder head.

For six or seven years this engine ran for about 15 hours a day, six days a week for nine months in the year, but for the last three or four years it had only run about 12 or 15 days during the entire year, and every time it became necessary to run it there was a general kick from the fireman.

The engine was connected to exhaust into the heating system, the back pressure in which varied from zero to 20 pounds. At the higher back pressure the engine would not carry its full load and was a steam eater. The fireman claimed that it made little difference whether the exhaust went to the heating system or not.

The engine was turned over to me with instructions to have the necessary repairs made to put it in a condition to run. I removed the high-pressure cylinder, which also formed the head for the low-pressure cylinder, and separated the high-pressure cylinder from the low-pressure cylinder head by drilling a series of holes around at the point where the front ports entered the cylinder and faced it off. As the high-pressure valve was of the piston type this left a hole through which the steam formerly passed from the high-pressure cylinder to the low-pressure steam chest. A flange was secured over this hole by cap screws, and to this, by means of nipples and an ell, the throttle valve was attached, as shown in Fig. 1.

FIG. 1. HOW THE THROTTLE VALVE WAS ATTACHED TO THE STEAM CHEST

Another condition prevailed which was unsatisfactory. The steam piping entered the engine room through an 8-inch header. From this header steam was taken out of the top through a 5-inch short nipple and ell, and then through about 4 feet of pipe running at a right angle to the header with a turned-up ell at the end; then through a short nipple and another ell with about 3 feet of pipe running parallel with the header, on the end of which was an ell turned downward and from which the pipe led down to the separator and throttle valve. This formed a large pocket where water could collect, both when the engine was shut down and when running light. When the engine was started or a sudden load came on, more water would come over than the separator could handle. I had this piping taken down and the order reversed, taking steam from the bottom of the header and leaving no point in which water could collect. What condensation there was came gradually to the separator, where it was taken care of. The changed piping is shown in Fig. 2.

FIG. 2. NEW ARRANGEMENT OF THE STEAM PIPING

The engine was then put together and started up. To the surprise of all, it ran so smoothly that standing 10 feet away one could not hear it run, not only with no load but with full load, when handling a 10 to 20 per cent. fluctuation without the attendant ever knowing that there had been a change in the load.

The engine exhausted from the bottom and immediately under the cylinder there was a valve to prevent the water from backing up into the engine from the heating system when the engine was shut down. The pipe dropped about 20 inches into a trench and extended horizontally about 8 feet, and then turned up and went to the heating system through an oil separator and past the relief valve.

At the ell where the pipe turned up out of the trench there was placed a ¾-inch bleeder valve. With the engine shut down and the valve under the cylinder closed, all of the pipe, including the drop from the engine, the horizontal pipe in the trench and the riser, about 30 feet in all, would fill with water and before starting up it was necessary to drain this pipe by opening the bleeder. All would go well until the water got down to the level with the top of the horizontal pipe, when a water hammer would start. In order to remedy this I removed the valve from under the cylinder and placed it in the vertical pipe at a convenient hight with a bleeder tapped in just above the valve

Fig. 3. Valve and Bleeder in Vertical Exhaust Pipe

to drain what water might collect above this point. This is shown in Fig. 3. Since then I have had absolutely no water hammer. Before this change it was necessary to go over the engine every day, and a straight run of 34 hours was the longest the engine had ever been known to run without a stop for adjustment. Since then I have made runs of 60 hours and there was no reason why it could not have continued in service as there was nothing to be done before starting again.

Iowa City, Ia.

Steam Plant Installation Costs

Published articles that would be of permanent value to engineers would be those dealing with the details of methods and materials used in installing engines, boilers and other power-plant apparatus. Also data regarding the prices paid per hour to erectors and other workmen, the time required and the material used for each separate piece of work.

One engineer could give reliable data about an installation of water-tube or fire-tube boilers and another about installing an engine, when they might not be in a position to give reliable cost data on an entire plant.

Descriptions of power plants can be found in almost every issue of technical journals, but very little itemized installing-cost data can be found in any of them.

The small amount of reliable information along this line makes it very difficult for an engineer inexperienced in this class of work to give his employer satisfactory information as to the cost of installing apparatus of various kinds. The novices will generally underestimate the cost and the difficulties of doing good work.

Of course, cost of material and labor vary in different sections of the country, but this matter could be adjusted to suit the conditions existing by the interested investigators.

Supply costs should be complete to the smallest detail to be of real value.

J. E. Noble.

Toronto, Can.

Throttling Governor Failure

A rather queer failure of a throttling governor came to my notice lately, which may be of interest.

The 4-inch governor was of the common type without a safety attachment of any kind. One night it was necessary to screw the stem up several turns more than was usual to make the engine carry the load and as shutting-down time arrived steam was cut off completely.

When the governor was taken apart, the pin through the nut was found sheared off, the nut had unthreaded and the plug had dropped down. A new pin was put in place and everything went all right for two or three nights more when it was again necessary to screw the valve stem clear up. Of course, it was expected that the nut had again worked loose, but to the surprise of all hands everything was all right, and when the governor was put together the load was carried with the stem in the usual position for a while, but it soon had to be put up again. When in this position the engine suddenly began to race and only the sprinting ability of the engineer on watch kept the flywheel in one piece. Next day the pipe line was examined for anything that might obstruct the passage of steam, but nothing could be found.

The engine and governor had always been cold when looked into. One more try was made but something still held the steam back. As the engine stopped, I took hold of the governor flyballs and tried to spread them, but with a very slight movement the plug at the end of the stem struck hard against the pin which limits the downward travel.

Here was the trouble sure enough, but as nothing could have made the stem longer the parts in the valve body must have shifted. Another look when everything was hot showed that the brass lining was up about ½ inch above its proper place. The valve body was of cast iron and the brass bushing had been pressed into it but no provision had been made to hold it in place. The difference in expansion between iron and brass allowed the bushing to drop down into its proper place as soon as it cooled off and as no one had never looked at it immediately after stopping, the bushing had never been noticed out of place. A good strong pin now holds it where it belongs.

My theory is that when first warming up the engine a slug of water or perhaps the steam would force it up before the expansion had tightened it.

Verne L. Ballou.

Shirley, Mass.

The Human Element in the Power Plant

Perhaps one could find a greater variety of opinions upon the subject of the human element in the power plant than any other; it may also be quite true that no two men can be handled in the same way, in consequence of which no set of rules can be applied in the handling and treatment of subordinates, whereby the most efficient results may be secured.

It is quite true that experience is the best teacher; however, one may have a variety of experiences, covering a great number of years, and yet be utterly incapable of securing results from his assistants, just because the subject never received logical nor analytical consideration.

Recently, a very successful chief engineer of a large paper mill laughed when I mentioned this subject of handling men to him and said that it was something one could learn only by everyday experience. Furthermore, he wanted to know if anybody expected to find out anything through a discussion in Power upon such a subject. I replied that the space would not be given up to a worthless subject.

His argument was that what might be a good line of procedure for one man would be ruinous for some other fellow to carry out. Furthermore, he was of the opinion that good judgment coupled with hard work and a good physique, together with plenty of push on the part of the subordinate, would go farther toward securing the best results than all the "dope" that could be devised or dug up in a century.

Continuing, he said, "I would rather have one good man than three of the general run of men found in this 'neck-of-the-woods'; really good men are hard to find, that is, men who will take a real, live interest in the plant and work to the end that the very best service may be secured at the least possible cost. In return one should make it worth their while in a material way to do good work and not make it just a 'thank you' proposition. If a man can achieve results where the other man did not, and perhaps could not, then he should receive a percentage of the saving made."

We both were of the opinion that if a man is energetic, possesses some initiative, is loyal to the chief and not afraid he may insubordinate himself too much, he is pretty sure to be a valuable man to his employer. On the other hand, if he is continually finding fault with the equipment and the management, and works along from day to day in a half-hearted manner, the concern and the chief would be much better off without him. Moreover, any man who requires careful handling and becomes incensed upon the slightest pretext, will not help to form a strong organization, but may be the means of disrupting it.

If a strong organization is desired, and success depends greatly upon the organization, there should be a sort of family feeling among the men, and every man should be a coworker with the chief, so that the plant may be run at the very highest degree of efficiency and economy. If there is a backbiter among the men, the sooner he is eliminated the better for all concerned.

One point which I have invariably noticed is that the wage is not always the sole attraction in securing and retaining valuable men. The candidate for a position asks such questions as, "How many hours will I be expected to put in per day, and will I be able to get a Sunday or two off out of each month? Would I be at all certain of my job, or might I expect to get the 'can' on the slightest provocation? What kind of a man is the chief; is he a grouch or is he one of those fellows that has no feeling for anybody but himself? If I show him what is in me, will he appreciate it and in time advance me when conditions permit?"

I have noticed that the "boys" appreciate little things in a really greater degree than they do the big things; for instance, after a hard day's work and it is two or three hours until quitting time, and nothing very urgent remains to be done, telling them to wash up and go home is only one of the many ways whereby the services of loyal and valuable men are not only retained but enhanced as well.

One more point. If the highest economy in firing and the use of supplies is sought, the men should be informed of the cost of the particular articles which they handle. The fireman should know how much the coal costs per ton; how much it costs per day for coal; tests should be made and the results explained in a simple way, so that they may understand what inefficient management and recklessness cost the company. This is why the chief should receive a bonus, as he will continually be after the men in respect to economy, continually impressing upon them that their success as well as his depends upon following out his methods and instructions.

WALDO WEAVER.

Middletown, O.

Prevented Water Hammer

Following is an account of how I beat a case of water hammer at a very small expense:

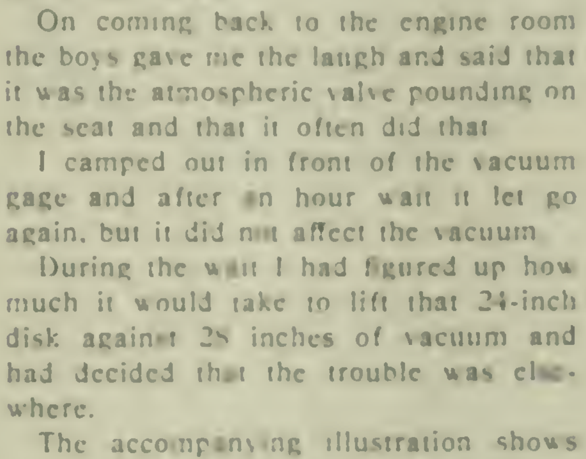
I had only been in the plant a few days when I was startled to hear a loud bang in the cellar and, although I looked over everything carefully, I could not place the noise.

On coming back to the engine room the boys gave me the laugh and said that it was the atmospheric valve pounding on the seat and that it often did that.

I camped out in front of the vacuum gage and after an hour wait it let go again, but it did not affect the vacuum.

During the wait I had figured up how much it would take to lift that 24-inch disk against 28 inches of vacuum and had decided that the trouble was elsewhere.

The accompanying illustration shows



ARRANGEMENT OF DRIP SYSTEM

the exhaust piping from the turbine and that the under part of the casting going to the atmospheric exhaust projects farther than the top side, causing a small percentage of the condensation to drain back into the offset in the line to the atmospheric valve, making a water seal on the wrong side.

The valve leaked and the vacuum drew the hot steam from the auxiliaries on the exhaust line into the cold water; a water hammer was the result.

I got an old galvanized hot-water boiler and piped it up, as shown, so that by leaving the top valve open and the other two closed the water came to the trap by gravity, and by closing the top valve and opening the others I could dump the trap into the hotwell.

At the first opportunity I opened up the atmospheric valve and found both guide stems broken. It was repaired and the disk faced off and there has been no trouble since. I dump the trap every hour and get 10 or 12 barrels of good water every day and that helps here, where the water is bad.

A. STEVENS.

Renfrew, Penn.

Corroding Economizer Tubes

I would like to ask if any reader has had trouble with corroding economizer tubes?

My economizer is placed between the boilers and chimney. The water is pumped through closed primary and auxiliary heaters and through the economizer to the boilers. The water enters the economizer at from 170 to 200 degrees Fahrenheit and leaves at a temperature of from 220 to 242 degrees Fahrenheit.

It is opened up once a year and a tube scraper run through the tubes and the headers are cleaned out; a soft scale more than [illegible] inch thick is found and looks like oxide of iron. It is not like the scale in the boiler tube, but forms in bunches and ridges, much resembling barnacles. Under this deposit the tubes are wasting away and some of them are not more than half of their original thickness and many are giving out.

The feed water is taken from the river and is considered good. It does not contain more than a trace of free carbonic acid and in the boilers it forms a slight scale that is quite hard. Soda ash and some kerosene are used. The economizer has been in service eight years.

If any engineers have had the same difficulty and found a remedy, I would like to know what it was.

C. B. SMITH.

South Framingham, Mass.

Trouble with Refrigerating System

There is one source of trouble in a refrigerating system upon which I have never seen any comments. In a system where brine is used as a refrigerating medium and where air is passed over (or through) the cold brine, the hot vapors are carried from the rooms that are being cooled to the brine tanks in which they are condensed. Thus the quantity of the brine is increased and its strength consequently reduced. The required density can be maintained only by removing the excess water by evaporation or by adding brine-making material.

It is this evaporation that I would like to see discussed. In my plant there is an overflow pipe from the brine tanks to a concentrating tank in which there is a set of steam coils to evaporate the excess water. When the brine is boiled down it is pumped back to the brine tank. I have had considerable trouble with this concentrating tank and with the steam coils in it. Due to its nature the brine is severe on iron when the brine is at or near the boiling temperature. I have to renew the coils about every four months and the tank itself does not last over two years. I have experimented with different kinds of coils without great success.

Stratford, Conn. W. O. WATSON.

Questions Before the House

Comment, criticism, suggestions and debate upon various articles, letters and editorials which have appeared in previous issues

Connecting High Pressure Drips to Heating Mains

I think that Victor Borm, in the February 21 issue, in trying to criticize W. T. Meinzer on the subject of connecting high-pressure drips to the heating mains, does not realize that condensed steam under a high pressure contains more heat units than under a lower pressure. Mr. Borm says that if the high-pressure traps were made to perform their function there would not have been very much heating done in the sewer. With Mr. Meinzer's arrangement the drips from the high-pressure traps are discharged to a lower pressure, part of the drips reevaporates and goes to the heating main and does work; the remainder goes to the return pipe. I think that this one point of economy is enough to justify the change made.

If there is not economy in saving the drips, why do engine builders do so? For instance, take the arrangement of steam jacketing and receiver reheating pipes on a triple-expansion pumping engine. Various arrangements are used but the following is simple and typical: Steam from the main steam pipe near the engine passes to the high-pressure jacket at boiler pressure, then to coils in first receiver, then through a reducing valve to the intermediate jacket and out to coils in the second receiver, then to a trap and from the discharge of this trap to the low-pressure jacket. The condensation from the exhaust side of the high-pressure cylinder, first receiver and inlet side of the intermediate cylinder goes to the low-pressure jacket, a valve being placed in the pipe so as to maintain the required jacket pressure. The outlet from the low-pressure jacket goes to a water seal in the basement of the building. The condensation from the working steam of the exhaust side of the intermediate cylinder, second receiver and inlet side of the low-pressure cylinder also goes to a water seal in the basement.

An illustration of the saving made possible by suitably employing high-pressure drips is that of a cross-compound condensing engine which once came to my notice. When the engine was installed, a testing engineer was sent by the builders to prepare and conduct the acceptance test. After getting ready he made several preliminary tests. He experienced some difficulty in getting the engine to perform the duty required. Among the several changes which he made one affected a high-pressure steam trap that removed the condensation from the coils in the receiver to the hotwell. Its discharge was connected into a pipe that drained the condensation of the working steam in the receiver to a trap. Part of the drips from the high-pressure trap reëvaporated and did work in the low-pressure cylinder. The tester claimed that this change caused a good gain in the duty of the engine.

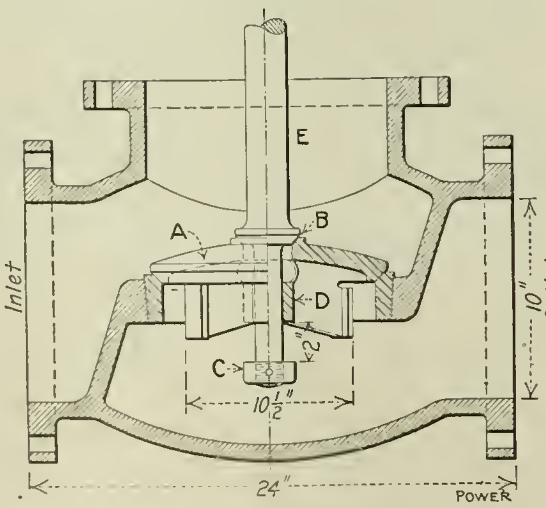
Mr. Borm states that he wonders why Mr. Meinzer did not think of putting in a back-pressure valve. This would undoubtedly have been more effective in preventing the back pressure from blowing the seal into the drip return; also, it would have been more simple.

R. E. Enigne.

Kansas City, Mo.

Special High Pressure Valve

I read with great interest the articles in recent issues of Power dealing with the danger to boilers and piping when opening a stop valve suddenly. As to the side from which steam should enter



Valve with Internal Bypass

a valve, I fully agree that the steam should act on the bottom side of the valve; that is, the valve should close against the pressure. But with large valves and high pressures the opposite may sometimes be adopted with advantage.

A bypass arrangement should be fitted to all high-pressure valves over 4 inches in diameter to help when opening or closing the valve. Most engineers know that it is next to impossible to open a large parallel slide-type valve without using the bypass arrangement.

A few years ago I worked with Richard Pohle, Limited, of Riga, in Russia, when they were constructing the new electric-power station at Windau. All large valves, according to specification, were to have an arrangement for slow opening and be fitted with bypasses.

We made a valve after the design shown in the accompanying figure. In this valve the pressure comes on the top of the disk. This arrangement was preferable as we had experienced considerable difficulty in keeping large valves, closing against the pressure, from leaking when shut.

What the total pressure against a valve disk really is, only few engineers know. In the case of a 10-inch valve under 150 pounds pressure per square inch the total pressure would be upward of five tons. To keep the valve from leaking, the spindle must force the disk downward with at least six tons' pressure. For the Windau power station we therefore preferred to let the steam help to keep the valve tight.

Referring to the figure, the spindle *E* has a collar *B* which acts as a bypass valve in the topmost part of the disk *A*. The lower part of the spindle passes through a guide *D*, cast as a part of disk *A*, and is fitted with a nut *C* which allows the spindle to be lifted 2 inches before acting on disk *A*. The slightest turn of the spindle will admit steam through the bypass *B*.

Penn, England.

Action in Emergency

The description of the engine wreck at the Boott mill, Lowell, Mass., reminds me of two experiences along the same line which I have had.

The first took place in a five-story mill with a 2000-horsepower engine. Owing to the distance of sections of the mill from the engine room, the manager decided to have the mill wired and to have push buttons located in every room. Then, in the event of an accident, an overseer could ring the emergency bell in the engine room as a signal to shut down.

As first arranged, the push buttons were fastened to the walls without cover or notice relative to their use. One forenoon, about a month after the system was installed, the bell rang and before I had the throttle valve half closed the bell rang again. When the machinery began to slow down, the superintendent, the master mechanic and some of the overseers came to inquire where the trouble was. Not having an indicator on the line wire I could not say from which room the alarm came.

After the officials had investigated and found no cause for the alarm being rung in, the order was given to go ahead. In about half an hour the superintendent came back and said, "Who authorized you to stop the engine when that bell rings?" I replied that no one, in just so many words, but that I had been consulted in regard to its location, had helped to install the system and I took it as generally understood that I was to shut down when signaled. "Well," he growled, "hereafter when that bell rings don't stop the engine until you get word from me or the master mechanic."

I had thought him a lightweight and that superficial remark confirmed my opinion—the absurdity of such an order! There were three large mills and both superintendent and master mechanic were liable to be anywhere about the works, therefore, often difficult to find. But, fortunately for me at least, the manager had an automatic engine stop and speed limit installed to be operated through the system of wires already in use.

In another plant I worked under a very different type of superintendent. The engine was a compound, size 24 and 44 by 72-inch Corliss and ran at 62 revolutions per minute. This engine was not fitted with safety cams to prevent the engagement of the steam-valve latches when the governor is at the lowest point. On account of its hight the starting valve had to be operated while standing on a step ladder, always kept there for the purpose.

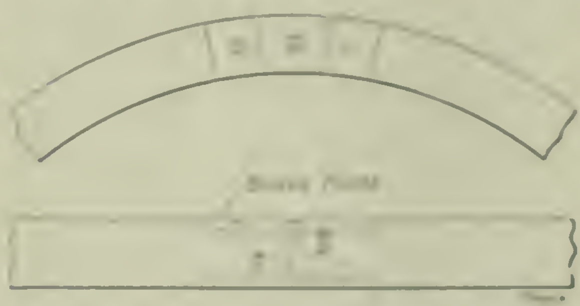
One day, while working at the bench, I heard the engine speed up, and looking around I saw the governor had stopped, which startled me so that I thought of a number of things in a very short time. My first impulse was to mount the step ladder and shut the starting valve, but the accelerating speed of the connecting rods convinced me that the process would be altogether too slow, so I jumped down to unhook the wristplate. At that instant, however, I realized that the consequences of instantly arresting the valve motion at an unknown point in the stroke might be disastrous. So I grabbed a lever connected with the governor and raised the balls to their highest point; this prevented the valve latches from hooking on. I held them in that position until the engine had nearly stopped, then I released the lever, ran up the step ladder and shut the starting valve.

In a moment the superintendent came in and with the help of a machinist and an electrician we straightened out the tangle and had the engine going after a few minutes. This superintendent, instead of trying to browbeat me for the slight shutdown throughout the mill, complimented me on my quick action in preventing what might have been a very serious accident.

Clinton, Mass. J. W. Parker.

Piston Rings

In the March 7 issue is a contribution on piston rings by Lloyd V. Beets in which lap-joint and diagonally cut piston rings are criticized. The criticism is well taken. An improvement which I have found to be satisfactory is shown in the



Arrangement for Preventing Leakage

accompanying figure. Care must be taken with thin rings to use tap screws of proper proportion.

George H. Handley.

Newburgh, N. Y.

Neglecting Opportunities

The editorial in the March 14 issue entitled, "Neglecting Opportunities," certainly is worthy of considerable notice and serves as food for thought on the part of a majority of the men who are operating isolated plants.

The assertion that certain men are contented to let a piece of apparatus run in any condition is only too true and, as a rule, they will not put it in proper condition unless compelled to.

In regard to getting after a repair job as soon as possible, such men often do put it off until Sunday, and frequently it happens that the apparatus gives out before that day comes, resulting in a shutdown which at times proves very expensive.

As far as thinking that you may make a thing worse instead of better is concerned, a man who thinks this way, as a rule, generally does make them worse when he gets at them; the only way to do a good job, so far as I know, is to determine to do it and then go ahead.

A great many men do poor work simply because a job is distasteful to them and in their eagerness to get it off their hands do it in any old way as long as it will stand up until they leave the job.

Any man who will allow a number of tubes or nipples to leak in a boiler is indeed a poor business man for, as the editorial states, he could make them tight in a very short time if he would only get at it.

With reference to leaky and improperly set engine and pump valves, I venture to say that if engineers generally would formulate a plan to examine and test the smaller apparatus intrusted to their care, a good deal of power-plant loss would be done away with and the central station would have less to do.

H. H. Hurley.

Brooklyn, N. Y.

On Assisting the Inspector

It is a remarkable fact that those men who by training, experience and general knowledge are best qualified to judge every condition affecting the plants under their charge are the very ones who afford every possible aid to a boiler inspector, while those whose conceptions are of the very crudest concerning the proper maintenance and operation of the machinery in their keeping view the service of inspection and supervision with everything from good natured indifference to open hostility.

The same conditions seem to obtain among owners. Let any movement be started toward a provision for more rigid supervision of boilers and a great hue and cry goes forth. Many a costly object lesson is required and perhaps many lives sacrificed before opposition is sufficiently removed to allow a betterment of conditions.

I am a boiler inspector and, operating as I do in a field where absolutely no form of regulation is provided by statute, I am often brought face to face with conditions of ignorance and indifference that are absolutely appalling. Time and again have I known of the inspection service being refused because of the safety limitations imposed, even when concessions beyond what good engineering practice would dictate had been granted. In one instance, perhaps the most cold blooded that has come to my notice, I was severely upbraided by an owner whose partner had made application for inspection, when I told the engineer of the dangerous condition of a boiler he was operating. The boiler was twelve years old, designed for 125 pounds pressure and was at that time carrying 190 pounds. I do not doubt that my judgment was a matter of considerable derision, for I was informed that other boilers of the same type had carried over 200 pounds and still held together. I did not dare attempt to explain safety factors for fear that anything below the ultimate strength would be considered all bluff.

However, the inspectors' pet aversion, so-called engineers, it is a constant source of friction to find safety valves screwed down to points where release of all the steam generated is impossible, to find the gage hands set back and other simfices intended to deceive. I will say that this practice is most common on the boilers used for logging purposes and where few engineers as we understand the term are found. It is a matter of real pleasure to find one of the three gage cocks on these rigs in working order, while for all of them to be in order should make the engineer almost deserving of honorable mention.

There is one thing, however, to be brought to the attention of a great many engineers, men who are really skilled good men, men who are making real successes at their vocation, and that is the conditions under which an inspector is required to work. In many of the plants the boilers are not or for some reason cannot be sufficiently cooled and the heat is terrific. More than a passing glance at the various portions is beyond human endurance. Even at that, there is little that the inspector misses but a little less onerous conditions would add to his efficiency.

Then, there is that matter of cleaning the parts sufficiently. How much less effective must an inspection be and how much it adds to the disagreeable part of the work, to dig out the buried blowoff pipes, to crawl around in a foot or two of soot and ashes to look over with minute care several thousand feet of tubes and a number of drums and headers. It is little wonder that cases of incipient failure and the progress of corrosion and attendant evils escape the notice of one working under such handicaps.

The more frequent use of the hydrostatic test has been suggested as one means of reducing the number of disastrous failures. Yet, there is a question as to whether the strain so set up at the time of such a test, commonly 50 per cent. in excess of the working pressure, might not cause incipient failure not discernible at the time, especially in the case of buried and covered drums and the seams of horizontal tubular boilers. Little uneasiness need be felt regarding those boilers which are free of access and whose parts can be well examined, even if subjected to the visual test only.

Perhaps the best and safest plan to pursue is to adopt some such rule as that in force in the State of Massachusetts, fixing a factor applicable to the age of the boiler, for the fact that the material undergoes a change is very apparent from the manner in which the metal of an old boiler works when attempts to use it for other purposes are made, and one is often led to wonder that it lasted as long as it did when the crumbly, brittle and nonfibrous nature is noted.

Unfortunately, instead of thus reducing the burden upon a boiler whose age should be respected, even if not respectable, the common practice is to add more pressure as the business grows, then to place in the battery boilers of newer, later type and let the old well tried servant continue to carry the limit. How many plants are found with such units in them, where the pressure is limited only by the original design of the oldest boiler in the plant. No comment is necessary on this practice, yet owners and, in many cases, operators, would have to be shown signs of actual distress before discarding them.

At most, upon finding undesirable conditions, the inspector can only recommend the cancelation of the insurance. At that, his influence often ends. This fact is frequently taken advantage of by both owners and operators. To overcome the handicap imposed by these conditions, the inspector is required to be more or less of a diplomat. He must accomplish by other means than the absolute authority of Federal and State officials, the safeguarding of the lives and property of those most concerned and at the same time maintain pleasant business relations between his employers and their clients. Considerable judgment and decision are necessary to require immediate action in place of promises and to refuse to accept faulty arrangement even if imminent danger cannot be pointed out.

Certainly a little thought along the foregoing lines will make it easily apparent to any engineer in what manner he may for his own part help to make the work of an inspector a still greater medium of safety. With the proper coöperation and influence of the engineer, the present appalling list of disasters can be reduced to the minimum.

HORACE HANKS.

Portland, Ore.

Burning Lignite

Referring to Mr. Bergman's letter under the above in the March 7 issue, I wish to say that I have been burning North Dakota lignite for about eight years and have obtained higher efficiency from boilers and grates with lignite than with any other soft coal. This is due no doubt to its cleanness; it forms no soot on the tubes during an 8- or 10-hour test and such a test can be run without making a general fire cleaning. This may not be true, however, of all the Dakota lignites. The Wilton coal is considered to be of the best grade. It has a heat value of about 7000 B.t.u. per pound, contains from 5 to 6 per cent. ash and from 35 to 40 per cent. moisture.

Mr. Bergman states that he evaporated four pounds of water per pound of coal, which contained 6029 B.t.u., and secured an efficiency of 68 per cent., which I consider to be a very good showing.

Lignite burns much like wood and does not require much air. As a general thing too much air is admitted and the heat is carried through the boiler and lost up the stack. It has been truly said that in order to generate steam there are only two steps required: First, produce the heat, and, second, transfer the heat to the water in the boiler. I have made many tests with lignite and under favorable conditions have evaporated 4.86 pounds of water per pound of fuel, containing 35 per cent. of moisture, 5.92 per cent. of ash and 6591 B.t.u. This is equal to evaporating 8.80 pounds of water into steam from and at 212 degrees Fahrenheit per pound of combustible, and shows an efficiency of 76.98 per cent.

Engineers employed by the Government have made tests with North Dakota lignite and from the reports of such tests that I have seen no such efficiency was obtained. No doubt the poor results were due to the fact that those who were in charge had not learned how to burn North Dakota lignite. Many have turned down lignite for the same reason, but some day the large fields of lignite will be of great value to the people of the United States. I regret to see the Government use coal from Pennsylvania and Ohio for its buildings in this State.

C. P. LARSEN.

Bismarck, N. D.

Smoke Abatement

In the March 21 issue, I notice that Waldo Weaver makes some criticism of my letter in the January 3 number on the smoke problem.

It may be true, as he says, that it requires a good man to use the coking method of firing; but so far as my experience goes, it requires a man with no more physical capacity than the other methods and gives far better results as regards economy and smoke. As far as keeping steam is concerned, none of the plants where this method is used, to my knowledge, has had any difficulty in producing all the steam it required. In fact, these plants have been keeping up the pressure with one less boiler than was formerly used, mainly due to the increased economy resulting from this method of firing, since through this method all of the volatile matter which formerly went up the stack in smoke is now consumed, resulting in a considerable increase in evaporation per pound of coal or, for the same steaming capacity, a considerable reduction in the amount of coal fired. When it comes to forcing a boiler beyond its normal capacity, no method of firing can be used which will result in smokeless combustion. If one fires frequently with a thin layer of fresh coal all over the fire, a very considerable amount of volatile matter is driven off in smoke and is unconsumed. This is never economical, nor is it preventing smoke.

The question of which method to indorse is a question of which is the most satisfactory from the smoke-prevention standpoint and economy. The fact that the spreading method is used far more frequently than the coking method is due to its being easier, not necessarily more economical.

I quite agree with Mr. Weaver that the bonus system of payment is well worth considering.

HENRY D. JACKSON.

Boston, Mass.

The Benefit of Organization

Mr. Levy hits the nail on the head in the February 28 issue when he says in his letter under, "Engineer or Laborer": "There is no mistaking the fact that the engineers of this country must organize. Not only engineers but every man engaged in the generation and transmission of power should be a member of one organization." The engineers and firemen of this city have just formed an organization such as he mentions, called the Brotherhood of Power Workers, composed of engineers, firemen, oilers and other power-plant workers. The consolidation of all power workers into one organization has proved a good move and the engineers, firemen and others can readily see that it is to their advantage to pull together.

According to a circular being distributed, there is nothing in the rules or by-laws of this organization that the most timid and conservative need object to. I quote a few lines from the circular:

"This organization does not demand a uniform wage for its members as conditions differ in every plant. It does not demand recognition of the brotherhood or the signing of agreements; neither does it ask that none but members of the brotherhood be employed in any particular plant. It has eliminated everything that would cause needless friction between its members and their employers. The brotherhood has a labor bureau for the benefit of unemployed members, also a system of education on trade lines that will raise the efficiency of the membership. License legislation and enforcement of the present law will be followed up. It will pay a sick and accident benefit of $5 per week and at the death of a member his beneficiary will receive $1 for each member in good standing. To raise the efficiency of power workers, to secure the results due a higher efficiency and to establish an insurance department that will bury the dead and care for the sick and disabled members, is the work cut out for this organization."

It will be seen from the foregoing that possible causes for friction are removed, such as the demand for "closed shop," etc. The organization is not affiliated with any labor union (though it is not opposed to unions) and has provided for fine or expulsion of any member who takes the position of any organized worker trying to better his condition. The brotherhood has received inquiries from many of the surrounding cities and towns asking for information. It is said that steps will soon be taken to organize this section of the State.

C. C. HARRIS.

Springfield, Mass.

Pumpless Condenser

I read with interest Mr. Fryant's article in the March 7 number concerning a pumpless condenser. Here in the copper country there are several such condensers. In the plant where I am engineer there are two; only one of these is ever in use at one time. The exhaust of three engines is received by the condenser a part of the time.

The condenser is about 75 feet above the engine-room floor and there is about 50 feet of horizontal exhaust pipe before the rise to the condenser begins. Water comes to the condenser under a pressure of about 40 pounds. The reason why the condensers are so high above the engines is because the discharge water is used for cooling the jackets of a blast furnace which is considerably taller than the power house.

F. W. BAIR.

Hancock, Mich.

Grouting Bedplates

I take exception to that part of Mr. Knowlton's article in the March 14 issue which deals with the wedging and grouting of engine bedplates. First, he states that when using concrete foundations the bottom of the bedplate cannot be planed. But, what is the use? Seeing that the bedplate and cylinder have to be leveled and alined, and there is to be at least 1½ inches of grout put under the bedplate, it is a useless expenditure of time and money to plane the bedplate. Further, the grout will not take as strong a hold on a machined surface as it will on a rough one.

If the grout is properly placed it does not make any difference whether a rib is 4 or 6 inches wide as far as the prevention of end motion is concerned. Nor is it necessary to have machined wedges with which to level up an engine bedplate as he states. The practice of two of the largest engine builders in America bears me out in this. The usual supply of packing plates and wedges furnished to their road men is made from ordinary bar steel and consists of plates of assorted thicknesses, such as 1/4, 3/8 and 1/2 inch and 2 or 2½ inches wide by about 5 inches long. The wedges are made of the same material, but drawn to an edge of about 1/16 inch. As these wedges and plates are usually pulled from under the castings by the erecting men before leaving the job and either left on the premises or thrown away, it will be seen that it is not good economy to furnish very expensive material.

Assuming that the foundations are built of concrete (in modern practice this material is used almost exclusively), if the upper surface of the foundations is smooth, it should be roughed up, with either a diamond-point chisel and sledge or a pick, and then thoroughly cleaned of all fragments and dust. After placing the bedplates and cylinders and raising them to and leveling them at the proper hight the surface of the foundations should be thoroughly wetted with clean water.

Should pockets or spaces between ribs in the interior of the casting not be provided with vent holes, short pieces of 1/2- or 3/4-inch pipe can be bent into a U-shape and inserted in each pocket or between the ribs that have no core holes cast in them. The pipes should be stood in a vertical position, so that the upper ends will be at least 6 inches above the surface of the foundation. A dam built of boards or other material can then be built around the engine at a distance of 3 inches from the edge of the casting. The dam can be made practically water tight by placing ordinary sand against the outside. Grout can now be mixed in a box made for the purpose. The proportions should be one part of sand and one of cement. Water should be added until the mixture is of the consistency of good thick paint. It may then be bailed out of the box and poured under the casting until it reaches a hight of at least 4 or 5 inches above the bottom of the castings.

After a lapse of 48 to 60 hours the grout will be found to be hard enough to require a hammer and chisel in cutting away all of the surplus material extending outside the bedplate.

The purpose of the U-tubes is to allow the escape of any air that might otherwise be trapped when the grout was poured. The trapped air might prevent the grout from flowing under the casting evenly if there were no means provided for the escape of the air.

After the grout beyond the edge of the casting has been trimmed off, the job is completed and the engine about ready to start. The wedges can be withdrawn and the U-tubes cut off with a hammer and chisel at the face of the bedplate. It is a safe plan to remove the wedges as this will eliminate any tendency of the engine to move. It is a well known fact that two metal bodies move more easily on each other than metal resting on some other material such as concrete. If the surface of the foundation has been properly prepared so that the grout can form a good bond to the foundation, there need be no fear of the engine becoming loose if anchor bolts should become loose.

[illegible]

[illegible]

Inquiries of General Interest

Questions are not answered unless accompanied by the name and address of the inquirer. This page is for you when stuck—use it

Loss of Steam Through Nozzle

What would be the loss in horsepower per hour through a nozzle if the circular opening at the end is 11/64 inch in diameter, blowing into the atmosphere with 110 pounds boiler pressure?

R. A. H.

The opening at the end of a short, smooth converging nozzle may in this case be regarded as an orifice from which the steam will issue at a velocity closely approximating 900 feet per second. The area of a circular orifice 11/64 inch in diameter is 0.0232 square inch, and at a velocity of 900 feet per second there will be discharged

$$\frac{0.0232 \times 900}{144} = 0.145 \text{ cubic feet}$$

One cubic foot of steam at 110 pounds gage pressure weighs 0.2791 pound and the discharge per hour will be

$$0.145 \times 0.2791 \times 3600 = 145.65 \text{ pounds per hour}$$

Calling a boiler horsepower the evaporation of 30 pounds of water per hour, the horsepower required to supply the steam blowing through an 11/64-inch nozzle at 110 pounds pressure will be

$$\frac{145.65}{30} = 4.855 \text{ horsepower}$$

Using Napier's formula

$$W = \frac{A\,P}{70}$$

for the flow of steam from an orifice, in which

W = Pounds of steam discharged per second,
A = Area of orifice, square inches,
P = Absolute pressure, pounds per square inch,

the flow would amount to

$$\frac{0.0232 \times 125}{70} = 0.041 \text{ pound}$$

and

$$0.041 \times 3600 = 147.6 \text{ pounds per hour}$$

$$\frac{147.6}{30} = 4.92 \text{ horsepower}$$

Waterproof Belt Dressing and Cement

Please give me formulas for waterproof belt dressing and waterproof belt cement.

W. N. K.

Gutta percha dissolved in enough bisulphide of carbon to make a liquid of the consistency of molasses makes a reliable waterproof belt cement.

Neatsfoot oil containing 10 per cent. of dissolved beeswax makes a dressing which preserves the leather and makes it somewhat repellent of moisture. A repellent quality can be imparted to the leather during the tanning process by the use of bichromate of potash.

Single Valve Engine

What is meant by the term single-valve engine?

S. E.

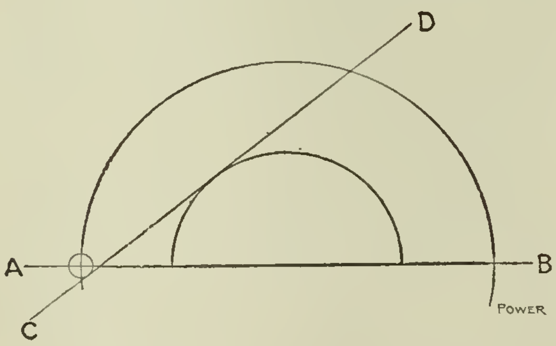
A single-valve engine is one in which one valve controls the admission, distribution and exhaust of steam for both ends of the cylinder.

Point of Cutoff

If the travel and lap of a plain slide valve are given, how can the point of cutoff be found?

V. C. P.

On the line $A\,B$ draw a semicircle with a radius equal to one-half the valve travel. From the same center draw another with a radius equal to lap of the valve and at the intersection of the valve-travel semicircle and the line $A\,B$ a circle with a radius equal to the lead of the valve. Then where the tangent line $C\,D$ cuts the outer semicircle will be the point in the path of the crank pin where the cutoff will take place.



FINDING POINT OF CUTOFF

Protection for Cotton Hose

What preparation can I use on the outside of cotton fire hose to prevent decay?

H. C. P.

None at all. Keep it perfectly dry and free from dust that may collect and hold moisture.

Motor Operation on Circuit of Higher Voltage

Can a 110-volt motor be operated on a 220-volt circuit without injuring it? If so, how?

L. S.

Yes; by connecting it in series with a resistance the number of ohms of which is equal to 110 ÷ *motor current.* It must be operated at constant load; if the load is reduced the motor speed will increase, and *vice versa.*

Alternating-current Phase Relations

Is the working or power component of an alternating current in phase with the wattless current or with the impressed e.m.f.?

F. W. G.

It is in phase with the impressed e.m.f. Two different components of anything cannot coincide; if they did there would not be two of them.

Steam Consumption and Power Factor

If the power factor of the load on an alternator is 80 per cent., will the engine driving the alternator take more steam or less than it would with 100 per cent. power factor, the true power being the same in both cases?

C. W. N.

Slightly more steam, due to the fact that the armature losses are greater with the lower power factor. For the same true power and terminal e.m.f., the armature current will be 25 per cent. greater at 80 per cent. power factor than at 100 per cent. The difference in total driving power required, however, is very small, because the increase is 25 per cent. of a small percentage of the net output.

Gas Engine Power and Cylinder Temperature

Does the power of a gas engine increase with an increase in the cylinder temperature?

F. E. W.

Not necessarily. When it does, the increase is not great enough to justify running the engine over-hot.

Merit and Bonus System Combined

In a special message to Congress, President Taft transmitted the twenty-seventh annual report of the Civil Service Commission. The report shows that the commission is in favor of the merit system, because it is indispensable to economy and efficiency in governmental affairs.

The commission urges legislation looking to increased efficiency in the service, especially a reclassification of salaries in accordance with the work performed, with enough grades to insure frequent promotion.

Although the merit system will work to the advantage of large corporations and those employed by them, and also to the benefit of power-plant owners, it is not so attractive to engineers and firemen employed by them.

It would seem that a combination of merit and bonus systems would work well in the power plant. If this kind of a system were adopted, it would not mean that the man who did good work would occupy the best position, but that the man who did good work and operated his shift more efficiently than the other man would be the favored one.

For instance, a power plant is operated with three shifts of men. On each shift there is an engineer, an assistant engineer, two oilers and four firemen. The men on each shift draw the same pay and use the same amount of supplies and fuel. In fact, one costs the company as much money as the other.

The engineer of one shift, however, begins to take an interest in cheaper operation. He has a talk with the chief engineer who agrees to give the men a certain percentage of the money they can save the company by being more careful in the use of supplies and in the consumption of fuel. The men on the shift are notified and every avenue of needless waste is closed. There can be no doubt but that this shift will make a better showing than the other two shifts in the cost of delivering electrical energy to the switchboard.

And it is not far to look for the reason. The men of one shift have been working for additional pay, the men of the other two shifts have simply been working to earn their weekly wage. Let them know that the men of one shift have been drawing a bonus of a dollar or more per week, because they used a little extra precaution in doing their work, and a protest will be made because they also have not been given an opportunity to make extra money. In one case the men were merely holding their jobs and firing coal; in the second case they shoveled coal with intelligence and were paid according to their ability to save.

Not glory, nor a burning desire to save the company money prompts a fireman to save coal, or an engineer to prevent needless loss of steam because of leaky valves; the incentive is the dollar. Hang one up and men will struggle to reach it. Tell them it is theirs if they earn it, and they will fight for it. Tell them that a percentage for every dollar saved over existing operating conditions in the power plant will be theirs, and a saving will be made in the operating expenses of the plant.

A bonus to the men rather than a check to the coal dealer for an amount several times in excess of their increase looks like a profitable investment. Try it out and see.

Low Pressure Turbines with Gas Engines

In a gas engine having an efficiency of thirty per cent., seventy per cent. of the heat furnished to the engine, minus the small amount lost by radiation, is voided in the jacket water and the exhaust. The jacket water may be delivered at a temperature approaching that at which water will boil at atmospheric pressure. The exhaust gases leave at temperatures upward of a thousand degrees. The jacket water, if placed in a vacuum, would, without further heating, give off considerable steam which might be used in a low-pressure turbine, and the gases could be used in a boiler which would furnish steam at a higher pressure. The two could be used in a mixed-flow turbine, or the jacket water could be used as the boiler feed and all the steam sent to the turbine at the higher pressure.

The hot gas as it comes from the producer has, by reason of its high temperature, considerable potentiality for steam making, but this is largely absorbed in the boiler or vaporizer which makes steam for the producer itself, and any attempt to take low-pressure steam off from the hot water coming from the wet scrubber would similarly involve trouble from carrying impurities into the turbine.

The possibilities of the subject are discussed in an article by Edwin D. Dreyfus in this issue, and it is suggested that by a system of thermal storage the heat voided by gas engines when running upon light and normal loads may be accumulated and used in a turbine to help over the peak.

The Scrap Habit

A noted English engineer on being asked what single feature of American shops most impressed him, replied: "The scrap heap." It is undoubtedly one characteristic of American practice to discard machinery as soon as it becomes out of date or inefficient, without much regard to its physical condition. The Englishman is economical of material and less so of labor. Here it is the labor that counts and, until recently, material has received scant courtesy.

It is not, however, of this phase that we wish to speak, but of individual economies, of private scrap heaps.

The corporation may scrap valuable machinery and the superintendent in his official capacity may approve of it, but the individual in his private life still retains traits of frugality and economy which have come down to him from his Puritan ancestry. When a man is living in a log cabin in the wilderness, he naturally saves every scrap of leather, every bit of iron, for he does not know when or where he may get others; and in the old-fashioned country villages with every man his own tinker, similar customs prevailed.

A recent issue of one of the standard magazines contains an article in which a well-to-do business man is represented as jumping from his carriage to pick up a new brick by the wayside and as saying that he gets enough bricks in this way to save a large part of the expense of repairs about his premises. He furthermore intimates that even if he has no use for the brick, he hates to see good material wasted. None but a rich man, whose time has ceased to have a market value, can afford to get his brick in this way. No, this is not economy, it is just the old Puritan habit of collecting and saving everything in one's path, whether useful or useless, a miser's instinct. The man just mentioned might, with as good reasons, have extended his drive to the railroad yards and picked up fragments of coal, thereby reducing the heating bill at his residence.

One who is constantly picking up scraps of leather, brass and iron, old hinges, bolts, nuts or pieces of pipe, usually has his labor for his pains. The stuff is never used and gradually accumulates in the attic or cellar, on the bench or under it until the would-be owner gets desperate and throws it all away. The argument used to be: "Save it, for you never know when you may want to use it." The argument should be: "If you never know when you may want to use it, don't save it."

There is a reasonable excuse at the house for saving twine and wrapping paper, for experience has taught that there is always use for them. In the engine room, nuts and bolts, pipe fittings and pieces of brass or leather may have future value. If saved, each should have its pigeon-hole or compartment, where it can be found when wanted.

A miscellaneous collection of junk, such as is found in some engine rooms, is wasteful rather than economical and should be disposed of to Tony or Isaac for what he will give.

Experience is a good teacher in this matter; in each particular vocation—the man-at-home, the superintendent or the engineer, has learned by experience that certain things are in demand and always find use; such things can well be saved.

Shall I keep this stove bolt and nut? Yes, I do use one occasionally and it may save a trip to the store.

Shall I keep this cast-iron bracket? I never did have a use for one and I do not know that I ever shall. No, better throw it away than to litter up your bench or floor "on suspicion."

The writer speaks feelingly on this subject for he has had the habit in its worst form. Repeated cleanings of attics and sheds and boxes and barrels have finally convinced him that much scrap means weariness and vexation of spirit and he has reformed. He does not pick up pins or bent nails or bricks; he passes by on the other side and leaves them to the Good Samaritan who has a carriage with which to haul them home.

The rusty hinge and the old bolt have no further attractions. He does not even save a piece of string unless he sees in the immediate future a use for that particular kind of string. He has more time available, he enjoys walks abroad and has no longer the terrifying prospect of an attic or a cellar crowded and disfigured with miscellaneous junk.

Apparent Efficiency

Just now we are hearing a lot about efficiency; the salesmen have taken it up as their slogan and even the daily newspapers have begun preaching it, since the recent claim of a certain Bostonian to the effect that he could save the railroads of this country a million dollars a day by introducing more efficient methods. Ostensibly, efficiency is the goal to be aimed at in all fields of activity, whether railroading, power generation or purely commercial enterprises, but in every case the meaning of the term "efficiency" in its broadest sense—the relation of useful result to effort—should be kept in mind. Too often only one phase of the problem is considered and "apparent" efficiency is attained at a sacrifice in economy. This is illustrated more particularly in the generation of power where the installation of a certain piece of apparatus may effect a saving of three or four per cent. in energy between the grates and the switchboard; yet its first cost and the cost of maintenance may more than offset the saving in energy.

It has been estimated that, excluding special cases, the cost of power in a manufacturing establishment amounts to from two to four per cent. of the cost of producing the manufactured article. Hence a piece of apparatus effecting a saving of three per cent. in the production of power would save only twelve-hundredths of one per cent. on the cost of manufacture, which slight gain might not warrant the extra investment. It is always well in such cases to carefully consider economy as well as efficiency before passing snap judgment.

It is a good thing to know that a steam line is thoroughly drained. Water has a habit of smashing things if, while traveling at high velocity, it is brought to a sudden stop.

Some engineers can tell you all about the horses and sporting events generally but when it comes to intelligently explaining the why of the simplest things in the engine room, they are all at sea.

A nonreturn valve in a steam main may never pay for the cost of the paint on the outside, but if a pipe or fitting should burst, there are great possibilities that it will pay for itself a hundred times over in preventing loss of life and damage to property.

Have you ever noticed how reckless the man in charge sometimes is when it is necessary for him to personally work with his hands? He should be the man to set an example to others of being careful.

According to their talk, some men can do anything, but when put to the test they cannot do even a third-class job without help.

Have you noticed how some engineers, repairmen and others leave everything to the last minute and have to stay on and finish after shutdown when the repairs could have been made just as well during the day?

You know that there are always some men who can run your plant far better than you are doing it.

A small trouble neglected will often cause a big shutdown.

Not much use throwing coal into a furnace while the safety valve is blowing.

An engineer cannot get experience for nothing; it must be paid for.

Reduction Gear for D.C. Generator

A multistage turbine running at three thousand six hundred revolutions per minute, driving a direct current generator through a seven to one single reduction gear.

Heretofore, the steam turbine in large sizes has found application only in driving alternators and in the propulsion of ships, very little progress having been made in adapting it for driving direct-current or other machinery of moderate speed. High speeds applied to direct-current generators involve serious commutator troubles and structural difficulties, and it is conceded by most designers that the speed of 1000-kilowatt machines should not exceed 600 revolutions per minute and this speed has, in fact, been found most suitable for smaller machines even down to 500 kilowatts.

This speed, however, is entirely too low for the ordinary turbine. The speed of a turbine may be reduced in two ways: First, by increasing the diameter of the rotor, and, second, by increasing the number of stages. To accommodate it to the speed of a direct-current generator would necessitate a rotor of such a diameter as to seriously affect its strength; on the other hand, this speed would require such a large number of stages as to make the machine unusually long and thus introduce other difficulties and losses. The alternative then is to introduce reduction gearing between the turbine and the generator.

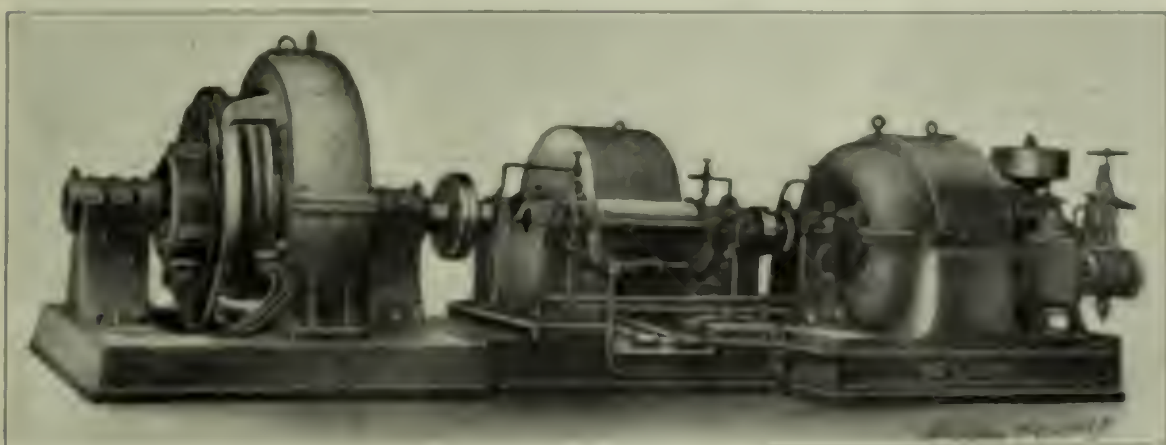

Fig. 1. Turbo-generator Complete

The De Laval Steam Turbine Company for a number of years has employed single- and double-helical reduction gears on its small- and large-sized single-stage machines, respectively; the latter, however, driving only alternators or high-speed pumps. But only recently have they applied the single-helical gear to the multi-stage turbine for driving a direct-current generator of large size.

This unit, which is shown in Fig. 1, consists of a four-stage turbine driving a 500-kilowatt direct-current Crocker-Wheeler generator through a pinion and single gear, the speed of the turbine shaft being 3600 revolutions per minute and that of the generator 500 revolutions per minute, making the reduction ratio over 7 to 1.

The main casing, which is of cast iron, is nearly cylindrical in shape, being split horizontally so that the top half may be lifted off to give access to the revolving and stationary members of the turbine. The casing is supported on a level with the center of the shaft by two pedestals rising from the bedplate, one on each side, and is bolted down only at one end, thus permitting expansion and contraction in an axial direction between steel guides. As the endwise position of the shaft is also determined by a thrust bearing at the same end, the results of axial expansion are largely compensated for.

Steam is admitted to the turbine first through a strainer case and then through a combined trip and throttle valve, shown in Fig. 2; next through the adjacent governor valve and, after passing through steam nozzles, impinges upon the blades of the first-stage wheel. Partial admission is used in the first stage, and full admission in the succeeding stages. The wheels are of the standard De Laval type, and as a protection against flying pieces of metal in case a wheel should break, it is completely surrounded by a heavy steel band.

The governing mechanism, which is also shown in Fig. 2, is in duplicate, that is, there is a speed-regulating governor and a speed-limiting or emergency governor. The former is mounted at the top of a vertical shaft and is driven by a worm gear from the turbine shaft. It controls the movement of a vertical double-seated poppet valve similar to that used on standard De Laval turbines. The lower end of the governor shaft is connected to an oil pump which supplies the bearings of the machine and the pinion and gear. The emergency governor is located at the end of the turbine shaft and is ordinarily not in contact with the trip. Upon touching the latter, however, steam pressure is at once released from under a piston, by means of which a toggle gear is released, allowing the combined trip and throttle valve to close under the pressure of the steam in the supply pipe.

Fig. 2. Governor and Trip Valve

The pinion and gear are shown in Fig. 3. The gear is of the double-helical or herring-bone type, differing from the standard gears supplied with De Laval turbines only in size and the fact that a single gear is used for large capacities. The pinion is cut from a solid bar of steel and is carried in plain babbitted bearings supported in a rigid cast-iron frame, which also supports the gear bearings. The pinion bearings are lubricated by sight-feed oilers from the pump system, the excess oil overflowing to the wells of the gear bearings, which are ring oiled. The gear consists of a solid cast-iron center upon which are shrunk two thick steel rings, and the hub is mounted on a stiff shaft, which carries at one end half of the flexible coupling for connection to the driven machine. The lubrication of the gear and pinion teeth is accomplished by jets of oil directed at the line of contact on the entering side. This oil after use is passed through an oil strainer located in the base of the turbine, then through a cooling and settling chamber and finally to the oil well, from which it is again pumped through the circuit. Temperature measurements taken after the machine had been running for several hours showed a difference of four degrees between the oil entering the gear case and that leaving the case.

The operation of the turbo-generator is remarkably free from vibration and noise and as it stands in the test room, supported upon small screw jacks without other means of support, it is hard to tell at a distance of a few yards whether or not the turbine is running without noting the moving parts.

It might be mentioned in passing that the determination of the efficiency of such gears within reasonable limits of accuracy is a comparatively simple matter and does not require the use of cumbersome and expensive hydraulic brakes or similar mechanisms. That is, since all energy lost in friction in the gear must be converted into heat, the measurement of the heat emanating from the gear case will give an accurate measure of the loss of energy in the gears. Such measurement of the heat is not difficult. The radiation from the casing can be determined accurately for any given temperature by observing either the rate of cooling under fixed conditions or by keeping the casing warm by means of hot water or steam. The amount of heat removed from the gears by the lubricating oil is even more easily determined by measuring the inlet and outlet temperatures and the weight of oil used per minute or per hour.

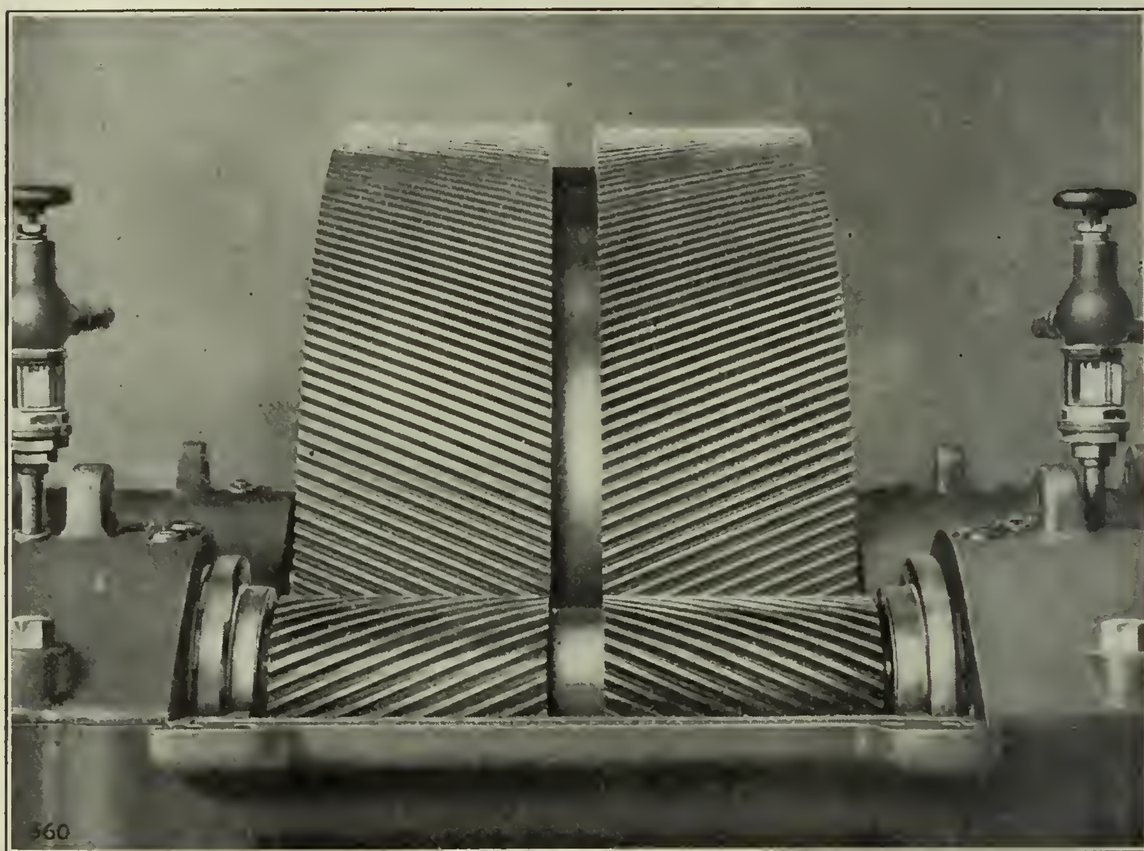

Fig. 3. Pinion and Gear

Blank Flange Bursts with Fatal Results

The fracture by water hammer of a blank cast-iron flange on the side outlet of a 20-inch tee in a live-steam line in the Amoskeag Mills, causes the death of three men. The pipe had a pitch of 20 inches in 500 feet and was drained by a trap. The damage to the plant was confined to the blank flange.

As a result of water hammer, a cast-iron blank flange on a tee in a 20-inch live-steam pipe at the new power plant of the Amoskeag Manufacturing Company, Manchester, N. H., fractured early Monday morning, March 27, causing the death of three men.

This 20-inch pipe runs the entire length of the 500-foot boiler room to the pump room, where it drops down to the basement under the turbine room. There are two 20-inch pipes, one supplying steam to two turbines, the other delivering steam to what is known as the Langdon mill.

Just inside of the basement wall under the turbine room the pipe running to the Langdon mill has a steel-riveted tee connection, put in so that the side outlet faces lengthwise of the basement, as shown in the illustration. This tee is constructed of $\frac{3}{8}$-inch steel and has a $\frac{1}{2}$-inch thick flange. The blank flange was made of 1-inch cast iron, ribbed on the outside. It was this flange that fractured, a V-shaped piece being blown from the solid section, as shown.

This particular tee was put in place when the pipe line was constructed to provide an outlet connection for another pipe line when desired.

The accident occurred just at the time the engineer of the Langdon mill was getting his reciprocating engine up to speed for the day's run. Two shocks of water hammer were felt by men employed at the far end of the boiler rooms; these were followed by a third and more severe shock, which was immediately followed by a roar, as the steam in the 20-inch main, fed by 16 boilers, rushed through the opening in the fractured flange.

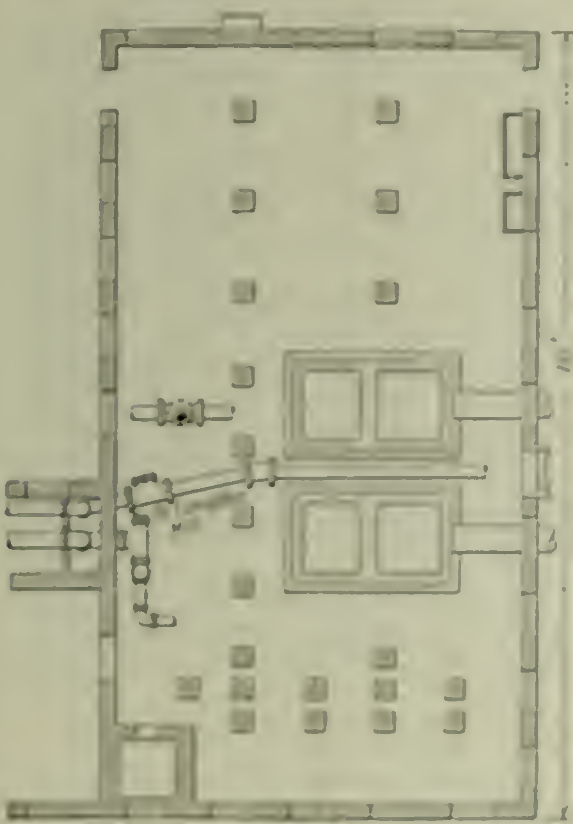
Engineer Pettigrew and Electrician Webster escaped without serious injury. As soon as Pettigrew heard the roar and saw the steam coming up through the cracks in the temporary plank flooring, he made his way through the steam to the door leading into the pump room and on into the boiler room where the steam was shut off. Webster, on his way past the one turbine that was in operation at the time, pulled the automatic which shut the unit down and probably prevented serious damage to the electrical end from running with a load while moist vapor filled the room.

A steam pressure of 170 pounds per square inch was carried on the pipe, and before the flow had been gotten under control, one man was dead, two so severely burned that they have since died and several others were burned, but not dangerously so.

Horace Crawford, an electrician, was so badly scalded that he died in a few hours. He had been at work all night and at the time of the accident had some wire in his hand. Later a window was found broken and the wire was on the outside, but evidently Crawford became confused and attempted to find another means of exit. When found he was on the floor near the double door at the end of the turbine room.

James Cassidy, a piper's helper, was found dead on the floor near where he had been last seen crossing the room. He was enveloped in steam which came up through the loose flooring. It is supposed that he inhaled steam, and immediately succumbed.

Frank Dyer, 18 years old, the last to die, was the son of Engineer Dyer, also



SHOWING LOCATION OF TEE AND NATURE OF THE FRACTURE IN THE BLANK FLANGE

seriously burned. He was just about to begin work during his Easter school vacation in order to gain experience in engineering. He had gone down into the basement to enter the wash room that was located on the opposite side of the basement from the tee connection and near the far end. He was just about to open the wash-room door (the key was later found in the lock), when the accident occurred. With rare presence of mind, Dyer ran around the end of the wash room and, opening a window that faced a dry raceway, dropped a distance of 20 feet, ran across the raceway, climbed up a ladder and jumped into a canal, doubtless to relieve his suffering. The burns and the shock of the ice-cold canal water was more than his system could withstand.

The only damage to the plant was the rupture of the blank flange. The fractured flange showed no indication of a flaw or other weakness. A new 3/4-inch steel blank flange, bumped to a radius equal to that of the diameter of the pipe, has been riveted to the dead end of the tee in place of the cast-iron blank flange.

Just why water hammer should have occurred is not known. The pipe was drained by a trap and Engineer Dyer had gone down to ascertain if a new trap that had been put in place the Sunday before was working properly. As it was, he left the basement just before the flange fractured. The steam pipe has a 20-inch pitch toward the discharge end.

Contrary to the accounts published by the daily papers, concerning the secrecy maintained by the officials of the company regarding the accident, it is but just to state that such reports were false. A POWER representative received most courteous treatment while investigating the accident and every question was freely answered.

Water Rights in California

An important decision regarding water rights for power and irrigation purposes in California has been handed down by Judge Hutton, of the superior court, Los Angeles. It distinguishes between the rights of private appropriators and the rights of riparian owners, the case at issue involving the right of the use of a 10-inch stream known as Garden Gulch creek, both parties relying on claims to prior appropriation.

On this subject, Judge Hutton rules: "It is a great mistake to assume that the waters of a stream under these conditions are the subject of appropriation. The only waters that may be appropriated are the waters of streams on Government land and this before the rights of settlers upon the stream, who, by reason of their settlement became riparian proprietors, have accrued.

"The system of riparian rights is in full effect in California; that is to say, that the riparian owner, as against all other classes of appropriators, has a right to the full flood of the stream, undiminished in quantity and unaffected in quality, except that each riparian proprietor may divert so much of the stream upon his riparian or bank land for irrigation purposes as he can put to economical, beneficial use. From the date that the rights of the settler attach to the land no appropriation can be made that will interfere with his riparian rights. His riparian rights are just as much a part of the land as the trees upon it, and unless taken away before the settler's rights accrue, he must be left in the enjoyment thereof unmolested. The evidence discloses that the plaintiff (the upper riparian owner) is threatening to take water, not from the stream proper, but from a nearby spring which obviously must either feed or be fed from the stream, and belongs to the watershed. Plaintiff has no right to carry his threats into execution and to remove all or any part of this water from the watershed. He cannot, even temporarily, do this without the consent of defendant (lower riparian owner)."

This decision shows conclusively upon what waters appropriations may be filed, and the extent of the appropriator's power of diversion.

Pressure Tank for Sprinkler System Explodes

By Edward T. Binns

On March 14, the pressure tank for the sprinkler system at the old Press building, Pittsburg, exploded. Considerable damage was done to the property and three persons were seriously injured. The tank was 72 inches in diameter and 21 feet long. It was made up of three 86-inch sheets 1/2 of an inch thick. The seams were triple-riveted lap joints, 3/4-

RUPTURED HEAD OF AIR TANK

inch rivets being used on a 3-inch pitch. The heads were made of 11/16-inch plate and were not braced.

There was no safety valve or pressure regulator on the tank, the pressure being regulated by the engineer in the engine room. The tank was located on top of the house. The boiler pressure carried was 80 pounds, and a duplex pump with a ratio of two to one was used to pump up the pressure in the tank. Some idea of the force of the explosion may be gained from the fact that one of the heads was blown out and driven broadside-on through the wall of the building. It lodged under the floor of the adjoining apartment, bending five 8x10-inch steel I-beams. Several fragments of metal and piping were blown clear through the main building and out onto Fifth avenue, a distance of 300 feet. The body of the tank was wrenched loose from its moorings, moved about 20 feet along the roof, stopping with several feet of its length protruding over the street, where hundreds of people pass constantly.

New Power House Equipment

What the inventor and the manufacturer are doing to save time and money in the engine room and power house. Engine room news

Vater System of Water Purification

This can be briefly described as a hot-process water-purifying system which takes advantage of the well known fact that chemical reactions are much more rapid and complete when they take place at high than at low temperatures. The system depends essentially on three fundamental propositions. First, the use of solutions of uniform strength; second, feeding in proportion to the load, and, third, plenty of time for the reactions to take place.

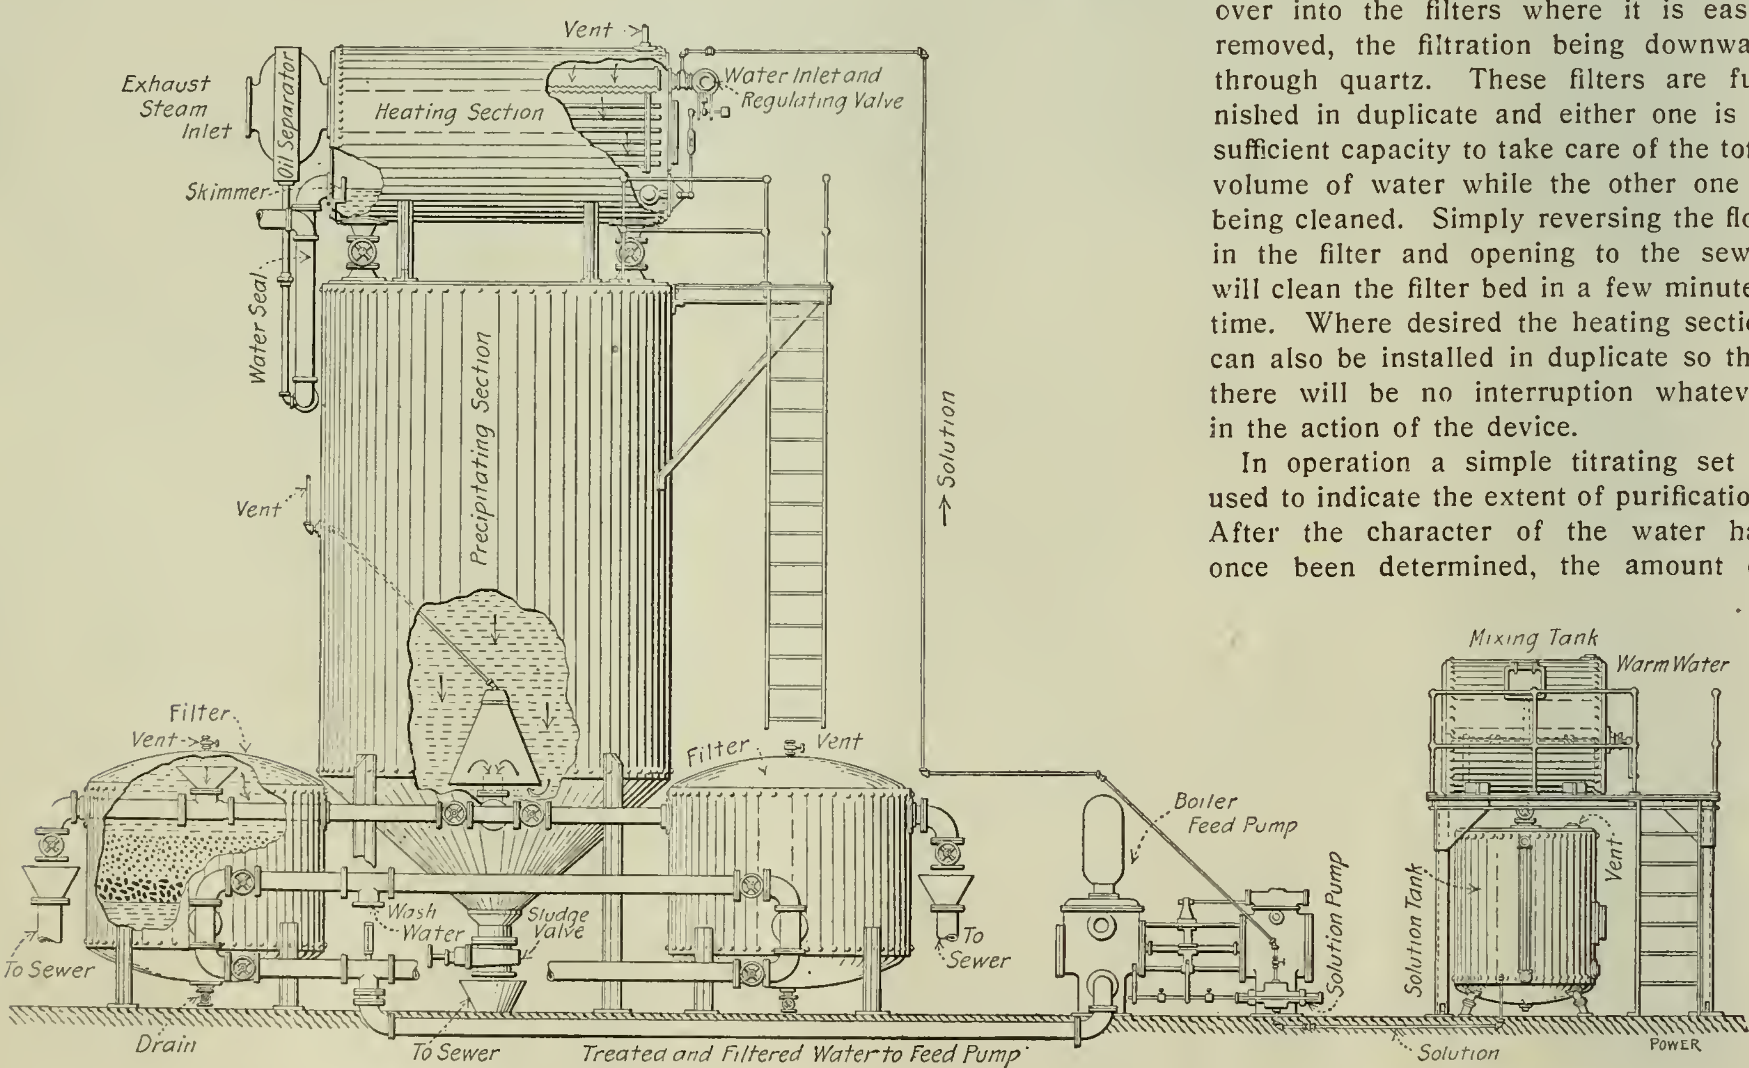
A mixing tank with paddles and crank for hand operation is provided, as shown in the part-sectional illustration. Here the reagents are mixed in the proportion indicated by the character of the water. After the mixing has been done and the solution has settled and clarified it is siphoned into the holding tank below, from which point it is taken by a special solution pump attached to the crosshead of the boiler-feed pump and delivered to the purifier proper. The solution pump is specially designed for this purpose, with a variable stroke which can be adjusted while the pump is in operation and provision is made to withstand the action of the reagents on its working parts. By providing a mixing tank and solution tank as shown, continuous runs can be made, the effect of the two tanks being the same as if this piece of apparatus were provided in duplicate.

The purifier proper consists, first, of a heating section, which is an induction open heater, in which is arranged a system of pans designed to break up the water into small particles and facilitate the transmission of heat, and, second, a precipitating tank. An oil separator is connected to the heater, which removes any oil that may be in the steam and allows the condensed steam to form part of the treated water.

A float valve control is arranged in the heater, maintaining the water level at the desired point, and two valved connections are arranged for the water to descend into the precipitating section. As the solution pump is connected to the feed pump, just the amount necessary for softening the water being used is introduced into the heater, where it is raised to exhaust-steam temperature and intimately mixed with the water before entering the precipitating tank.

The latter has been designed to give ample time for the reactions to take place. It is found that 90 per cent. of the impurities are precipitated at this point in the form of a sludge which can be blown out from the cone-shaped bottom of the tank. The light, flocculent material passes through the inverted cone-shaped intake, over into the filters where it is easily removed, the filtration being downward through quartz. These filters are furnished in duplicate and either one is of sufficient capacity to take care of the total volume of water while the other one is being cleaned. Simply reversing the flow in the filter and opening to the sewer will clean the filter bed in a few minutes' time. Where desired the heating section can also be installed in duplicate so that there will be no interruption whatever in the action of the device.

In operation a simple titrating set is used to indicate the extent of purification. After the character of the water has once been determined, the amount of color given to a test sample when titrated is a correct indication of the condition of the purified water. The operator is given a small bottle of water properly colored and he uses this as a guide when making up his solution. If he finds on titrating a sample that he has mixed a solution



Showing Arrangement of the Vater System of Water Purification which is too strong, or, in other words, if the result of his test shows too much color in the sample, he simply reduces the stroke of the solution pump so as to feed the solution in less quantities. Similarly, if he finds the solution weak he can increase the stroke of the pump to compensate for this weakness.

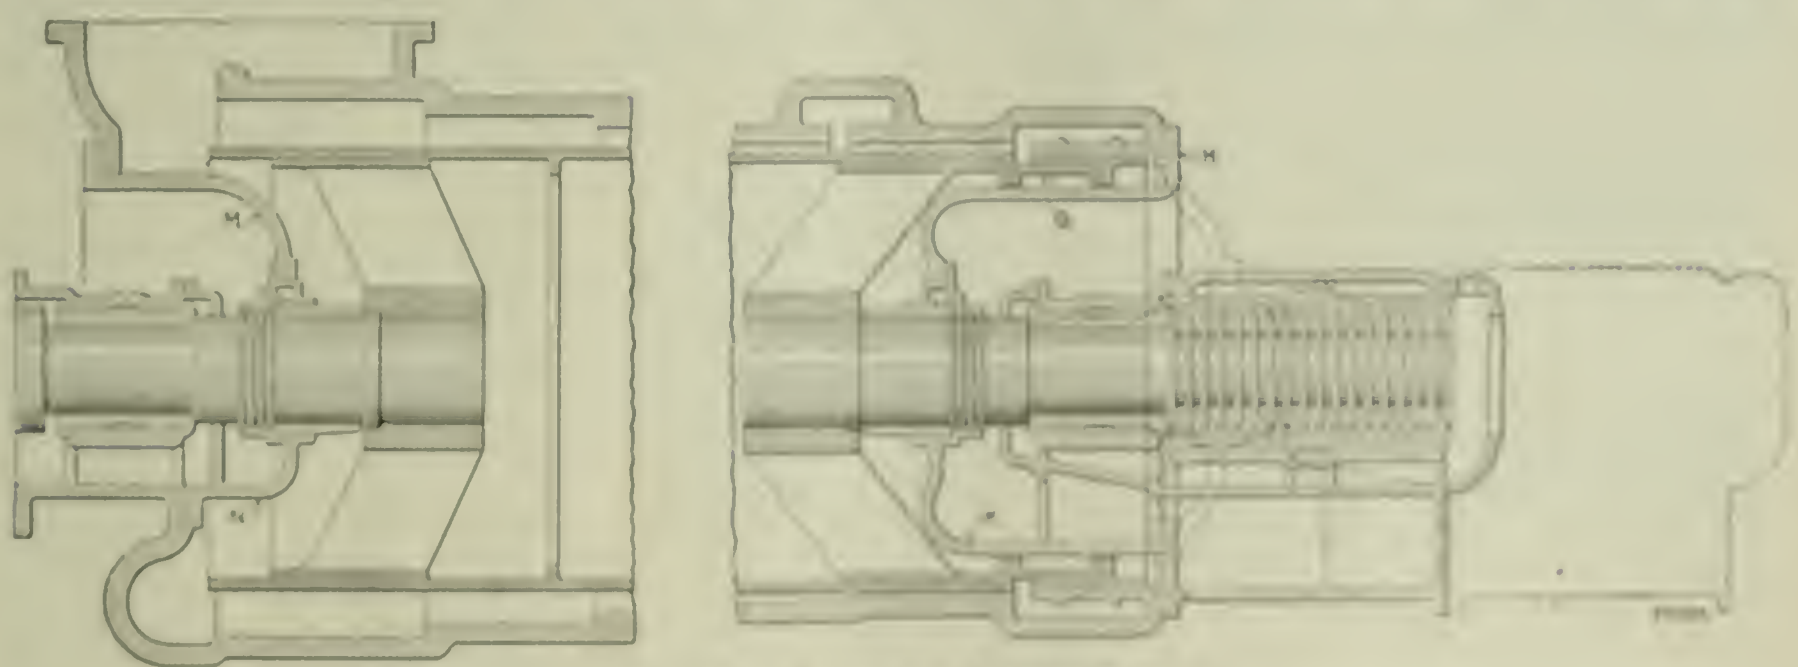
It is claimed that the apparatus will reduce the incrusting solids to as low as 1½ grains per gallon, with an excess of solution not exceeding ½ grain per gallon. Any combination of reagents can be used without making alterations in the equipment and the water is delivered to the boilers at a high temperature, thus doing away with the necessity for a feed-water heater where a softener is installed.

The Vater water-softening system is built by the Power Plant Specialty Company, Monadnock block, Chicago, Ill.

New Parsons Turbine Casing

When the turbine casing is made in halves, with the ends cast on, the end or head cannot project inside of the rotor drum, as it would not allow the latter to be lifted out; nor indeed to be inserted. A British patent has just been issued to the Hon. Charles A. Parsons for a casing of which the form illustrated herewith in an example.

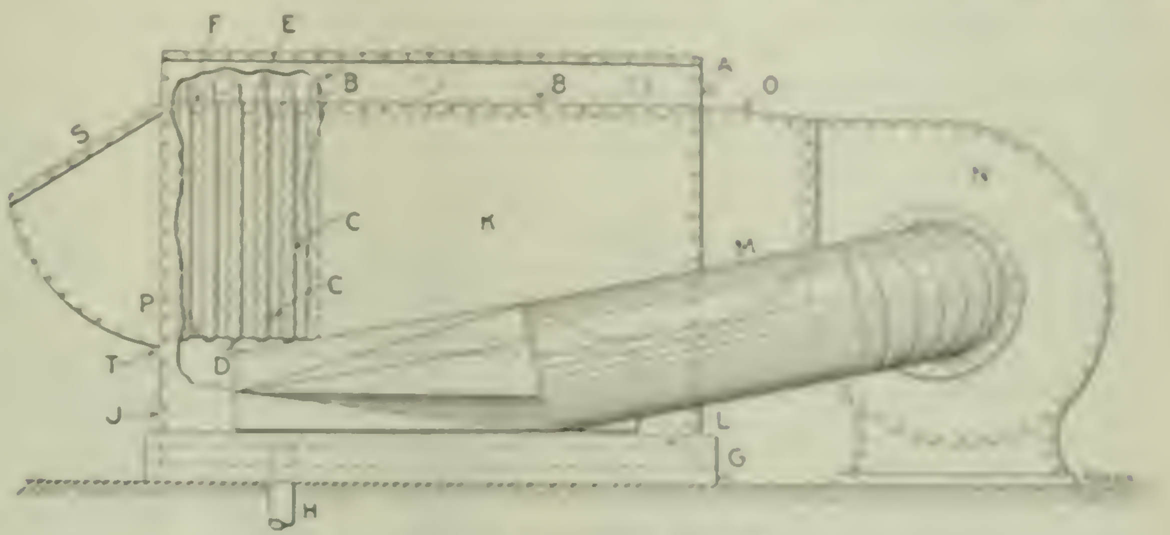
The cut shows the casing, parted longitudinally at the center as usual, but with the heads cast in the four separate pieces H K and M N. The rotor G, including the driving pistons, extends well over the head, but the latter can be unbolted and removed in sections, the under halves being turned around the shaft and lifted out like the lower boxes of a bearing. Were the heads cast integral with the rest of the casing the bearing and thrust block would extend at least to the dotted position, greatly increasing the length and weight of the turbine, and the difficulties which go with a long rotating member.



New Type of Casing for Parsons Turbine

A Liquid Cooler

The accompanying illustration represents a liquid cooler that has been designed for the purpose of cooling liquids, such as condenser water from ammonia coils.



Details of Liquid Cooler

The cooler consists of a blower and a bank of double cooling tubes inclosed in a sheet-iron casing. The liquid to be cooled flows through a header (not shown) and is distributed over the pan A by the short pipe connections B B; it then takes a downward course through the bank of tubes, between the tubes C C and D D. E, it will be noticed, is only an extension of the tubes D, bringing the top of the tubes far enough above the tube sheet F to prevent the liquid from flowing over the top into the center of the tubes D D, thus producing a hollow column of liquid.

The lower ends of the tubes D are expanded just large enough to pass snugly through the larger tubes C, thus making a regulating valve of each set of tubes so the flow of liquid can be controlled, as the time taken by the passage of the liquid through the tubes plays an important part in the final temperature. The liquid is then received into the tank G, the level of which is maintained by the height of the top of the return pipe H through which the liquid is returned to the point it came from as hot liquid to again do its mission as a cooling agent.

The extension J at the bottom of the casing K drops below the liquid line L maintained by the top of the pipe H, thus forming a seal for the purpose of keeping the air drawn downward through the tubes D and to prevent the outer air entering the suction pipe M of the blower N and destroying the vacuum thus created.

The air is then discharged back through the connection O into the chamber around the outer tubes C and between the upper and lower tube sheets P and F and finally is discharged out of the cooler through the connection S.

The water which is carried over with the blast of air through the cooler is allowed to drain back through the opening at T; thus none of the liquid is wasted but is all finally carried back to the tank G. The temperature of the liquid can be lowered from 100 degrees to about [illegible] degrees in summer weather, it is stated. The cleaning of any sediment or deposit that is common in an equipment of this kind can be easily removed at any time without stopping the cooler at all, on account of the arrangement of the tubing.

The adjustment of the flow of the liquid is accomplished by a lever (not shown) which, by a movement either up or down, increases or diminishes the flow of the liquid through the inner tubes *D*.

The only additional water used is the water with which the air is sprayed—this makes it possible to reach a low temperature during the hot and sultry days of summer. This spray is at the top, over the pan *A*, and is not lost as it unites with the water being circulated through the cooler.

This device is made by F. P. Hopkins, 1361 Bonnie View avenue, Lakewood, O.

New Era Self Lubricating Metallic Packing

The packing shown herewith is an improved product, which, consisting of a nonelastic, compound mass of metallic lubricants, requires no lubrication whatever except that contained within its own substance. It is claimed by the manufacturer that it never becomes charred or otherwise unfit for service and that it will not lock or score the rods, plungers, or shafts on which it is used. Fig. 1 is a sectional view of the packing in place, as manufactured by the New Era Manufacturing Company, Kalamazoo, Mich. *A* represents the piston rod; *B* the body or stuffing box; *C* the stuffing-box gland; *D* the main body of packing container; *E* the supplementary gland; *F F* the bearing rings; *I I* the self-lubricating metallic packing, and *J* the metallic rings which surround the rod in three sections, as illustrated in Fig. 2.

The bearing rings *F F* admit lateral motion to the main body of the packing container *D*, and supplementary gland *E*, to compensate for any movement of the piston rod when out of alinement.

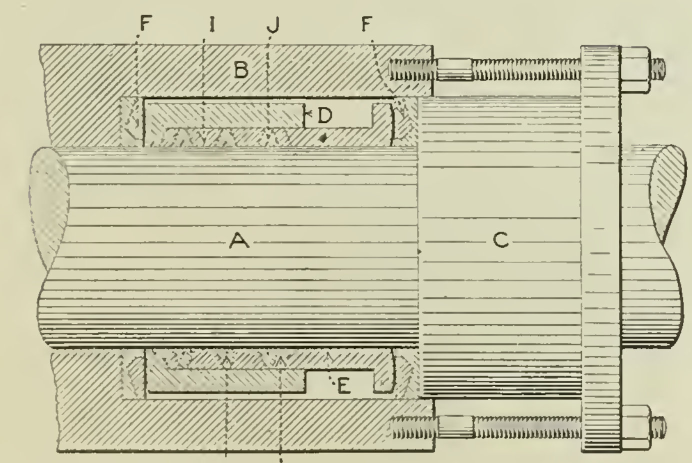


Fig. 1. Sectional View of Packing Container

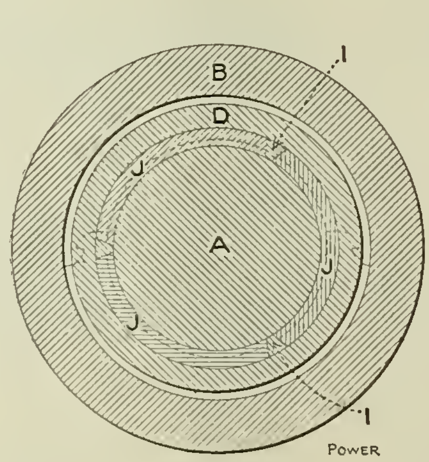

Fig. 2. Transverse Section

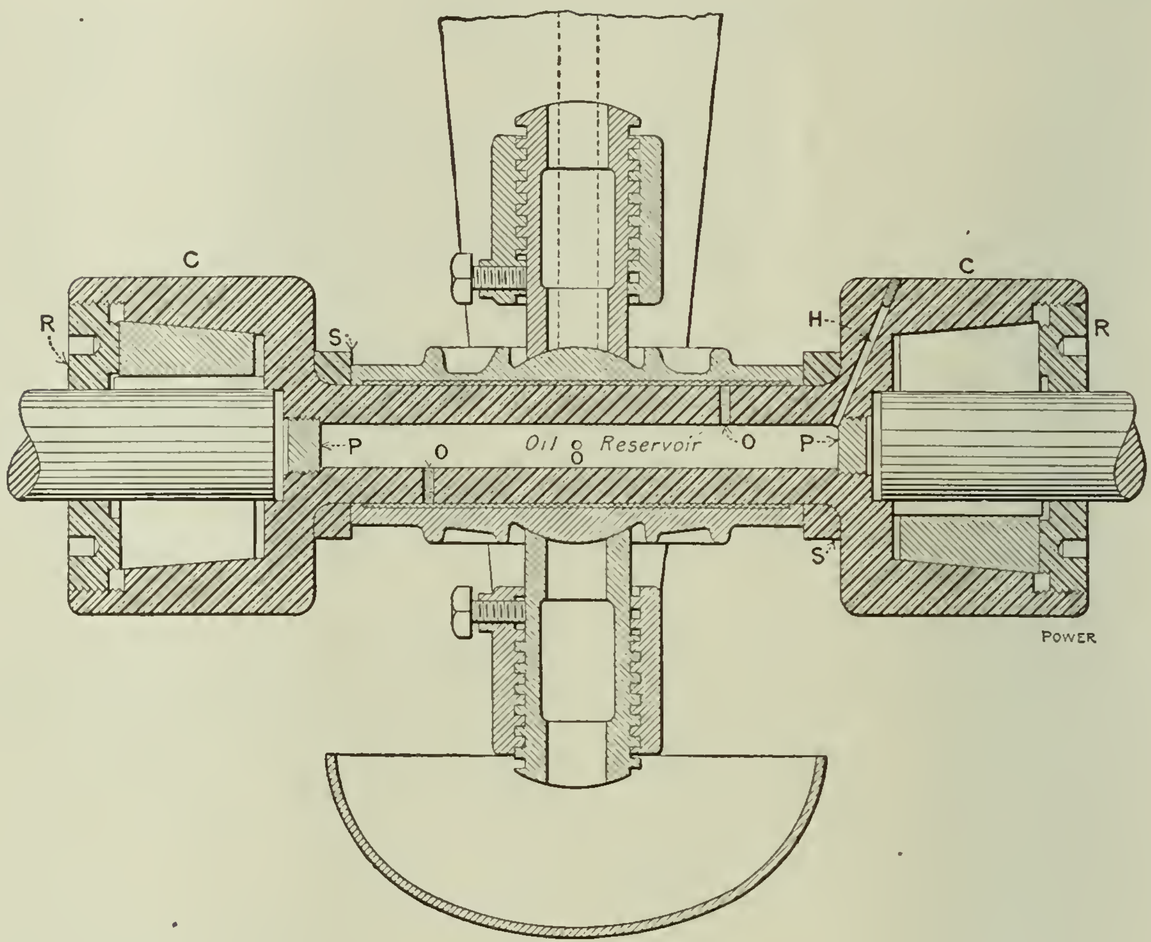
As shown in Fig. 2, there are three metallic packing rings surrounding the rod, the space between their ends being occupied by the plastic packing *I*. This latter may be renewed whenever necessary and serves to take up wear on the packing as it occurs. It can be placed on an engine without dismantling and when occasion requires.

A Self Oiling Hanger Coupling

In the accompanying drawing is shown a self-oiling hanger coupling, the object of which is to connect two sections of a line shaft at a hanger, thus providing more space on the shaft for pulleys. It is made with a reservoir for holding lubricating oil that is fed to the bearing through the oil holes *O*, which are fitted with felt to prevent the oil from flowing too rapidly.



Combination Hanger and Coupling

This style of coupling supports the shaft at its weakest point. The coupling can be used on any standard hanger and can be made with or without the oiling device.

It consists of a steel forging *C*, which is turned in the center to form the journal, and has the cone cups on each end to receive the ends of the two sections of shafting to be coupled together. The cones are forced in by the threaded rings *R* with a spanner.

The split rings *S* are used to take up the lateral play of the shaft.

In making the oiler for the coupling, a hole is drilled through its entire length and the ends are closed by the cast-iron plugs *P*. To fill the reservoir the passage *H* is drilled from the outside, and the outer end plugged by a tight-fitting screw.

This hanger is the invention of H. C. Williamson, 309 London street, Portsmouth, Va.

Coal Land Frauds

It was reported on March 28 that Charles F. Munday, a lawyer of Seattle, Wash., was placed on trial in the Federal court on a charge of having conspired to defraud the Government of $100,000,000 coal lands near Katalla, Alaska. He and Earl E. Stacey, private secretary to the late M. J. Heney, builder of the White Pass & Copper River and Northwestern railroads, the latter the property of the Morgan-Guggenheim syndicate, and Archie W. Shields were indicted by a Federal grand jury sitting at Tacoma last October.

Generally, the indictments charge Munday and his associates with having several years ago induced dummy locators to file on the claims best known as the English group for the Alaska Development Company and the Pacific Coal Company. These claims comprise 6087 acres of what is declared by experts to be among the richest coal lands in Alaska.

Notice!

Paul Kirk, who formerly represented POWER as a subscription solicitor in New York City, is no longer in the employ of this paper.

Large Plant Taken Over by Central Station

It is reported in the daily press that the Walworth Manufacturing Company has signed a five-year contract with the Edison Electric Illuminating Company, of Boston, for all the light and power service in its big manufacturing plant in South Boston. The contract calls for service to replace five steam plants aggregating a total of 1100 horsepower capacity. The business of the Walworth company has increased to the point where the management was confronted with the necessity for a practically complete renewal of its steam-power system, the installation of an electric light and power plant of its own or the adoption of the service of the Edison company, and the central station won out.

Central Station Welfare Work

The public-policy committee of the National Electric Light Association, which, during the past winter, has been devoting considerable attention to the various aspects of welfare work as related to the central-station industry, held a final meeting at the New York headquarters in the United Engineering building on March 28, when the report which has been prepared through a series of long conferences was unanimously adopted, and the recommendations and suggestions were put in definite shape for presentation to the member companies, in number nearly a thousand, at the annual convention in New York next May.

Several of the companies already have in force some of the schemes proposed, but it is not assumed that every company will wish to adopt every form of relationship outlined in the report. The plan includes accident insurance, sickness insurance and death benefits, service annuities, profit-sharing, employees' savings and investment funds, and life insurance, although with regard to the last item it is suggested that the companies limit themselves to providing their employees with all possible information in connection with safe low-cost life insurance, and do not put in force any plan of their own.

The coming report will give in detail the methods by which provision can be made under each of the other heads. By unanimous vote the term "pension" has been dropped and the service annuity adopted as the recognition of an automatic recompense for continuous service, and the committee is of the opinion that member companies should provide such annuities for every male employee reaching the age of sixty-five, and every female employee of sixty years after continuous and satisfactory record of ten years of service. The details of profit sharing are based upon the idea that it is better to have those engaged in the industry as partners rather than employees and that preferably profits of the employee based upon his wage scale should reach him in the securities of his company and that dividends upon such securities should be paid in cash, in the manner customary with other security holders. Details are also given with regard to savings funds and investment funds, with the object of promoting thrift amongst employees and, where feasible, combining the plan with profit sharing, it having been found that the two work out very satisfactorily together.

The report will be awaited with interest by all connected with public utilities and by economists in general.

PERSONAL

John B. Youngblood, formerly State examiner for the Cleveland district, has been appointed assistant chief examiner with headquarters at Columbus, O. Thomas Eaton has been appointed to fill the vacancy left in the Cleveland district.

On April 1, James A. Donnelly, of New York City, addressed the Robert Fulton Association, Illinois No. 28, National Association of Stationary Engineers, in the rooms of the association in the Masonic Temple, Chicago. His subject was "Steam Circulation."

Robert Bosch, of Stuttgart, Germany, designer and inventor of the Bosch products, has arrived in the United States. Doctor Bosch is much interested in our great manufacturing industries, and with Otto Heins, president of the Bosch Magneto Company, of New York, is making an extended tour of the United States with the object of visiting some of the larger American industries as well as natural points of interest.

OBITUARY

George Bowers Caldwell, of Yonkers, N. Y., died, March 31, 1911. Mr. Caldwell was born at Lawrence, Mass., in 1863 and was for many years connected with the engineering department of Westinghouse, Church, Kerr & Co., as one of the chief mechanical engineers. Prior to his connection with this company he was employed for thirteen years in the machine shops of the Lawrence Manufacturing Company, of Lowell, Mass., and the Washington Mills Company of Lawrence, Mass., also in charge of their new construction and repair work.

During his connection with Westinghouse, Church, Kerr & Co., which began in 1893, he was connected with the design and construction of the following important pieces of work:

The mechanical and electrical features of the South Terminal Station, Boston, Mass., the terminal station of the Pittsburg & Lake Erie Railroad, the railroad shops of the P. & L. E. R. R. at McKees Rocks; the construction of the Kingsbridge power station, New York City, for the Third Avenue Railroad. He also supervised the design and installation of the Long Island Railroad Company's electrification, including the large power house at Long Island City. His last work was in charge of design and construction of the mechanical and electrical features of the Pennsylvania terminal station in New York City, which he was obliged to relinquish just before it was completed.

Mr. Caldwell was a member of the American Society of Mechanical Engineers and the American Society of Civil Engineers. He was also a member of Grecian Lodge A. F. & A. M. and Mt. Sinai Chapter R. A. M., of Lawrence, Mass. He leaves a wife, four children and his father, Lewis H. Caldwell, the latter being a resident of Los Angeles, Cal.

SOCIETY NOTES

The board of governors of the American Society of Heating and Ventilating Engineers held a meeting at the headquarters of the society in the Engineering Societies building, 29 West Thirty-ninth street, on Friday afternoon, March 24. Twenty-five applications for membership were approved and ordered prepared for the usual membership ballot. It was voted to issue during the present year the proceedings for 1909 and 1910. The proposal to hold the summer meeting on a three days' steamship trip on June 27, 28 and 29 on Lake Michigan and Green bay was favorably received and it was decided to canvass the membership to learn if a sufficient number may be counted on. Tentative arrangements have been made to charter one of Lake Michigan's leading steamships. Special entertainment is planned for the three evenings taken up in the journey; proper periods of morning and afternoon are reserved for the technical sessions and a considerable number of stops at interesting cities and interesting places with perhaps an hour's sojourn in each case are possible.

NEW INVENTIONS

Printed copies of patents are furnished by the Patent Office at 5c. each. Address the Commissioner of Patents, Washington, D. C.

PRIME MOVERS

[illegible]

[illegible]

ELASTIC-FLUID TURBINE. Carl Richard Waller, Trenton, N. J., assignor to De Laval Steam Turbine Company, New York, N. Y., a Corporation of New Jersey. 987,842.

INTERNAL COMBUSTION ENGINE. Jamie Hunter Batchelor and Herbert H. Smith, Dothan, Ala. 987,848.

GAS ENGINE. John T. Cowie, New Westminster, British Columbia, Canada, assignor of one-half to Henry Schaake, New Westminster, Canada. 987,860.

ROTARY GAS ENGINE. Franklin D. Thomas, Saginaw, Mich. 987,929.

AUTOMATIC WAVE APPARATUS. Robert Max Mobius, San Diego, Cal. 988,012.

INTERNAL COMBUSTION ENGINE. Perry Okey, Columbus, Ohio, assignor of one-half to Sarah Louise Okey, Columbus, Ohio. 988,021.

TURBO DISPLACEMENT ENGINE. Lewis Hallock Nash, South Norwalk, Conn., assignor to Nash Engineering Company, a Corporation of New York. 988,133.

BALANCED WATER MOTOR. Philander T. Dodson, Creston, Iowa. 988,256.

INTERNAL COMBUSTION ENGINE. Geo. W. Brown, Salamonie township, Huntington county, Ind. 987,860.

BOILERS, FURNACES AND GAS PRODUCERS

MECHANICAL STOKER. Arthur R. Selden, Rochester, N. Y. 987,834.

FURNACE. Herman A. Poppenhusen, Evanston, and Joseph Harrington, Riverside, Ill. 987,911.

FURNACE. Herman A. Poppenhusen, Evanston, Ill. 988,027.

OIL BURNER. Ernest L. Kendall, Riggold, Tex. 988,111.

FURNACE. William McClave, Scranton, Penn., assignor to McClave-Brooks Company, Scranton, Penn., a Corporation of Pennsylvania. 988,123.

INJECTOR BURNER. Nicholas S. Sibert, Neodesha, Kan. 988,216.

FEED-WATER HEATER. Jared S. Sweeny and William W. Grindle, Decatur, Ill.

POWDERED-COAL BURNER. Alva D. Lee, Boston, Mass., assignor to Lee Furnace and Burner Company, a Corporation of New York. 988,271.

POWER PLANT AUXILIARIES AND APPLIANCES

BOILER SKIMMER. Byron Epson Foss, Chicago, Ill., assignor of forty-nine one-hundredths to Richard H. Malcomson, Chicago, Ill. 987,710.

ROTARY PUMP. Adelbert Fournier, Sprague, Wash., assignor to James F. O'Brien, Seattle, Wash. 987,711.

LUBRICATOR. George H. Menzies, Pittsburg, Penn. 987,735.

VALVE. John W. Smith and Elmer H. Smith, Minneapolis, Minn. 987,757.

INJECTOR. William Henry Stirling, St. John, N. B., Canada, assignor of one-half to James E. Hogan, St. John, N. B., Canada. 987,769.

ENGINE CROSSHEAD. Robert W. Bryan, Aberdeen, Wash., assignor of one-half to George B. Reid, Aberdeen, Wash. 987,853.

PUMP. Charles Williams, Brooklyn, N. Y. 987,934.

TURBINE PUMP. Walter L. Forward, West Berkeley, Cal., assignor to Byron Jackson Iron Works, Berkeley, Cal., a Corporation of California. 987,976.

BEADING TOOL FOR BOILER TUBES. Eugene Wiet, San Francisco, Cal. 988,054.

OILING DEVICE. George W. Cook, Jr., Bainbridge, N. Y., assignor to American Separator Company, Bainbridge, N. Y., a Corporation of New York. 988,080.

SEPARATOR FOR BOILERS. Joseph E. Harrison, Harvey, N. D. 988,264.

APPARATUS FOR PREPARING GROMETS OR PACKINGS FOR STUFFING BOXES. William Heron, Birkenhead, England. 988,267.

MECHANICAL MOVEMENT FOR AUTOMATIC STOKERS. William McClave, Scranton, Penn., assignor to McClave-Brooks Company, Scranton, Penn., a Corporation of Pennsylvania. 988,275.

ELECTRICAL INVENTIONS AND APPLICATIONS

ELECTRIC HIGH-WATER ALARM. Edwin E. Brackett, Central Falls, R. I. 987,694.

ALTERNATING-CURRENT MOTOR AND CONTROLLING DEVICE THEREFOR. Vance I. Gray, Toledo, Ohio, assignor to the F. Bissell Company, Toledo, Ohio, a Corporation of Ohio. 987,979.

Engineering Societies

AMERICAN SOCIETY OF MECHANICAL ENGINEERS

Pres., Col. E. D. Meier; sec., Calvin W. Rice, Engineering Societies building, 29 West 39th St., New York. Monthly meetings in New York City. Spring meeting in Pittsburg, May 30 to June 2.

AMERICAN INSTITUTE OF ELECTRICAL ENGINEERS

Pres., Dugald C. Jackson; sec., Ralph W. Pope, 33 W. Thirty-ninth St., New York. Meetings monthly.

NATIONAL ELECTRIC LIGHT ASSOCIATION

Pres., Frank W. Frueauff; sec., T. C. Martin, 31 West Thirty-ninth St., New York. Next meeting in New York City, May 29 to June 2.

AMERICAN SOCIETY OF NAVAL ENGINEERS

Pres., Engineer-in-Chief Hutch I. Cone, U. S. N.; sec. and treas., Lieutenant Commander U. T. Holmes, U. S. N., Bureau of Steam Engineering, Navy Department, Washington, D. C.

AMERICAN BOILER MANUFACTURERS' ASSOCIATION

Pres., E. D. Meier, 11 Broadway, New York; sec., J. D. Farasey, cor. 37th St. and Erie Railroad, Cleveland, O. Next meeting to be held September, 1911, in Boston, Mass.

WESTERN SOCIETY OF ENGINEERS

Pres., O. P. Chamberlain; sec., J. H. Warder, 1735 Monadnock Block, Chicago, Ill. Meeting first Wednesday of each month.

ENGINEERS' SOCIETY OF WESTERN PENNSYLVANIA

Pres., Walter Riddle; sec., E. K. Hiles, Oliver building, Pittsburg, Penn. Meetings 1st and 3d Tuesdays.

AMERICAN SOCIETY OF HEATING AND VENTILATING ENGINEERS

Pres., R. P. Bolton; sec., W. W. Macon, 29 West Thirty-ninth street, New York City.

NATIONAL ASSOCIATION OF STATIONARY ENGINEERS

Pres., Carl S. Pearse, Denver, Colo.; sec., F. W. Raven, 325 Dearborn street, Chicago, Ill. Next convention, Cincinnati, Ohio, September 12-15, 1911.

AMERICAN ORDER OF STEAM ENGINEERS

Supr. Chief Engr., Frederick Markoe, Philadelphia, Pa.; Supr. Cor. Engr., William S. Wetzler, 753 N. Forty-fourth St., Philadelphia, Pa. Next meeting at Philadelphia, June 5-10, 1911.

NATIONAL MARINE ENGINEERS BENEFICIAL ASSOCIATIONS

Pres., William F. Yates, New York, N. Y.; sec., George A. Grubb, 1040 Dakin street, Chicago, Ill. Next meeting at Detroit, Mich., January 15-19, 1912.

INTERNAL COMBUSTION ENGINEERS' ASSOCIATION

Pres., Arthur J. Frith; sec., Charles Kratsch, 416 W. Indiana St., Chicago. Meetings the second Friday in each month at Fraternity Halls, Chicago.

UNIVERSAL CRAFTSMEN COUNCIL OF ENGINEERS

Grand Worthy Chief, John Cope; sec., J. U. Bunce, Hotel Statler, Buffalo, N. Y. Next annual meeting in Philadelphia, Penn., week commencing Monday, August 7, 1911.

OHIO SOCIETY OF MECHANICAL ELECTRICAL AND STEAM ENGINEERS

Pres., O. F. Rabbe; acting sec., Charles P. Crowe, Ohio State University, Columbus, Ohio. Next meeting, Youngstown, Ohio, May 18 and 19, 1911.

INTERNATIONAL MASTER BOILER MAKERS' ASSOCIATION

Pres., A. N. Lucas; sec., Harry D. Vaught, 95 Liberty street, New York. Next meeting at Omaha, Neb., May 23-26, 1911.

INTERNATIONAL UNION OF STEAM ENGINEERS

Pres., Matt. Comerford; sec., J. G. Hannahan, Chicago, Ill. Next meeting at St. Paul, Minn., September, 1911.

NATIONAL DISTRICT HEATING ASSOCIATION

Pres., G. W. Wright, Baltimore, Md.; sec. and treas., D. L. Gaskill, Greenville, O.

BUSINESS ITEMS

"Boiler Room Tactics" is the title of a booklet, which has been issued to give some general rules for the care and management of the Heine boilers. The booklet contains a good deal of very useful information for those having this type of boiler in charge and will be sent on application to the Heine Safety Boiler Company, 2449 East Marcus avenue, St. Louis, Mo.

A 36-inch Swartwout horizontal oil separator was sold last month to the Holly Sugar Company, Huntington Beach, Cal., by the Ohio Blower Company, of Cleveland, Ohio. Other oil separators were sold to the Michigan Paper Company, Plainwell, Mich.; D. C. Armbrust, Los Angeles, Cal.; Ellwanger Barry Realty Company, Rochester, N. Y; M. D. Olds, Cheboygan, Mich., and Bachelor Timber Company, West Branch, Mich.

F. L. W. Saunderson has been appointed the Canadian manager of the Magnolia Metal Company, with factory and offices located in Montreal. Mr. Saunderson graduated at McGill University in class of 1891, taking a course in electrical engineering and afterward took a special practical electrical course with the Thomson-Houston Electric Company, and for the past fifteen years has been identified with the mill-supply business in Canada.

Persons having a liking for mechanical devices will be interested in an ingenious model, now being distributed by the Harrison Safety Boiler Works, Seventeenth and Clearfield streets, Philadelphia, Penn., to illustrate the valve-timing gear in the new Cochrane steam stack and cut-out valve feed-water heater and receiver. The model, which is constructed of stiff celluloid, illustrates neatly the fact that when the heater is cut off from the exhaust steam supply, the separator attached to and forming a part of the heater continues to furnish exhaust steam purified of oil to the heating or drying system, while the trap is cut off from communication with the heater, but still continues to drain the separator. Upon the reverse of the model it is stated that full particulars regarding the application of these heaters in connection with all kinds of exhaust steam-heating systems are fully explained in the "Exhaust Steam Heating Encyclopedia," published by the manufacturer, which, with the model, is sent gratis to persons who are interested in the design, installation or operation of exhaust-steam heating systems.

NEW EQUIPMENT

Brockton, Mass., is contemplating the installation of a municipal electric-lighting plant.

Ernest Marshall, Oakes, N. D., has been granted franchise to install an electric-light plant.

The Standard Ice Company, Seattle, Wash., is planning to erect a new boiler-house addition.

Troy Laundry, Hagerstown, Md., is in the market for a 125-horsepower return-tubular boiler.

The Ottawa (Ont.) Electric Railway Company will build an addition to its power house.

The Lowes Laundry, South Norwalk, Conn., is contemplating installing a 60-horsepower boiler.

The Preston Fertilizer Company, Laurel Hill, R. I., will install boiler, engine and pumps.

Power plant of the Milwaukee Electric Railway Company, at Racine, Wis., was burned.

The cities of Marshfield and North Bend, Ore., are planning a joint municipal water system.

POWER

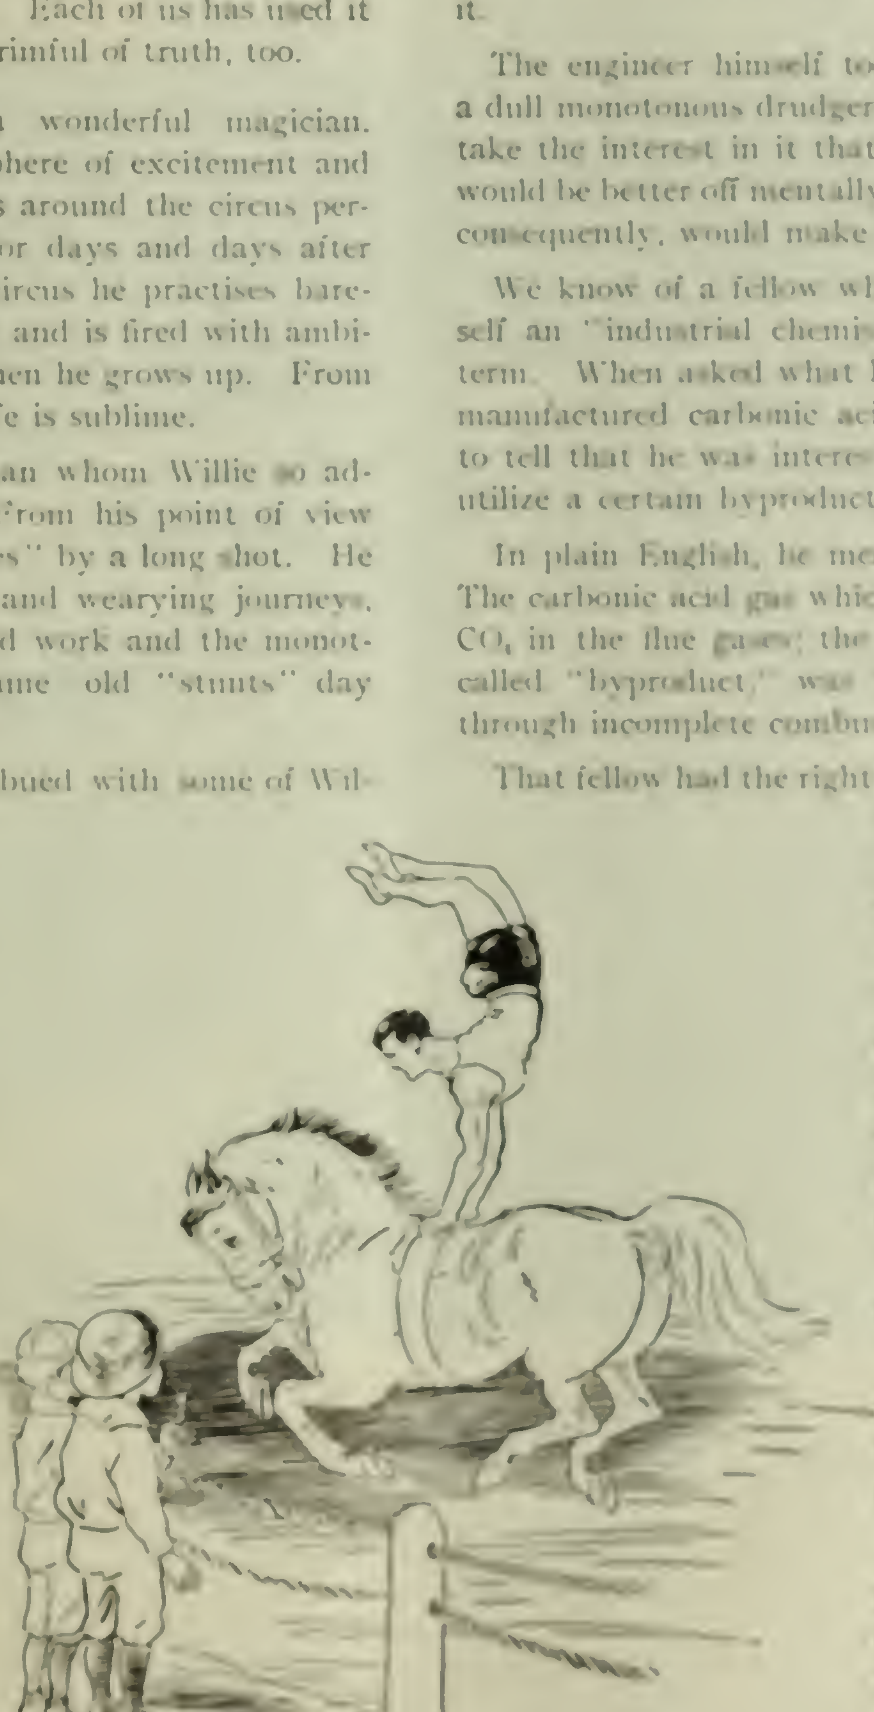
NEW YORK, APRIL 18, 1911

"IT ALL depends on how you look at it"—a familiar quotation that. Each of us has used it time and again. It is brimful of truth, too.

Old "Point-of-view" is a wonderful magician. For instance, what an atmosphere of excitement and fascinating romance he throws around the circus performer for the small boy. For days and days after little Willie has been to the circus he practises bareback riding on a kitchen chair and is fired with ambition to become a performer when he grows up. From Willie's point of view circus life is sublime.

But, how differently the man whom Willie so admires looks at the matter! From his point of view life is not all "beer and skittles" by a long shot. He sees the long, uncomfortable and wearying journeys, the one-night stands, the hard work and the monotony of going through the same old "stunts" day after day.

If he could but become imbued with some of Willie's romantic views of his profession, how much more contented he would be, and what a much better performance he would be likely to make. There would be a dash and style to his act that would stamp him as an ARTIST.



In many ways the engineer and his work are similar to the circus performer and his.

To "hoi polloi" the engineer is a wonderful institution and his occupation is full of fascination. He can make all sorts of machines work just when and as he wishes; he understands their intricate construction and when trouble occurs, he knows how to seek it out and eliminate it.

The engineer himself too often considers his work a dull monotonous drudgery. If he would but see and take the interest in it that the layman often does, he would be better off mentally, would do better work and, consequently, would make better, faster progress.

We know of a fellow who once, in fun, called himself an "industrial chemist"—quite a high sounding term. When asked what his line was he said that he manufactured carbonic acid gas. Then he went on to tell that he was interested in the study of how to utilize a certain byproduct, carbon monoxide.

In plain English, he meant that he was a fireman. The carbonic acid gas which he manufactured was the CO_2 in the flue gases; the carbon monoxide, what he called "byproduct," was the CO which was formed through incomplete combustion.

That fellow had the right point of view. He saw the interesting side of his work. He dug into the reasons why certain causes produce certain results, not sometimes but always. He studied. The more he learned the more interested he became. He applied the interesting knowledge that he had acquired "for the fun of it" and he made a wonderful showing.

Today he is superintendent of motive power for a big industrial concern at a salary of $[illegible] a year.

He still has the right point of view. He gets enjoyment out of his work. No wonder he is making good.

The Steam Turbine in Germany

By F. E. Junge
and E. Heinrich

This instalment of the series on A. E. G. turbines deals with features of design, taking up the frame, casing, bearings, lubrication, stuffing boxes, disks and blades, nozzles and regulation.

All types of A. E. G. turbines have the following features in common:

1. One rigid frame for the whole unit, as shown in Fig. 29.
2. Three bearings, there being only one bearing between steam turbine and electric generator, while a rigid flange coupling is provided on the side of the turbine.
3. A rigid shaft, the critical speed of which is above the normal speed.

Frame: Those firms who build both the turbine and the electrical equipment have the advantage that they can cast the two frames in one piece, allowing both parts to be erected and tested together. If turbine and generator are built by different firms, of course, separate frames and separate bearings must be provided and a flexible coupling between the two units arranged. In the latter case the aggregate unit cannot be tested until after erection in the power house, the reliability of operation depending very largely on the ability and thoroughness of the erecting engineers. Here is an element of technical importance which speaks for concentration of production in the shops of one and the same firm. The frame plates of the A. E. G. turbine possess considerable hight and their walls have considerable thickness so that great rigidity of construction is assured. This is important, because light frame plates are apt to bend during erection, changing the relative position of the surfaces which are to fit. The mass or weight of frame is increased by filling its cavities with brickwork or cement, so that no special holding-down bolts are required to fasten the frame to the foundation. If the condensing plant is located below the turbine, as obtains in most cases, the turbine resting on I-beams, a rigid connection by bolts in the manner shown in Fig. 30 commends itself for the sake of stability. From this figure it is seen also that in order to facilitate attendance and avoid stairs, galleries, etc., the frame is set below the engine floor.

Casing: The casing of multiple-stage turbines consists of three parts, the front cover and the upper and lower halves of the casing, the latter divided horizontally and containing the low-pressure portion. The front cover and the first wall of the inner partition form a chamber or receptacle in which the Curtis wheel, equipped with two or three rows of blades, revolves. While to this wheel steam is fed to only a portion of the circumference through nozzles, the following wheels, having each only one row of blades, are impinged by means of guide blades with parallel walls, admitting steam over the whole circumference. The guide blades are of polished nickel steel, very accurately cast between an external

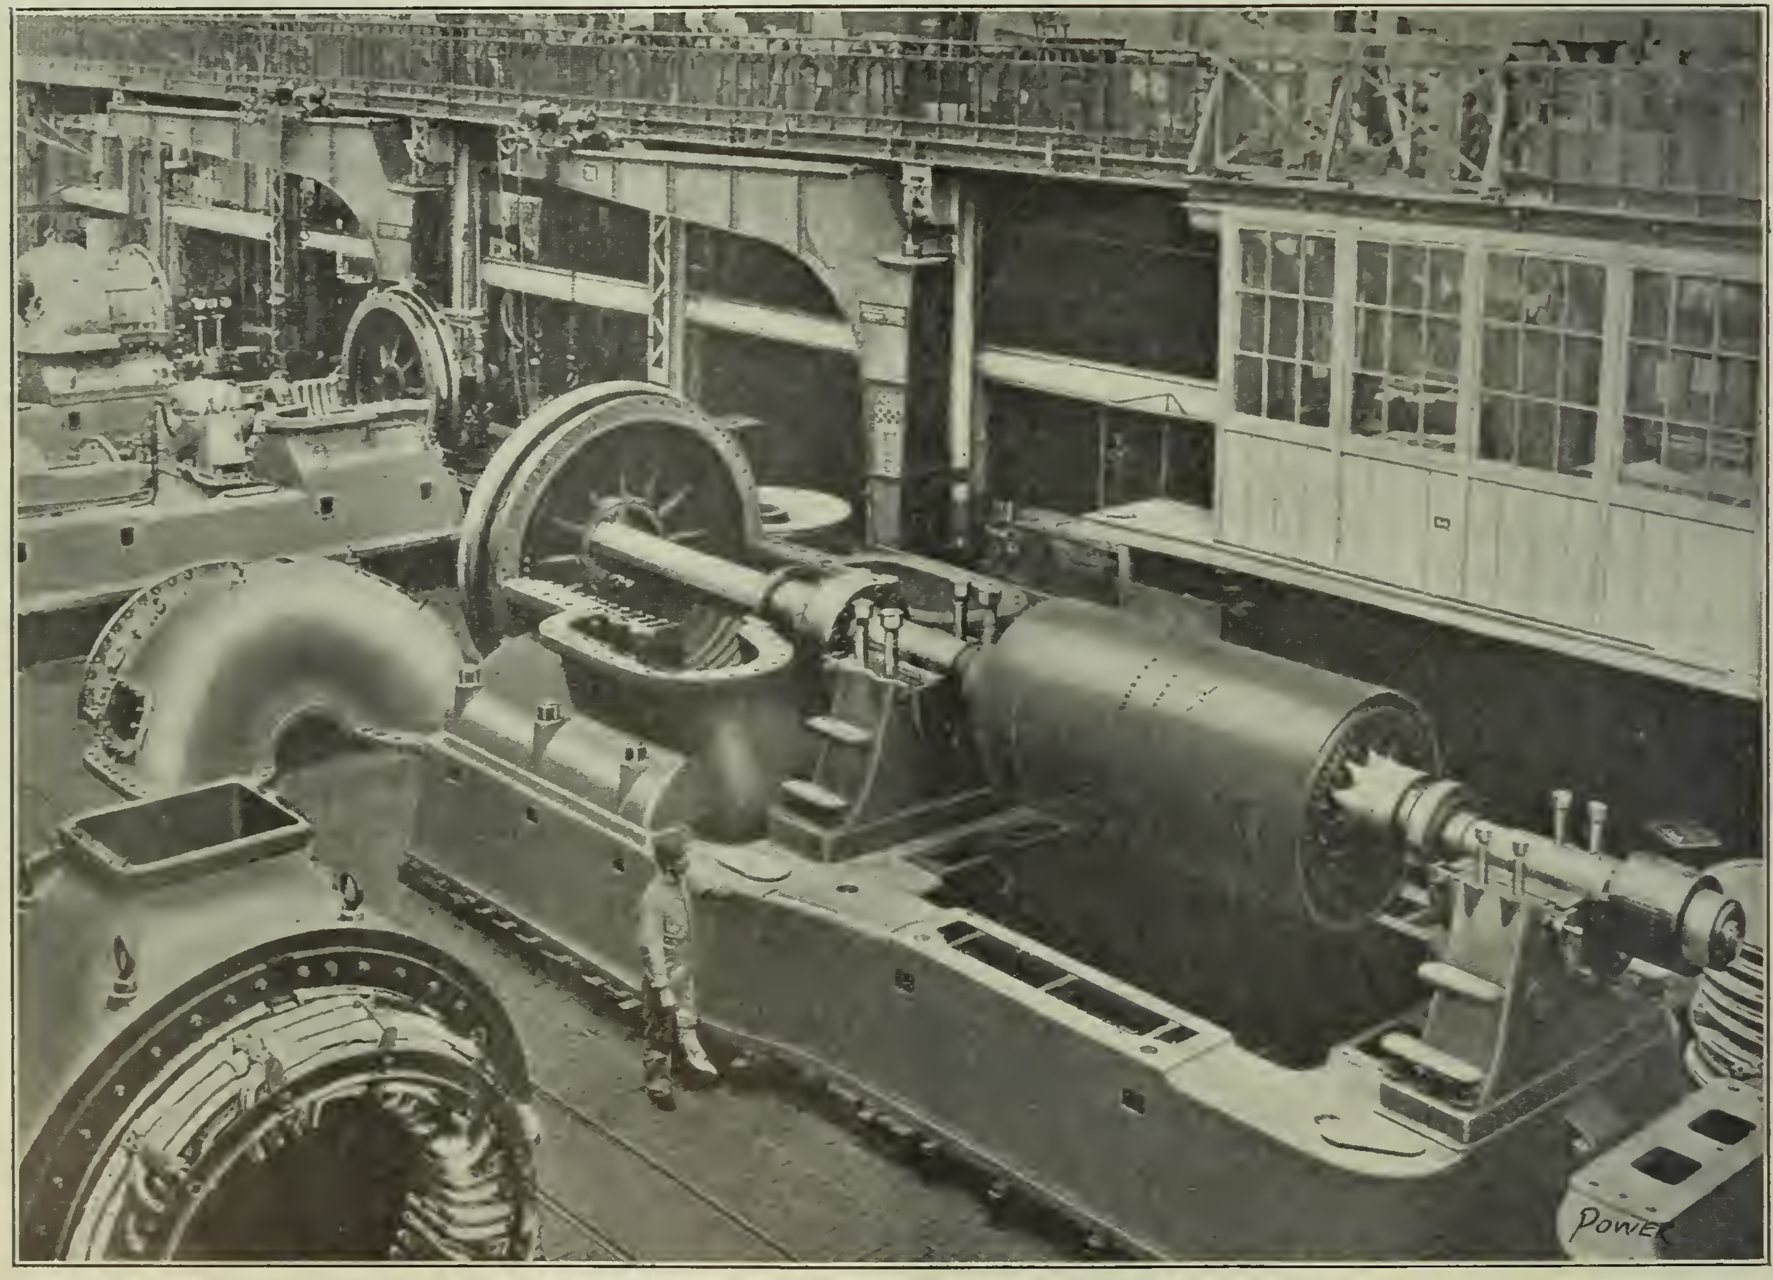


Fig. 29. A. E. G. Turbine Direct Connected to 6000-kilowatt Three-phase Generator in Course of Erection

and an internal cast-iron ring. These guiding rings are fastened in the two halves of the casing and remain there if the shaft, the wheels, and the separating walls are dismounted. The separating walls rest on the hubs of two consecutive low-pressure wheels. When the turbine is being mounted the key projecting from the inner circumference of the guiding rings engages the slots cut in the circumference of the separating walls. This construction is lately being replaced by another, which employs disks consisting of two parts, similar to those used in other makes. Disks made of one piece possess several disadvantages. If, for instance, the packing on the hub gets overheated, in order to obtain access to the source of trouble it is necessary to dismount the whole turbine and to withdraw the wheels from the shaft, which is a very difficult or, at least, complicated piece of work. This may occur when the turbine is connected with the exhaust, so that higher temperatures occur suddenly in the casing.

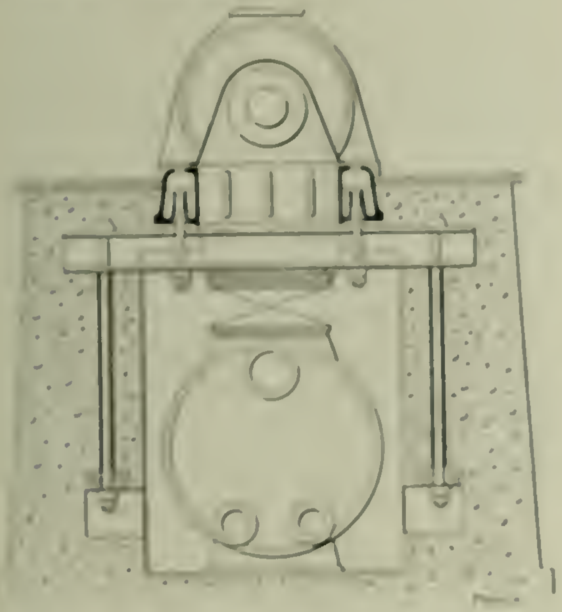

FIG. 30. FOUNDATION AND FRAME

The front cover is, as a rule, a steel casting, while the other sections of the casing are made of cast iron. Fig. 29 shows a turbine of high capacity (6000 kilowatts), of which the lower half of the casing with the guiding rings and the front cover with the nozzle segment are already mounted. The upper half of the casing lies on the floor. The two other turbines in the picture also show the composition of parts very clearly.

The construction of the high-speed type, in which two wheels are used, is somewhat different, no horizontal division throughout the casing being provided. The vertical section, Fig. 27, and the horizontal section, Fig. 28, show the details of construction very clearly, while Fig. 31 shows how this type of turbine is dismounted. First, the front cover is removed, then follows the first running wheel, afterward the intermediary guiding wheel, and finally the second running wheel. In order occasionally to inspect the inner working parts of the turbine, especially the nozzles and blades, it is not necessary to dismount the machine. As for the first stage, inspection can be made by removing one of the nozzle chests, while on the low-pressure part openings with covers are provided, permitting a complete inspection of the second stage.

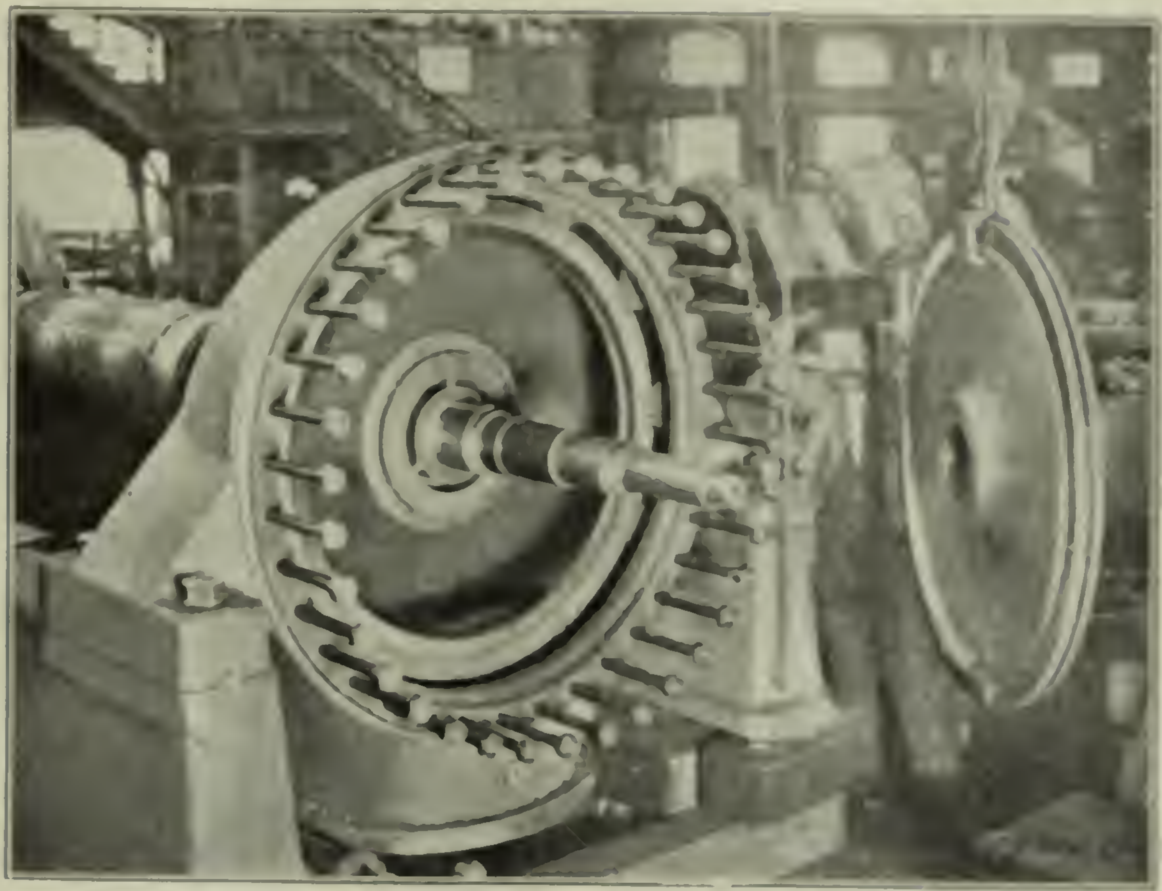

FIG. 31. A VIEW SHOWING INTERIOR CONSTRUCTION OF TURBINE

Though during operation the casing is subjected to low pressures only, all parts before leaving the shop are tested under several atmospheres of water pressure in order to locate porous or weak spots in the castings. In the A. E. G. construction the front bearing with the governor and oil-pump drive is connected by means of bolts to the front cover. Owing to the wide range of expansion in the first stage the temperatures in the casing are comparatively low; hence, this mode of construction is fairly free from objection. Some designers, however, prefer to separate the front bearing entirely from the casing by extending the base plate beyond the front side of the turbine.

Bearings: In the design of steam-turbine bearings the following general considerations arise: If p is the pressure per unit of area, u the circumferential velocity of the journal in units per second, l its length, d its diameter and μ the coefficient of friction, then we have $R = l\,d\,u\,p\,\mu$, the friction work of the journal per second and $r = \mu\,p\,u$, the friction work per unit area of the horizontal projection of the journal, or what is called the specific friction work. The results of all experimenters go to prove that the product $u\,p$ is constant for all pressures within the available limits; hence, we can use as a measure for the friction work per second the readily determinable product of the pressure and the circumferential velocity of the journal. Until lately this value was kept quite

FIG. 32. SECTIONAL VIEWS OF MAIN BEARING

low, especially when employing flexible shafts, the dimensions of bearings being laid out amply large. The value pv seldom surpassed 40 meter-kilograms, or, in English units, 1830 foot-pounds. Today all firms follow the example set by the Allgemeine Elektricitäts Gesellschaft. They shorten their turbine bearings, permitting a value $pv = 130$ to 150 in metric, or 6000 to 7000 in English units.

The construction of bearings embraces two parts: floor stands, or pedestals, and boxes. The former rest upon and are rigidly fastened to the base plate. The bushings are lined with white metal and are fitted by hand into the boxes, thus guaranteeing an oil-tight fit all along the surface; see Fig. 32. Lubrication is effected by means of oil pumps driven from the turbine. The oil piping is con-

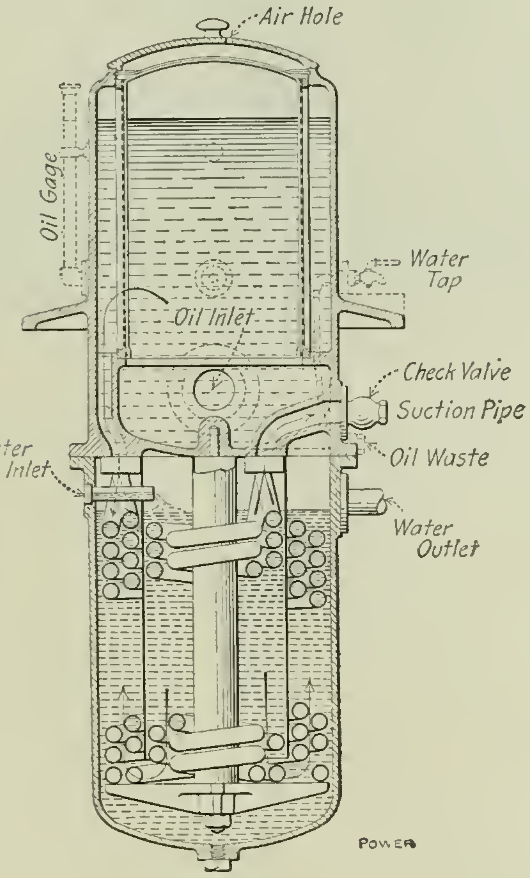

Fig. 33. Oil Cooler

nected to the pedestal and extends in its interior up to the bottom end of the bushing. The oil enters through a vertical channel into a broad groove, being driven by the revolving shaft toward the center line of the bearing, where the highest pressure occurs, and emerging on both sides into the cavities of the pedestal. The front bearing is constructed similarly to the rear one, with the difference that it contains the thrust journal. The main purpose of the latter is not to receive and absorb heavy shocks or stresses, but to maintain the relative axial position of rotating and stationary parts and to preserve and control the interstices and play which are provided during erection. As the pivot journal is subjected to wear the collars are not made in one piece with the shaft, but are attached to the latter, together with the worm gear for driving the governor, so that they may be easily exchanged.

Lubrication: The convection of the friction heat is effected partly in the bearing itself and partly by means of special oil coolers, similar to those used in other turbine systems. In one construction

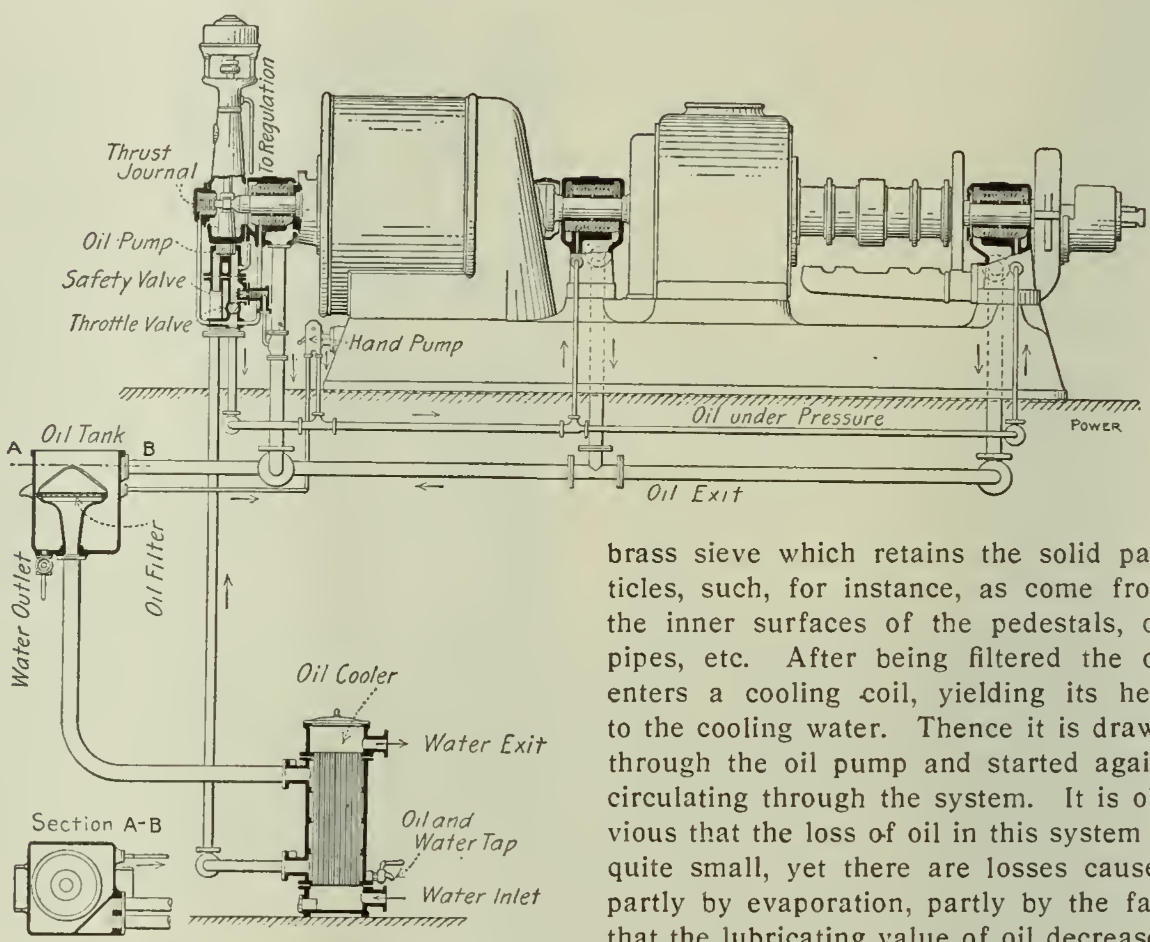

Fig. 34. Outline of Turbine Oiling System

the brasses are made hollow so that the cooling water may pass through them, before it enters the oil cooler. In other constructions the lubricating oil, coming from the oil cooler under pressure, is it-

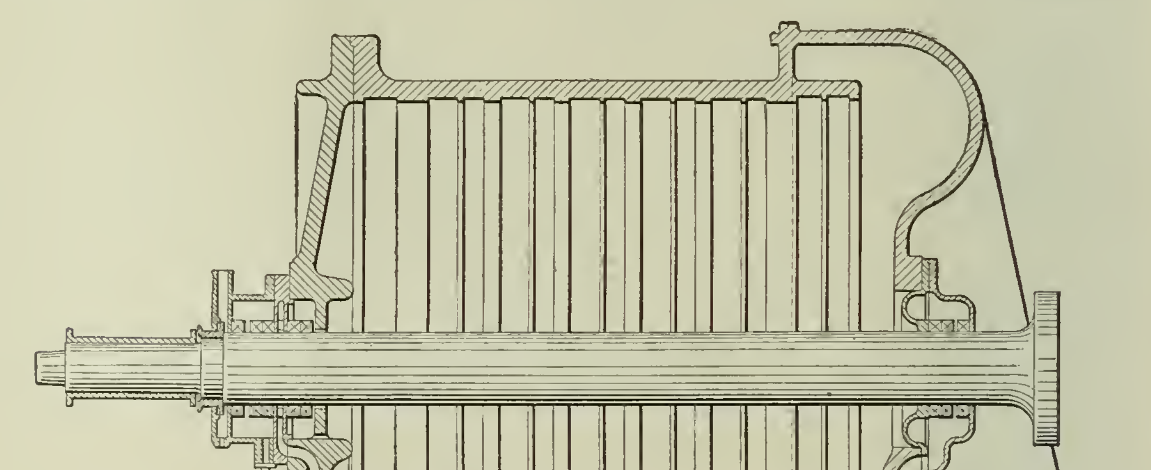

Fig. 35. Sectional View of Turbine, Showing Labyrinth Packing

self used to cool the bushing from without before entering the wearing surface within. The cooling of the oil is effected in a special apparatus, shown in Fig. 33. In the upper part the hot oil, returning from the turbine, is collected, and the impurities contained therein are allowed to settle to the bottom and can be removed from time to time. On its way downward the oil passes through a fine brass sieve which retains the solid particles, such, for instance, as come from the inner surfaces of the pedestals, oil pipes, etc. After being filtered the oil enters a cooling coil, yielding its heat to the cooling water. Thence it is drawn through the oil pump and started again, circulating through the system. It is obvious that the loss of oil in this system is quite small, yet there are losses caused partly by evaporation, partly by the fact that the lubricating value of oil decreases after some time, so that the oil must occasionally be renewed. The oil in the tank serves also as a reserve supply, guaranteeing the circulation in case, owing to some defect, the lubricant should leak out during operation. The oil pump which is driven from the governor consists of two spur pinions meshing in the ordinary manner. The absence of valves, pistons, springs, etc., favors reliability of operation. When starting, the speed of the governor and oil pump is too low to secure the delivery of sufficient oil under pressure. For this purpose a small emergency hand pump is provided, and for larger units a special steam-driven auxiliary oil pump is provided, which supplies the lubricant until the main turbine is up to speed. Oil circulation and pressure can be controlled through several gages, being switched in at different places by means of valves. The temperature of the oil is registered and observed both in the tank and on the bearings, for which purpose thermometers are inserted in the upper bushings. The whole scheme of oil circulation is illustrated in Fig. 34.

Stuffing Boxes: The packing of the turbine shaft on the high-pressure side is a comparatively simple matter, because in the first chamber the pressure is comparatively low. In the multiple-stage A. E. G. turbines the pressure difference is about three atmospheres. In the two-stage types the pressure is zero at full load and can even become negative at the lower loads. In this case the pressure of the atmosphere without is higher than the internal steam pressure, the effect being the same as on the low-pressure side. With the high circumferential speeds occurring in steam turbines it is, of course, impossible, to employ the same packings which are used in steam-engine practice. Neither soft materials pressing around the shaft nor metal packing rings can be used. As to the latter they could hardly be kept tight without being cooled, and would require lubrication which is apt to spoil the condensate for boiler-feeding purposes. A labyrinth packing is, therefore, employed in which the steam itself acts as a packing medium, being forced to flow through a series of ring grooves and being gradually throttled down, its acquired velocity being absorbed in enlarged spaces located between the grooves. The steam travels through the labyrinth packing from without to within, the low-pressure box being arranged behind the high-pressure stuffing box; see Fig. 35. The latter is surrounded by two annular channels which connect through radial passages with the labyrinth proper, dividing the latter into three parts. The outer channel receives the steam after it has been throttled in a reducing valve to a certain pressure, while the inner channel connects through a pipe with the annular chamber of the low-pressure stuffing box. Through this connection the vacuum in the low-pressure stage of the turbine draws steam through the middle labyrinth of the high-pressure stuffing box, but at the same time it draws steam from the first turbine chamber in and through the low-pressure stuffing box, so that the steam used for packing is included in the condensed water of the turbine. The low-pressure stuffing box also contains a special admission for throttled live steam which is used in case not enough packing steam is supplied through the above-mentioned connection. The short outer labyrinth chamber prevents the leakage of steam so perfectly that only a slight trace of vapor is visible, by which indication the proper adjustment of the admission of packing steam is controlled. On the high-pressure side the steam is emitted through a short vertical pipe in order to prevent the settling of sediment within the box. The collars of the shaft are made of steel, the meshing collars of the surrounding boxes of nickel bronze. Though the play allowed in the labyrinth is quite small it is ample to permit both expansion and contraction as result from the heating and cooling of the shaft.

Fig. 36. Disk Wheels with Factors of Safety of 5 and 10

Another form of packing which commends itself in certain cases employs rings made of carbon, which are pressed together by means of springs, the rest of the arrangement being identical with that above described; but for shafts which rotate at high speeds the labyrinth packing is preferable. Though not giving absolute tightness it has the great advantage that it works without friction and requires no lubrication, the steam friction in the labyrinth being a negligible amount. Thus the labyrinth packing makes possible one great advantage of the steam turbine over the steam engine; namely, the output of a condensate which is free from grease. The inner packings between two consecutive chambers are also of the labyrinth variety but simpler, the shaft having no collars but running through. The amount of play permitted depends entirely on conditions of operating reliability, the leakage of steam being accepted as an unavoidable loss.

Disks and Blades: Disks are made of high-class steel, a high factor of safety being assumed for their computation. Fig. 36 gives a comparison of a normal A. E. G. wheel built for tenfold safety with a wheel computed for half this amount. Wheels carrying two rows of blades have enlarged rims in which the blades are inserted. The heavily built disk hubs are fastened upon the shaft by means of conical caps in order to

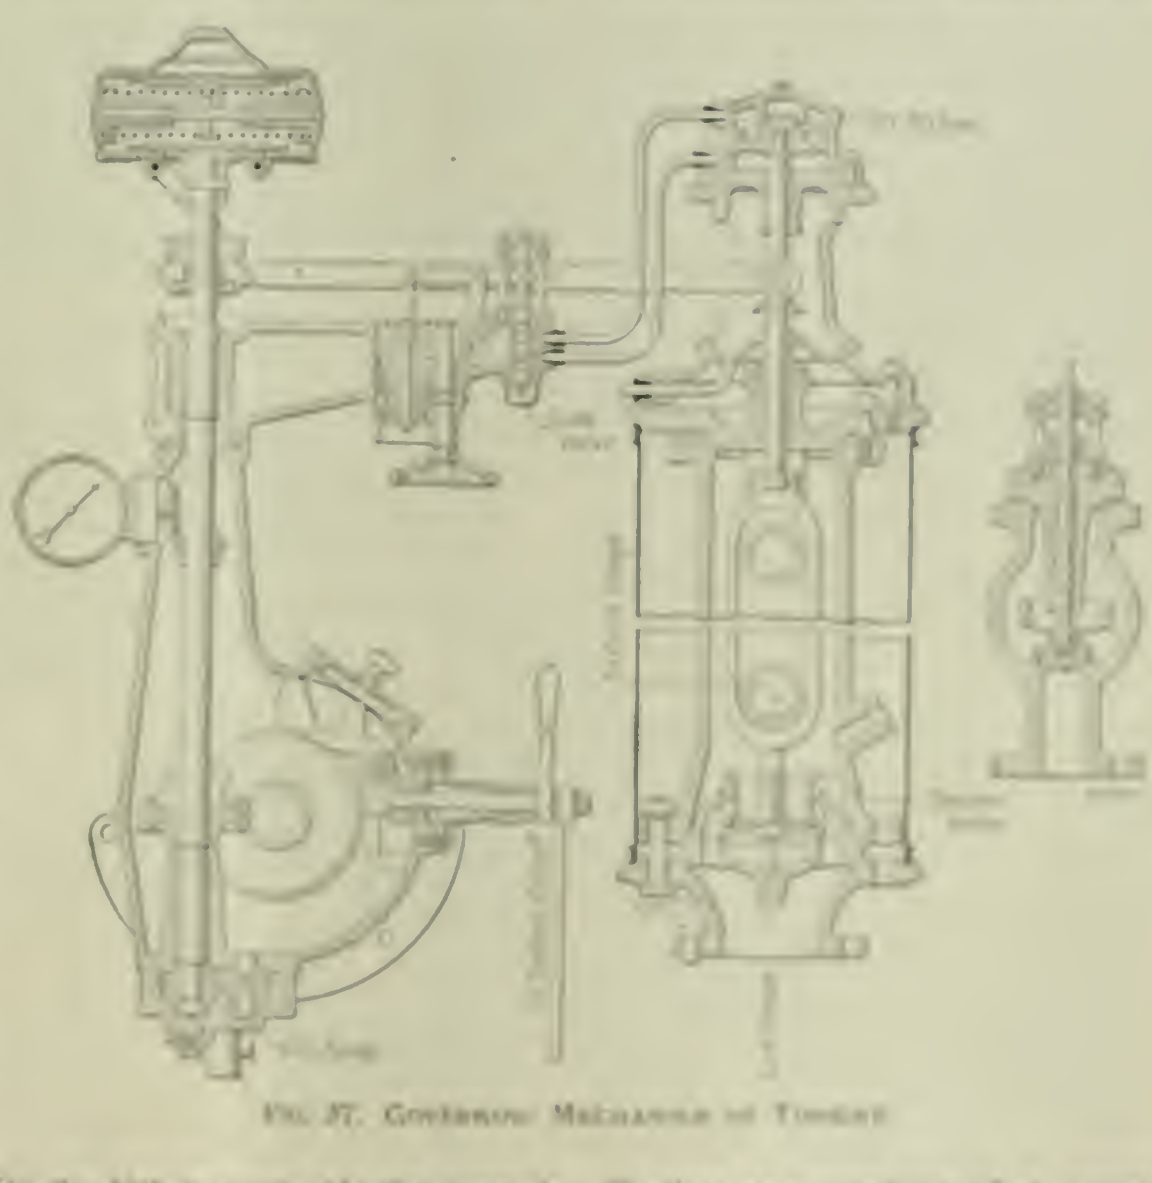

Fig. 37. Governing Mechanism of Turbine

secure accurate fit and ease of dismounting. The blades are made either of a special bronze alloy or of nickel steel. They are cut from solid profile bars, being set into the rim at an enlarged portion of the groove. The space between two consecutive blades is filled in with a special piece which projects as high as the foot of the blade and fits accurately into the profiled part of the blade. It thus insures the accurate spacing of the blades as well as their uniform inclination. After the whole circumference of the disk wheel has been filled with blades the distance pieces are staked so as to give an absolutely firm hold. Then the blade heads are connected by a steel band, which fulfils the double purpose of stiffening the blades radially and creating in the rotating wheel a closed channel for the working steam. The blades of the reversing wheels are built in the same way as the others. After being equipped with blades the wheels are carefully balanced statically, a dynamic adjustment being in most cases unnecessary on account of the symmetric form of the wheels.

Nozzles: The impingement of the steam upon the blades is effected either through guiding channels with parallel walls or through conically diverging nozzles. A longitudinal section through the nozzles of a two-stage turbine is shown in Fig. 27, which also shows how the nozzles are superimposed and with their rectangular mouths give a continuous outlet. As material for nozzles, bronze or nickel steel has given satisfaction. For the form of apparatus which is built for high superheat, a special grade of cast iron is employed. If corroded, these parts can be easily replaced without excessive cost. The ease of exchange is a desirable feature, particularly in cases when the operating conditions of the plant change materially, as when turbines are connected to a new boiler plant with different pressure, or when superheaters are installed.

Regulation: The requirements of electric drive necessitate the accurate maintenance of the normal speed at all loads as well as a small and short deviation from the normal number of revolutions at sudden variations of load. These requirements are more easily met with steam turbines than with reciprocating engines, because the degree of irregularity—using an expression from steam-engine practice—is almost zero, the mass of revolving parts acting like a flywheel toward the balancing of small irregularities. The governing device of A. E. G. turbines is shown in Fig. 37. The vertical governor is driven through a worm gear from the turbine shaft and moves a small balanced piston valve, which opens the ports to the cylinder, the piston of which controls the main steam valve at the slightest deviation from the center position. When the sleeve of the governor ascends the pilot valve descends, thereby opening one channel for the admission and another for the outlet of oil under pressure. The regulating valve proper, a double-seated balanced poppet

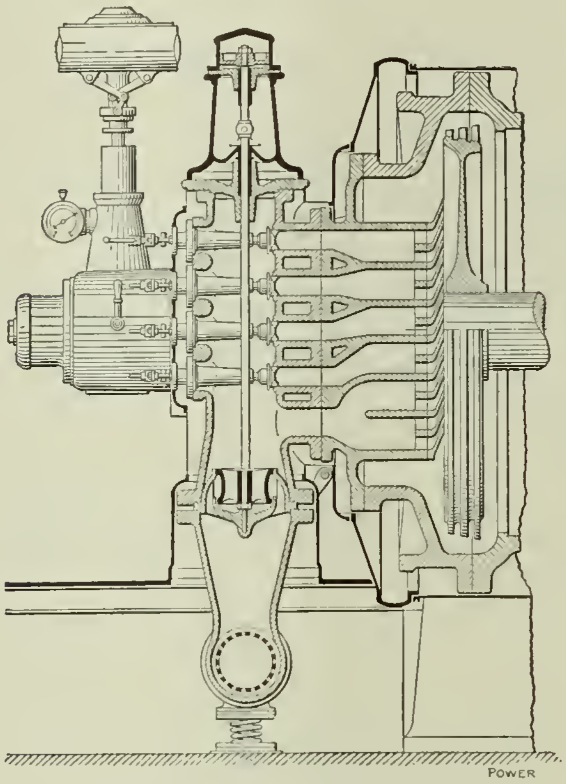

Fig. 38. Arrangement of Nozzles

valve, is rigidly connected to the piston of the controlling cylinder. When the speed of the turbine increases the governor throttles the admission of steam, the downward movement of the piston ceasing when the pilot valve is pushed back into the central position. As the lever has no fixed fulcrum the slide link must be considered as fulcrum. Thus to every definite position of the governor corresponds a certain definite position of the throttle valve. The oil for the pressure cylinder is supplied from the same pump which delivers the lubricant to the bearings under pressure. The advantage of this mode of governing is, of course, that it exercises no harmful back pressure on the governor, the sensitiveness of the latter being therefore quite high. For sudden load variations up to ± 25 per cent. the change in the number of revolutions does not amount to more than ± 1.5 per cent. At sudden drops from full load to no load a momentary increase of 5 per cent. takes place. In the condition of permanence the difference of speed between no load and full load is 4 per cent. Every turbine possesses a device for changing the normal speed by ± 5 per cent. during operation, which is essential for running alternating-current generators in parallel, the device being actuated either by hand at the turbine or from the switchboard.

In the above described system of regulation the governor changes the position of the throttle valve and thereby at the same time the quantity and pressure of the steam supplied from the boiler. This reduction of pressure, however, causes a certain loss of energy, which finds expression in an increased steam consumption per horsepower. The method of partial or graduated admission as employed in A. E. G. turbines makes it possible to transfer regulation of the quantity of steam admitted directly to the nozzles, so that at partial loads the throttle valve may be in a more elevated position whereby losses through reduction of pressure are diminished. The more perfect and differentiated the change of admission the more noticeable is the improvement of throttle governing.

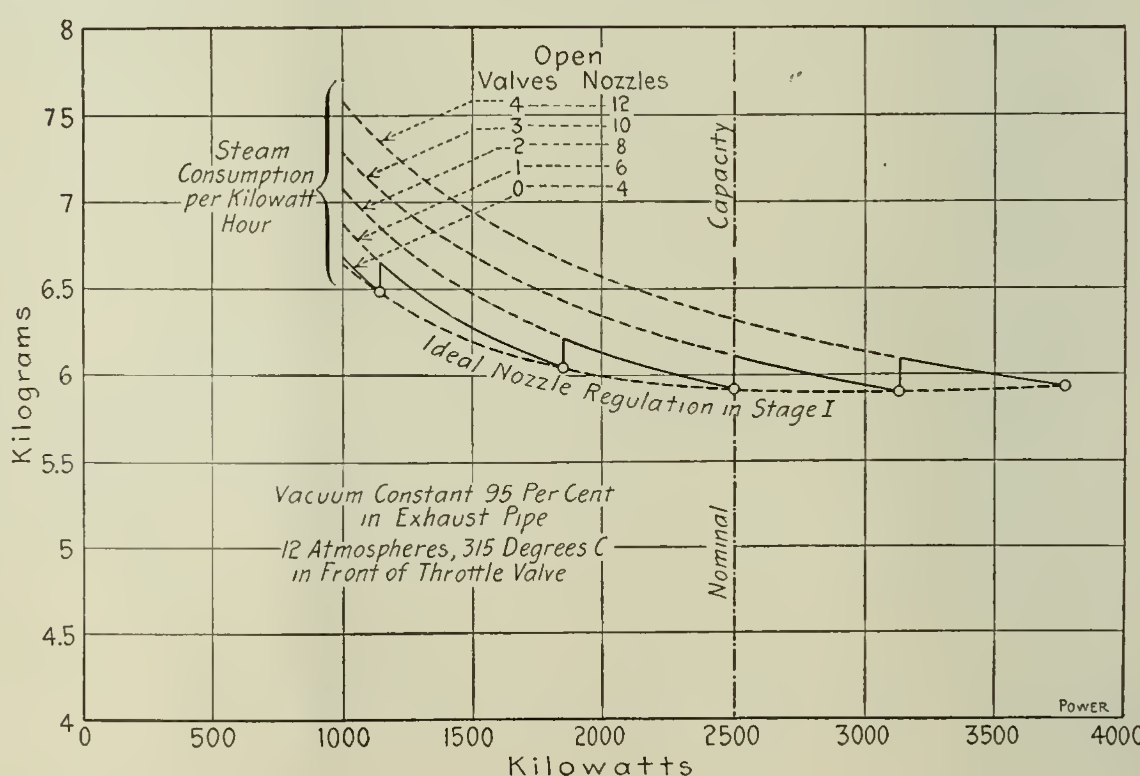

Fig. 39. Influence of Throttle Regulation on Steam Consumption

In the A. E. G. system of automatic nozzle regulation the pressure piston actuates a curved gear by means of which the single nozzles or groups of such are opened and closed through a series of valves. In this case of pure quantity regulation the throttle valve is eliminated entirely. Between complete cutoff and maximum overload the governor attends automatically to the most favorable grade of admission. This mode of regulation is commended wherever rapid load variations in irregular and short intervals are expected to occur, as in iron and steel works, rolling mills, mine hoisting plants, etc. In plants where wide load fluctuations do not occur irregularly, but at certain intervals and gradually, as in central stations and in most factories, it is sufficient to cut off one or more groups of nozzles by hand, according to the momentary requirement, regulation being effected automatically by throttling from the governor. The attendant notes from the gage pressure before and behind the throttle valve when a change of admission is necessary, no order from the switchboard being required. If the pressure difference between the steam coming from the boiler and the steam as recorded behind the throttle valve exceeds a certain measure, it is proof that there is too much loss by throttling and that the time is at hand to cut off one group of nozzles. In turbines of 3000 revolutions per minute, of the total system of nozzles of the first wheel, ordinarily two groups are arranged to be cut off, one of them being reserved for overload, while the other must be closed when the turbine is working on half load. In the larger types the nozzle system is divided into four groups (see Fig. 38), a portion of these always remaining open. Diagram, Fig. 39, shows the favorable effect of this mode of regulation on steam consumption.

The upper limit of load is fixed by the heating of the electrical part, the turbine itself being capable of standing overloads far beyond this limit, and for any length of time. The surplus steam required is admitted by opening additional nozzles. The latter are used also when operating conditions grow less favorable than was assumed for the design, especially when the condensing plant for some reason or other becomes defective and the turbine must exhaust into the atmosphere while the load is being maintained. For two-stage turbines working with atmospheric pressure in the first stage (at full load), there is, of course, no further drop of pressure in the second stage when the condenser is eliminated. The maximum load which under these circumstances can be carried by the first wheel alone reaches 80 to 100 per cent. of the normal full load. In this case the major part of the exhaust steam passes from the first chamber through an auxiliary outlet directly into the atmosphere. For very large units no arrangement of the sort is provided because it is assumed that the considerable quantities of additional steam required for direct exhaust cannot be supplied by the boiler plant, and because in most cases there is always a reserve unit available to take the place of the one whose condensation is defective; but for smaller plants the ability to carry heavy loads with direct exhaust means a great deal, wherefore the provision of additional nozzles is essential.

A COMPARISON OF THE A. E. G. AND CURTIS TURBINES

	A. E. G. Turbine		General Electric Turbine	
Trial number	1	2	3	4
Output, kw.	2,200	4,230	10,140	[illegible]
Pressure in front of turbine, kg. per square centimeter absolute	13.1	13.2	13.4	12.7
Temperature, deg. Cent.	331	330	271	262.8
Steam consumption per kw.-hour, D_e	[illegible]	[illegible]	5.86	5.919
Theoretical heat drop in metric units, H_a	233.5	249	240	220
Theoretical steam consumption, kg. per kw.-hour, D_t	3.90	3.45	3.58	3.907
Efficiency, η_e	62.8	63.6	61.2	66.2
Condenser pressure, kg. per square centimeter absolute	0.018	[illegible]	0.018	[illegible]

Besides the above described mechanism for speed regulation and the devices for securing stability of operation under less favorable working conditions, the A. E. G. turbines are equipped with an independent shaft governor, which serves exclusively for the purpose of preventing racing of the turbine, if the other regulating device should fail to work. The governor which was shown in Fig. 27 is so adjusted as to effect the immediate closing of the main admission valve, Fig. 40, if the speed surpasses the normal by 10 or 15 per cent.

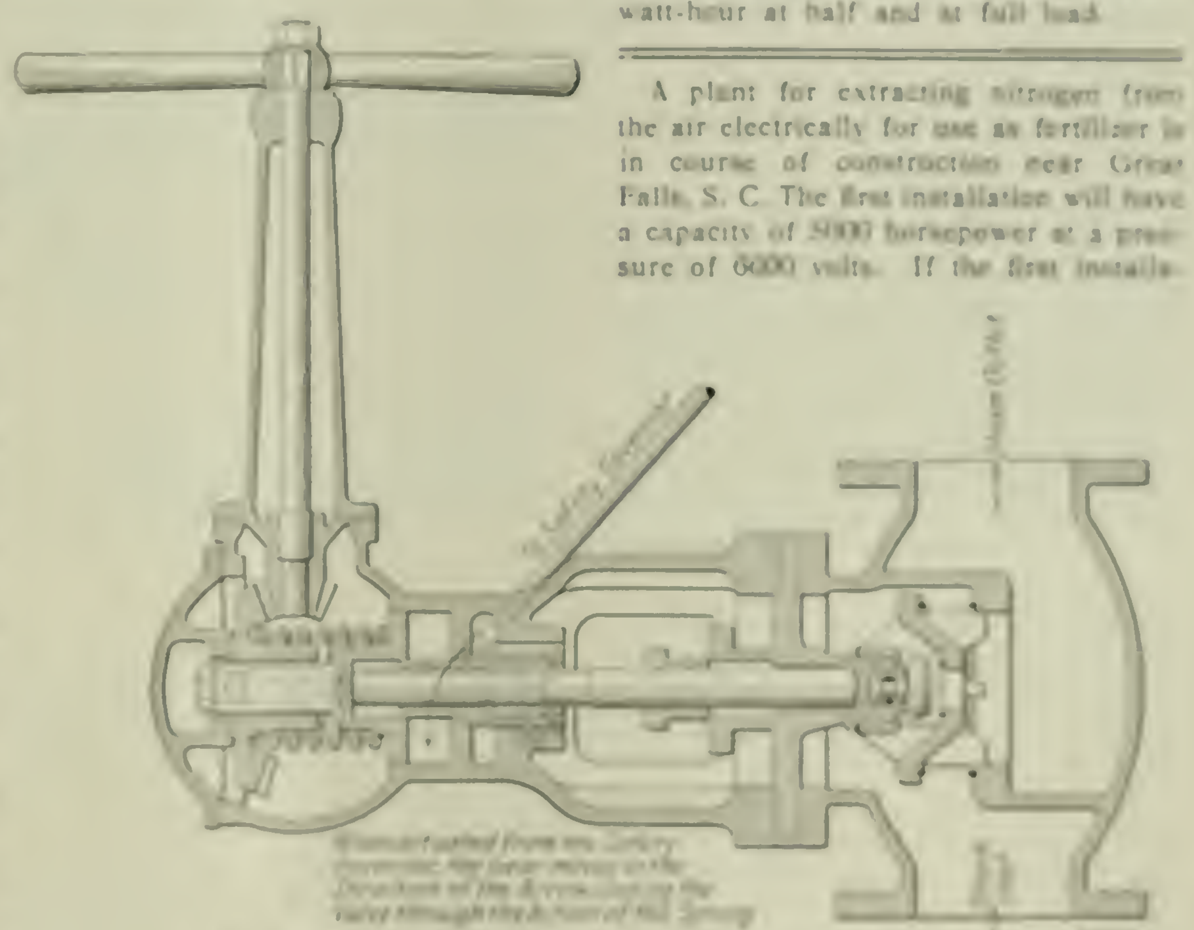

FIG. 40. MAIN ADMISSION VALVE AND SAFETY CUTOFF

In conclusion we give an interesting comparison of tests made on a 4000-kilowatt A. E. G. turbine (Rummelsburg central station), and on an 8000-kilowatt Curtis turbine built by the General Electric Company (Chicago, Fisk Street station), which will serve to illustrate our remarks on thermodynamic efficiency in the last article. From tests 2 and 3 it is seen that the 4000-kilowatt A. E. G. turbine, though having to transform a greater heat drop than the 10,000-kilowatt General Electric turbine, shows a superior thermodynamic efficiency than the latter. If the heat drop was equal in both cases, the comparison would come out even more favorable for the German turbine. How great the influence of heat drop actually is can be seen from tests 3 and 4, made on the General Electric turbine. At a drop of 220 units the efficiency is 66.2 per cent., at a drop of 240 units the efficiency is reduced to 61.2 per cent. Finally, the favorable effect of the nozzle regulation of the A. E. G. turbine is characterized by tests 1 and 2, showing practically equal steam consumption per kilowatt-hour at half and at full load.

A plant for extracting nitrogen from the air electrically for use as fertilizer is in course of construction near Great Falls, S. C. The first installation will have a capacity of 5000 horsepower at a pressure of 6600 volts. If the first installation proves a success additional equipment will be added to the plant later to bring the capacity up to 25,000 horsepower. No details of the process are available at present, but it is reported that the nitrogen is extracted by means of large electric furnaces and absorbed by means of crushed limestone.

Some Experiments with Gage Cocks

By W. H. Wakeman

Some of the methods of attaching gage cocks and glasses to steam boilers, with comments upon the advantages and disadvantages of each arrangement.

The first boiler of which I had charge was of the locomotive type and had three gage cocks tapped directly into the outer head as shown in Fig. 1. There was also a water gage on the same head. This is a very natural arrangement, because each cock is independent of the other; hence if one is disabled it does not interfere with the other two. If the water level, as indicated by the gage glass, agrees with the gage cocks, it is double evidence that the true level of the water in the boiler is known.

Another boiler which I operated was fitted with a water column, as shown by the full lines in Fig. 2. No valves were

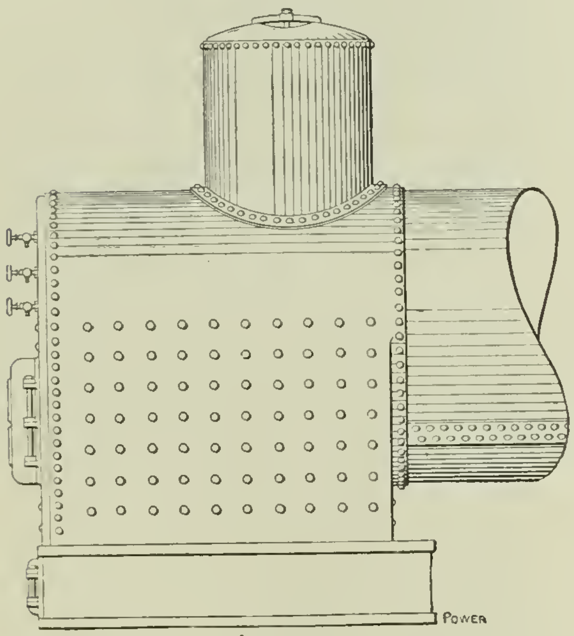

FIG. 1

inserted between the boiler and the gage cocks; hence the water column could not be shut off from the boiler. There was no drip valve connected to it, and this resulted in sediment collecting in the connections and causing trouble.

In another plant the boiler was fitted with a water column as already illustrated in Fig. 2, except that a 3/8-inch drip pipe was provided as shown by the dotted lines. This permitted some of the sediment to be blown out, but the pipe was not large enough to cause a rapid flow of water and steam through the connections, especially as it was not possible to shut off one while creating circulation through the other. When the drip valve was opened the water discharged directly onto the boiler-room floor, and this being far from pleasant, I bored a hole through the side of the building and extended the pipe through the wall. This disposed of the water as far as I was concerned, but there was danger of scalding people who passed the boiler house; hence the pipe was taken out and connected into the ashpit. Having cleaned the boiler front I proceeded to blow down the water column and in a few seconds practically the entire front of the boiler was covered with ashes, although the damper was wide open. Exactly the same result has been secured wherever I have tried a similar experiment; therefore, I consider the arrangement an unmitigated nuisance.

In three other places tubular boilers were fitted with gage cocks connected into the front head but, owing to the combustion chamber or smoke box being located at this point, it was necessary to provide a pipe about 20 inches long for each cock, also for each connection to the gage glass. These are illustrated in Fig. 3 but in the sketch the water gage

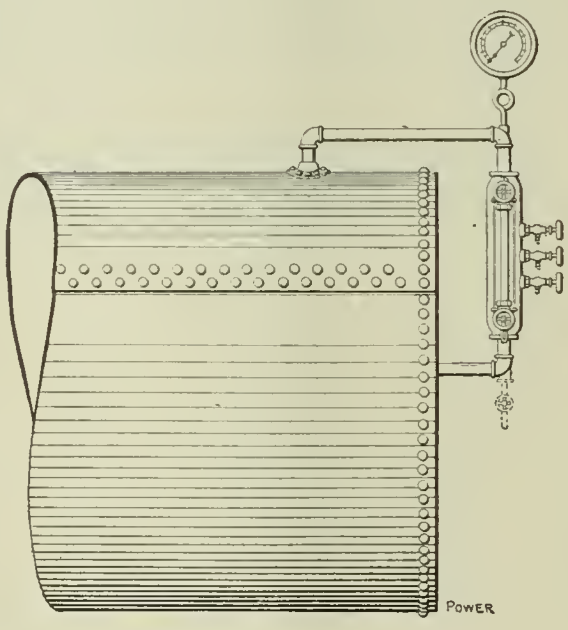

FIG. 2

is extended farther than it actually was in practice, in order to avoid interfering with the cocks. Some of these pipes were exposed to the direct action of the flames and hot gases while others were protected by sleeves consisting of pieces of larger pipes.

All of these connections slowly filled with sediment because the opening provided was not large enough to permit rapid circulation through the connecting pipe when a gage cock was opened. Special attention was given to cleaning these pipes when the boilers were cleaned, and sometimes it was necessary to remove the gage cocks in order to force sediment out with an iron rod. All of it did not bake hard in the pipes but when one of them was filled with a paste-like substance, it effectually prevented proper use of the gage cock. It was my custom to lift the weighted end of a gage cock and run a long wire into the pipe. This opened a passage temporarily, but sometimes it would fill and cease to discharge water before the cock was closed, thus proving very unsatisfactory. Such action always smeared the boiler front with mud.

At another plant the boilers were fitted originally with water columns having connections as shown for the water gage in

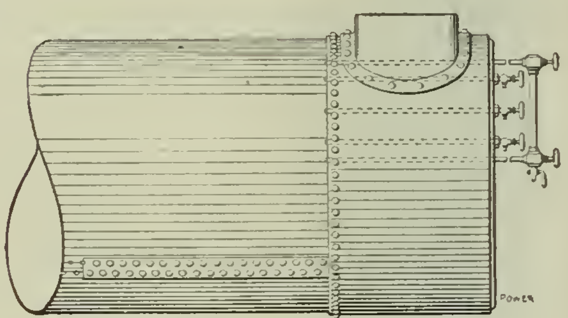

FIG. 3

Fig. 3. Valves were not provided in the connections; hence when anything happened to the water gage, or the three gage cocks attached to the column, it was necessary to remove all pressure from the boiler in order to make repairs. I accordingly altered this arrangement by placing a valve in each connection to the gage; therefore, when a glass broke, steam and water could be shut off while a new one was being put in. In order to prevent trouble from breakage of glasses

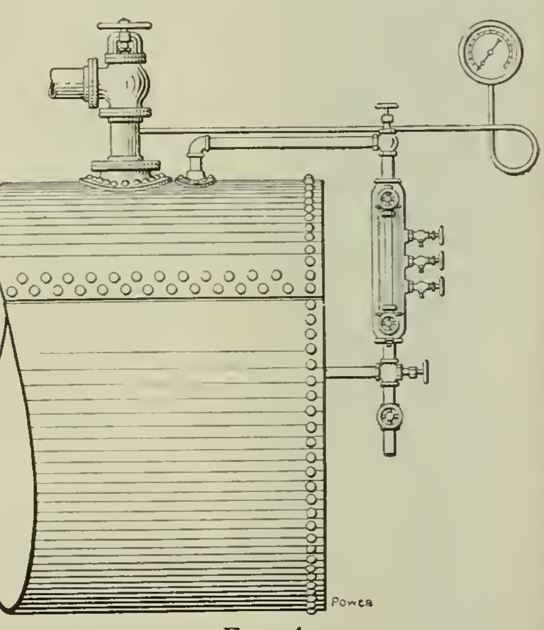

FIG. 4

during the night, the fireman made it a practice to shut these valves before he went home. Of course, this prevented the glass from showing a true water level in the morning, but he was intelligent enough to open them and ascertain how much water was in the boilers before starting the fires, as they were rebuilt every morning. A steam gage was attached to the top of each column, by a very short connection, in which there was no siphon to hold water. Examination of this piping when the boilers were empty, showed that a straight pipe extended down into the column below the water line, protecting the end of this pipe from steam except when the column was blown down to remove the sediment.

Upon taking charge of the boilers in another plant, I found the water columns attached as shown in Fig. 4, the connections consisting of 1¼-inch brass pipe. The drip pipes in this case were carried to the sewer without reduction in size, which proved very effective. These columns were also fitted with high- and low-water alarms. As a rule, I closed the valves in these connections, and opened the drip valves when leaving for the night; but one night I was awakened by a policeman who informed me that something was out of order in the boiler room, and he suggested that I go down and attend to it without delay. Upon arriving at the boiler room I found one of the alarm whistles blowing, as the valves had not been left according to my usual custom.

How do engineers manage to take care of columns fitted with high- and low-water alarms, that have no valves by which to shut them off at night? Do they make arrangements with the local policeman to attend to this duty in their absence, or is it possible to always have the water level low enough to keep one float down and high enough to support the other, and thus always prevent the whistle from blowing? Do accidents ever happen to the floats at night? If so, how are they repaired when pressure cannot be removed from the columns?

Gage cocks connected into these columns never become choked with sediment, the boiler fronts are not bespattered with mud when they are opened, and the connecting pipes are not in danger of filling with mud, nor of being burned by excessive heat. For these reasons one large connection above and another far below the water line, where neither is liable to be rendered useless except by gross carelessness continued for a long time, seem to be much superior to several small and independent connections located where they collect sediment readily, and are liable to be burned by the intense heat.

Flow of Steam and Design of Nozzles

By A. D. Blake

Development of formula showing the velocity attained by a jet of steam in expanding from a higher to a lower pressure and its application to the design of a simple nozzle.

In order to thoroughly understand the action of steam in flowing from a higher to a lower pressure it is first necessary to have a clear conception of the fundamental principles of work and energy. Consider a freely suspended body of mass M being acted upon by a constant horizontal force F. If all friction be neglected, the force F will produce an acceleration of the mass M equal to a feet per second per second; that is, starting from rest, the velocity at the end of the first second will be a feet per second, at the end of the next second it will be $2a$ feet per second, at the end of the third second $3a$ feet per second, and so on. Now let the mass be doubled. In this case it will require a force of $2F$ to produce an acceleration a, or a force F will produce an acceleration of only ½a. Similarly, if the original mass M be acted upon by a force $2F$, the acceleration will be $2a$. From this it is obvious that the force required must vary as the product of the mass and the acceleration, that is,

$$F = M a \qquad (1)$$

Next, consider a freely falling body of mass M acted upon only by gravity. At the end of the first second it will have attained a velocity of 32.16 feet per second; at the end of the next second a velocity of

$$32.16 + 32.16 = 64.32$$

feet per second, and so on, that is, a constant acceleration of 32.16 feet per second per second is produced by a force equal to the weight W of a mass M, and, according to formula (1), this may be expressed as

$$W = 32.16 \times M$$

from which the mass of a body is seen to be its weight divided by the acceleration due to gravity

$$M = \frac{W}{32.16} \qquad (2)$$

Reverting to the first case, that of a mass M acted upon by a force F and producing an acceleration a, at the end of t seconds the velocity V will be

$$V = a t \qquad (3)$$

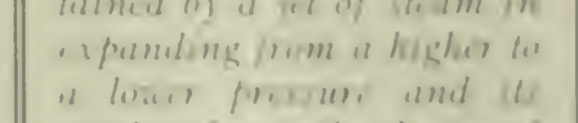
and the average velocity during this period will be

$$\frac{V}{2} = \frac{at}{2}$$

The distance d passed over during t seconds will equal the average velocity multiplied by the time

$$d = \frac{V}{2} \times t = \frac{at^2}{2} \qquad (4)$$

The kinetic energy of a body in motion



Section through Nozzle

is equivalent to the work done upon it, which equals the force multiplied by the distance through which it acts. Denoting the kinetic energy by K,

$$K = F \times d \qquad (5)$$

Substituting the values from equations (1), (3) and (4),

$$K = M \times a \times \frac{at^2}{2} = M \times \frac{V^2}{2}$$

But from (2)

$$M = \frac{W}{32.16}$$

Hence

$$K = \frac{W V^2}{64.32}$$

or the kinetic energy of one pound of any body in motion equals

$$\frac{V^2}{64.32} \qquad (6)$$

Having established this relation between the energy and the velocity of a body the flow of steam may be considered. If steam be allowed to expand from a higher to a lower pressure without doing external work, and its flow is unrestricted, the heat given up during expansion is transformed into kinetic energy, imparting velocity to the steam itself. The expansion in this case is said to be adiabatic and the quality at the lower pressure is less than at the higher. Denoting by H_1 the heat above 32 degrees Fahrenheit in one pound of steam at the initial pressure p_1, and the heat in the same pound of steam after expansion to a lower pressure p_2 by H_2, the heat given up during the adiabatic expansion from p_1 to p_2 is

$$H_1 - H_2$$

Since this heat drop is converted into kinetic energy and since one British thermal unit is equivalent to 778 foot-pounds, the kinetic energy of one pound of the steam may be expressed as

$$K = \frac{V^2}{64.32} = 778 (H_1 - H_2)$$

or,

$$V^2 = 64.32 \times 778 (H_1 - H_2) \qquad (7)$$

In a nozzle the expansion of the steam is not strictly adiabatic since the friction against the walls of the nozzle causes the steam to give up some heat. This heat (neglecting radiation which is small) is not lost but is given back to the oncoming steam and raises its quality; hence the quality at exit from a nozzle is slightly higher than that shown in the steam tables for adiabatic expansion

This heat, however, does detract from that which is convertible into kinetic energy. In view of this, it is necessary to slightly modify formula (7). Assuming the loss due to friction to be 10 per cent., this expression would be

$$V^2 = 64.32 \times 778 \times 0.90 \ (H_1 - H_2)$$

or,

$$V = \sqrt{64.32 \times 778 \times 0.90 (H_1 - H_2)} \quad (8)$$

With this as a basis the following problem may be solved:

What are the proportions of an expanding nozzle having a throat 3/16 inch in diameter, receiving dry saturated steam at 80 pounds gage and expanding to atmosphere? Also, what weight of steam will flow per second and what will be the velocity of the steam at exit?

That portion of a nozzle constituting the throat, for all practical purposes, may be considered as an orifice and the flow calculated accordingly. It has been proved experimentally that when steam expands through an orifice the pressure in the orifice cannot fall below 0.58 of the initial pressure. Furthermore, with the exit pressure bearing approximately this relation to the initial pressure, the flow through the orifice has been found to conform to the expression

$$W = \frac{p_1 A_1}{70} \quad (9)$$

Where,

W = Weight of steam flowing per second in pounds;

p_1 = Initial absolute pressure; in this case 94.7

A_1 = Area of orifice in square inches; in this case 0.02761, corresponding to a diameter of 3/16 inch.

Substituting these values in formula (9),

$$W = \frac{94.7 \times 0.02761}{70}$$

$$W = 0.03740 \ \textit{pound per second}$$

Now considering the nozzle as a whole, to determine the velocity of the steam at exit apply formula (8). From the steam tables or a temperature-entropy chart the total heat in one pound of dry saturated steam at 94.7 pounds absolute is found to be 1185 B.t.u., and after adiabatic expansion to atmospheric pressure it contains 1047 B.t.u. Hence,

$$V = \sqrt{64.32 \times 778 \times 0.90 \ (1185 - 1047)}$$
$$= 2490 \ \textit{feet per second}$$

If allowed to expand adiabatically from 94.7 pounds to atmospheric pressure the quality at exit would have been 89.5 per cent., but taking into consideration the heat of friction returned to the steam the quality at exit would be found as follows. The latent heat of vaporization at atmospheric pressure is 970.4 and the heat of friction returned to the steam was

$$0.10 \ (H_1 - H_2) = 0.10 \ (1185 - 1047) = 13.8 \ \textit{B.t.u.}$$

Then the increase in quality would be

$$\frac{13.8 \times 100}{970.4} = 1.42 \ \textit{per cent.}$$

and the final quality would be

$$89.5 + 1.42 = 90.92 \ \textit{per cent.}$$

Denoting the cross-sectional area of the exit of the nozzle by A_2, the weight of steam flowing by W and the density (cubic feet per pound) at atmospheric pressure and 90.92 per cent. quality by v_2,

$$W = \frac{A_2 V}{144 \ v_2}$$

The volume of one pound of dry steam at atmospheric pressure is found from the steam tables to be 26.79 cubic feet. Therefore, at 90.92 per cent. quality a pound of steam at this pressure would occupy

$$0.9092 \times 26.79 = v_2 = 24.3 \ \textit{cubic feet}$$

The value of W was previously found to be 0.0374 pound and V to be 2490 feet. Substituting these values,

$$0.0374 = \frac{A_2 \times 2490}{144 \times 24.3}$$

or,

$$A_2 = \frac{0.0374 \times 144 \times 24.3}{2490} = 0.0526 \ \textit{square inch}$$

This corresponds to a diameter of 17/64 inch.

The ratio of length to diameter (at the throat) of nozzles differs widely among different manufacturers, but a ratio of 12 to 1 is considered by many to be good practice. Therefore, the dimensions of the nozzle under consideration would be as shown in the illustration.

A New Process of Water Softening

The "zeolites" are distributed pretty freely among the older rocks of the earth's surface, though not entering into the constitution of the rocks themselves. They are found in a crystalline form in amygdaloidal fissures or cavities of trap or plutonic rocks, where they have apparently been deposited from water which has percolated into the cavities, thus probably being products of decomposing nepheline, or felspar, or hydrated felspars themselves. They are composed generally of varying quantities of silica, alumina, lime, soda, potash and water, the silica always largely predominating in all forms, though the other constituents are not necessarily found in all "zeolites." As an example of one form take analcime, which is composed of 54.5 per cent. of silica, 23.3 per cent. of alumina, 14.1 per cent. of soda, and 8.2 per cent. of water. These zeolites have, in contradistinction to other silicates occurring in nature, the property of being soluble, and they also decompose in dilute acids. They have also the very important property of being able to exchange their bases for others.

It has been found that when hard water is allowed to filter slowly through layers of these hydrated silicates of alkalies the lime in the water changes place with the soda in the filtering medium, and the water passes out softened; and this fact has been the means in Germany of instigating a series of experiments during the last two years, which have proved of great value, and which have shown that these zeolites can be produced artificially, with the result that the substance is now made much more regular in its composition and freer from impurities than that found in a state of nature. To these artificial zeolites has been given the name of "permutit," which in a moist condition is of a granular flaky form, and has a luster like that of mother-of-pearl. It has a high porosity, and in the dry state readily absorbs about 50 per cent. of water. It is obtained by fusing together felspar, kaolin, clay and soda in definite proportions, the resultant material being lixiviated with hot water, when permutit is left as a residue. The granular material is freed as much as possible from the final alkaline lye by washing and centrifugal action.

In *Engineering* the use of this material for softening water is briefly described as follows: The total hardness of water may consist of temporary hardness or of permanent hardness, or of the two combined, the former being caused by calcium and magnesium carbonates, and the latter by other salts of lime and magnesia. Boiling at atmospheric pressure precipitates the carbonates and the magnesia, but not the salts forming permanent hardness. In commercial processes at the present time, sodium carbonate is added to water as a means of precipitating the hardening constitutents of the water, there being an exchange of bases between the lime and manganese and the sodium carbonate. In like manner, if hard water be allowed to filter slowly (the slower the better) through layers of permutit, there is likewise an exchange of bases, the lime in the water taking the place of the soda in the permutit, one molecule of calcium bicarbonate being converted (in the case of temporary hardness) into two molecules of sodium bicarbonate, which latter remains in the water, being very soluble. The permutit in the filter will only retain this power so long as any soda remains to exchange with the lime in the water. Permutit suffers practically no loss during use, but when a certain amount of water has been passed through it, its softening powers disappear, but they can easily be restored, and the material can be used over and over again practically indefinitely.

The power of regeneration appears to be the chief novelty of the process; but before it is carried out a few essential points must be attended to. In the first place, the filter must be cleaned. Experience shows that filtration is most effective from the top to the bottom, and that, therefore, cleaning should take place in the reverse direction—namely, from the bottom to the top—so as to loosen the mass and remove any air that has collected in the material, soft water, if possible, being used for the purpose. After washing, the permutit is regenerated by a solution of common salt, the solution generally being of 10 per cent. strength. Previous to regeneration all water is removed from the filter down to the layer of permutit, after which the salt solution is introduced and allowed to flow slowly through the filter for from four to five hours. In addition to this, the brine is allowed to stand for a further four or five hours, just covering the layer of permutit, after which the filter is filled with water from the top, and an outlet cock at the bottom is opened for 20 or 30 minutes, or until the water no longer shows any hardness with ammonium oxalate or with soap solution.

The chemical reaction that takes place during regeneration consists in an interchange between the soda in the sodium chloride and the lime in the permutit (derived from the water which it has softened), calcium chloride remaining in solution in the regeneration water. It may be stated that in practice the most suitable rate for the water that requires softening to pass through the layers of permutit has been found to be from 13 to 17 feet per hour. The permutit is not only active at the surface, but also in the interior, in consequence of its porosity.

From information supplied from Germany it appears that filters using these artifical zeolites have been in practical use during the last two years, treating water for a variety of purposes, including use in boilers and for washing fine textile goods, and a plant has recently been installed in England for the latter purpose with satisfactory results.

In one case where a permutit filter was supplied to a steam laundry in Berlin more than two years ago, it is stated that in about nine months 1,174,800 gallons of water passed through the filter, which volume was completely softened without any apparent loss of permutit. The charge of permutit was about half a ton and about 1050 gallons of water passed over each pound of the material. In this case about 44,000 gallons of water per week were used, and regeneration was carried out twice per week, 88 pounds of salt being used per regeneration, although it is stated that it need not have been done quite so often. The cost of regeneration naturally depends on the price of salt, and on the degrees of hardness in the water. It is stated that water having 53 degrees of hardness has been reduced to 3.7 degrees by the process.

The system is now being introduced into England by Water-Softeners, Limited, 20 Copthall avenue, Throgmorton street, E. C., London.

A Record Breaking Turbine Test

The following results of a test conducted upon a 6000-kilowatt turbine at the Dunston power station of the Newcastle-upon-Tyne Electrical Supply Company are reproduced from *Engineering* of March 10. The turbine is of the Parsons type, having separate high- and low-pressure casings. It was designed to have its maximum economy at 9000 brake horsepower, with steam at 190 pounds gage and at 190 degrees superheat. In the test the superheat did not exceed 178 degrees Fahrenheit, but the vacuum was high, the absolute pressure in the condenser being 0.90 inch of mercury. This is 249.4 B.t.u. per kilowatt-hour with 90 per cent. generator efficiency corrected for condenser leakage which is 76.1 per cent. efficiency referred to the Rankine cycle, and the best of which we have learned. The test was conducted by Messrs. Merz and McLellan, consulting engineers to the Newcastle company.

The official steam-consumption trials of this plant were run on December 16, 1910. The contractors to the company for the complete unit were Messrs. Brown, Boveri & Co., Ltd., London.

Details of the plant are given in the accompanying Table 1.

TABLE 1

Turbo-Alternator:	
Normal output	6000 kw.
Speed	1200 r.p.m.
Turbine:	
Specified most economical load	9000 b.h.p.
Type	Two-cylinder Parsons
Type of blading	Parsons
Arrangement of steam passage	H.-P. cylinder single-flow; L.-P. cylinder, partly single-flow, partly double flow
Specified steam pressure	190 lb. per sq. in.
Specified superheat	190 deg. Fahr.
Alternator:	
Type	Rotating field three-phase
Continuous output	7500 k.v.a. at 0.8 power factor
Voltage (terminal)	6000 volts
Exciter	Direct-coupled self-excited
Condensing Plant:	
Surface	15,000 sq.ft.
Type	"Contraflo"
Diameter of tubes, external	1 in.
Thickness of tube	18 B.W.G.
Circulating water per hour	[illegible] gallons
Specified circulating water temperature	20 deg. Fahr.
Air-Pumps:	
Type	Edwards three-throw, motor-driven
Capacity	[illegible] cu.ft. per barrel
Volume swept through per minute by air-pump plungers	1500 cu.ft. per min.
Evaporator:	
Surface	400 sq.ft.

Preliminary unofficial trials were run on December 14 and 15 at various vacua and at various superheats to determine the corrections to be applied to actual figures in order to enable the actual results to be compared with those specified.

The results of the official trials are given in Table 2.

TABLE 2

Trial	1	2	3
Date	Dec. 16	Dec. 16	Dec. 16
Duration	9 a.m. to 10 a.m.	11.30 a.m. to 1 p.m.	2.30 p.m. to 4.00 p.m.
Output from generator to bus-bars (that kilowatt-hr.)	[illegible]	[illegible]	[illegible]
Speed, r.p.m.	[illegible]	[illegible]	[illegible]
Steam Quality

Total water used per hour, lb.	[illegible]	[illegible]	[illegible]
Water used per kilowatt-hour, lb.	[illegible]	[illegible]	[illegible]
Water used per kilowatt-hour corrected for condenser leakage, lb.	[illegible]	[illegible]	[illegible]
Steam consumption corrected for 190 deg. F. superheat and 29.1 in. vacuum, lb. per kw.-hr.	[illegible]	[illegible]	[illegible]

REMARKS

1. *Change of Load.*—An interval of 1½ hours was allowed between changes of load.
2. *Output.*—Measured by integrating wattmeter specially calibrated for the purpose.
3. *Steam Consumed.*—Weighed by the permanent weigh-tanks installed at the power-station.

The total output of the Roumanian oil-fields for 1910 is now stated by the *Moniteur du Pétrole Roumain* at 1,352,300 tons. This is an increase of over 55,000 tons, or 4.3 per cent., over the 1909 figure. The totals of the various companies are of more particular interest. The Steaua Romana fell off 25,800 tons, but still heads the list with an output of 410,250 tons. The Astra Romana comes next with an output of 287,800 tons and an increase of over 20,000 tons; then the Romano Americana with 145,300 tons (increase 24,800 tons). The Concordia fell off by 16,700 tons, but comes fourth on the list with an output of 95,800 tons; and lastly follow the Orion, 61,400 tons (increase 13,700 tons) and the Regatul Roman, 53,800 tons (decrease 28,600 tons).

The Small Turbine in Marine Work

The small turbine is being used extensively for such service as pumping, lighting, ventilating and forced draft, particularly in the United States navy where reliability is equal in importance to economy of space and weight. For forced-draft work the turbine has been especially successful.

On shipboard the space occupied by and the weight of the mechanical equipment are two extremely important factors, more important, oftentimes, than the first cost and economy in operation. Perhaps most important of all, however, is reliability of service. The development of the small turbine has made possible wonderful progress in economy of space and weight besides producing simplicity and dependability in operation. To show the extent to which this type of prime mover is being applied in marine practice, some of the uses to which it is put are specified below.

The Hudson River Day Line boats are each equipped with a turbine-driven centrifugal pump for use in trimming ship. When a boat is making a landing the passengers crowd to one side, causing it to list. This oftentimes seriously interferes with the steering and manipulation of the boat. To keep the boat on a level keel on such occasions two large tanks were built in amidships so that one or the other may be filled with river water whenever it is desirable.

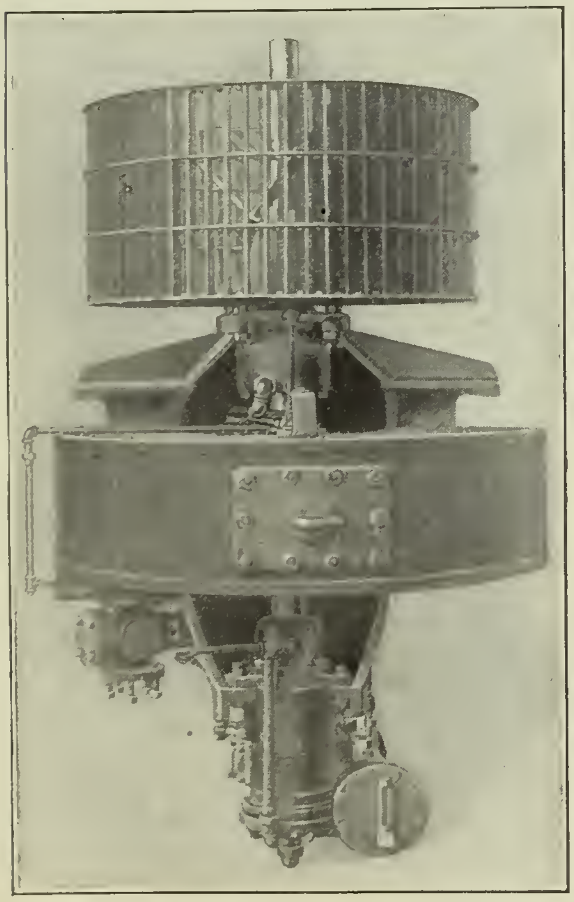

Fig. 1. Forced-draft Set for Torpedo-boat Destroyers

The pump is 8 inches in size and is driven by a 15-horsepower single-stage Terry turbine at a speed of 1800 revolutions per minute. These ballasting sets are guaranteed to develop their full capacity of 1000 gallons per minute within 20 seconds from the time of opening the throttle. The outfit is set down in the hold but it is operated from the engineer's platform so that the engineer may start the filling of a tank the instant that he sees the telltale arrow shift.

A use to which the turbine is now commonly being put is the driving of dynamos to furnish current for lighting, ventilating and other purposes. The United States Navy is particularly progressive in this respect. The flagship "Connecticut" has four 100-kilowatt turbo-generator sets and twelve revenue cutters are equipped with turbo-generators of capacities ranging from five to seven kilowatts.

At Boston the municipal fireboat, "George A. Hibbard" is fitted with a multistage centrifugal fire pump driven by a 100-horsepower turbine.

The most important application of the small turbine in marine work has been its adoption for forced draft. The use of turbines for forced draft has been extensive in the Navy where a continuous and sufficient air supply is always of first consideration. Fig. 1 shows a forced-draft set which is used on the new torpedo-boat destroyers "Roe," "Terry,"

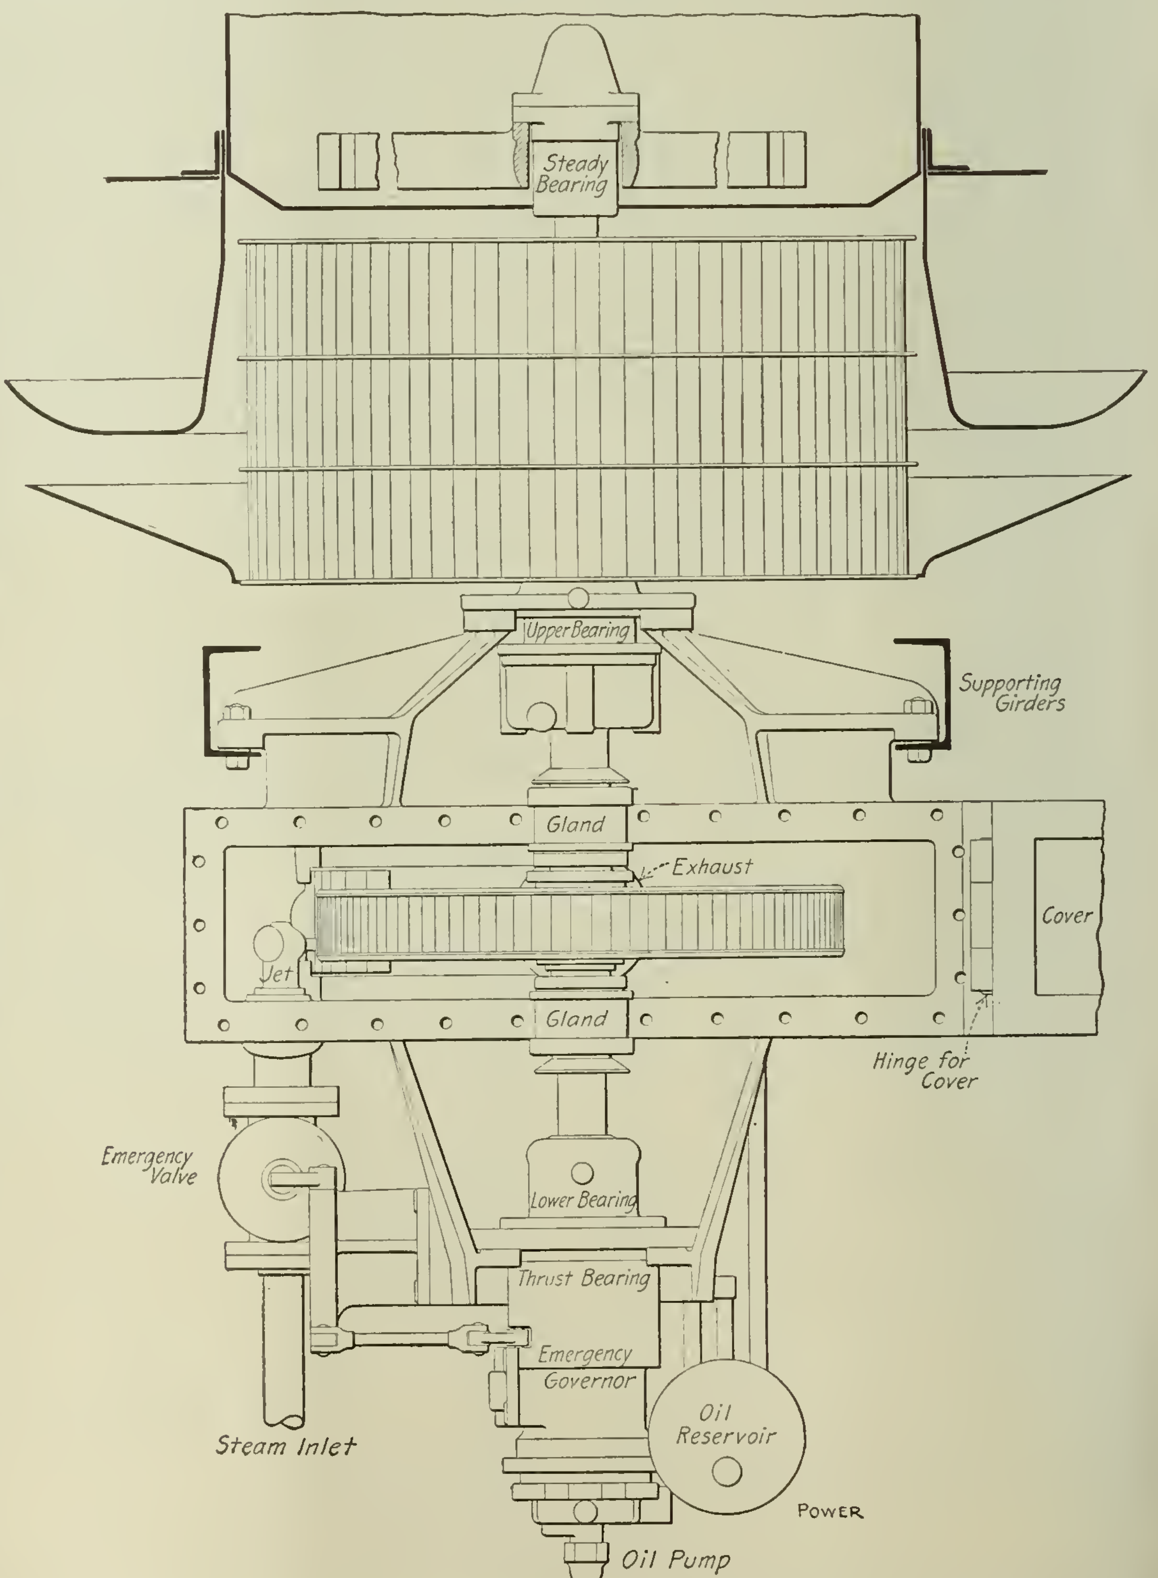

Fig. 2. General Design of Forced-draft Set for Torpedo-boat Destroyers

"Paulding" and "Drayton." The five destroyers, "Monoghan," "Fanning," "Jouett" and "Jenkins" which are now being built will also have sets of the same design. A set consists of a Terry single-stage vertical turbine and a Sirocco fan which has a 30-inch runner. Two sets are placed in each of the two stoke holds and each set delivers from 23,000 to 25,000 cubic feet of free air per minute at a pressure of from 3½ to 5 inches of water; the speed is about 1400 revolutions per minute.

Fig. 2 shows the general design of the set illustrated in Fig. 1. One feature of this design is that the entire unit, completely assembled, can be dropped through the ventilator which is 40 inches in diameter. The whole apparatus is so arranged that it can be mounted on I-beams suspended from the deck or bulkheads. The fan wheel itself is on a line with the deck immediately at the foot of the ventilator. The main casing of the turbine is divided vertically along the center line and the cover is fitted with a hinge so that the casing can be opened without the use of a crane or the removal of any of the parts.

The weight of the whole runner is carried by a ball bearing which is always kept flooded with fresh oil. The step bearing is in the lower bearing housing; below it is fitted an emergency governor of the unstable type which, when the weights fly out, releases a trigger which in turn allows the automatic stop valve to close, the valve being primarily kept open against a powerful spring.

At the extreme lower end of the shaft is fitted a small geared oil pump. This pump consists of two ordinary gear wheels, and is so designed that it will give a sufficient supply of oil to all of the bearings at any speed. A combined relief and bypass valve is placed between the suction and the discharge and set at a given pressure; thus, at low speeds the pump will deliver oil to the bearings at the same pressure as at high speeds. All of the oil is drained back from the bearings to a common reservoir; the position of this reservoir is slightly above that of the oil pump.

On the destroyers "Warrington," "Myrant," "Lawrence," "McCall" and "Burrows" sets composed of the same make of turbine and a special Sturtevant fan are used. The "Patterson" and "Ammen," now building, will be similarly equipped. The fans for these sets are of the standard Sturtevant design, except that the blades have a special contour in order to secure the greatest possible efficiency at the speed used.

It is a noteworthy fact that all of the destroyers which have been equipped with this type of forced-draft apparatus have gone through their acceptance trials without the slightest trouble due to lack of sufficient air or interruption of service from the blowers.

Steam Line Conduit of Low Cost

By Henry G. Pope

In connection with the installation of a steam power-plant equipment, it was necessary to arrange a steam line to connect the boiler house with the pump house shown in Fig. 1. The connection was to be a temporary one, to be replaced ultimately with a permanent and a larger pipe. Methods of carrying the line overhead were considered but were abandoned because of the radiation losses involved and because of the expense of erecting a supporting structure that would be strong enough to be reasonably safe against breakdown.

Several designs of conduit construction were considered, but the one suggested in Fig. 2 was finally adopted because of its low cost and ease of installation. It appeared to be sufficiently substantial to give good service for the few years that it would be in use. The conduit, Fig. 2, was constructed from rough pine planks held together with common steel spikes. Joints between all plank ends were broken and a piece of waterproofed building paper was tacked over each joint in the roof. All of the planks forming one of the sides of the conduit were wider than those forming the other, so that the roof plank would have a pitch to better enable it to shed water that percolated through the soil. In building the conduit, the three lower planks, *A*, *B* and *C*, Fig. 2, were assembled in trough-like sections and lowered into the trench and the ends of the sections were there spliced together. After the pipe had been laid in, the cover plank was nailed on and the trench refilled with earth.

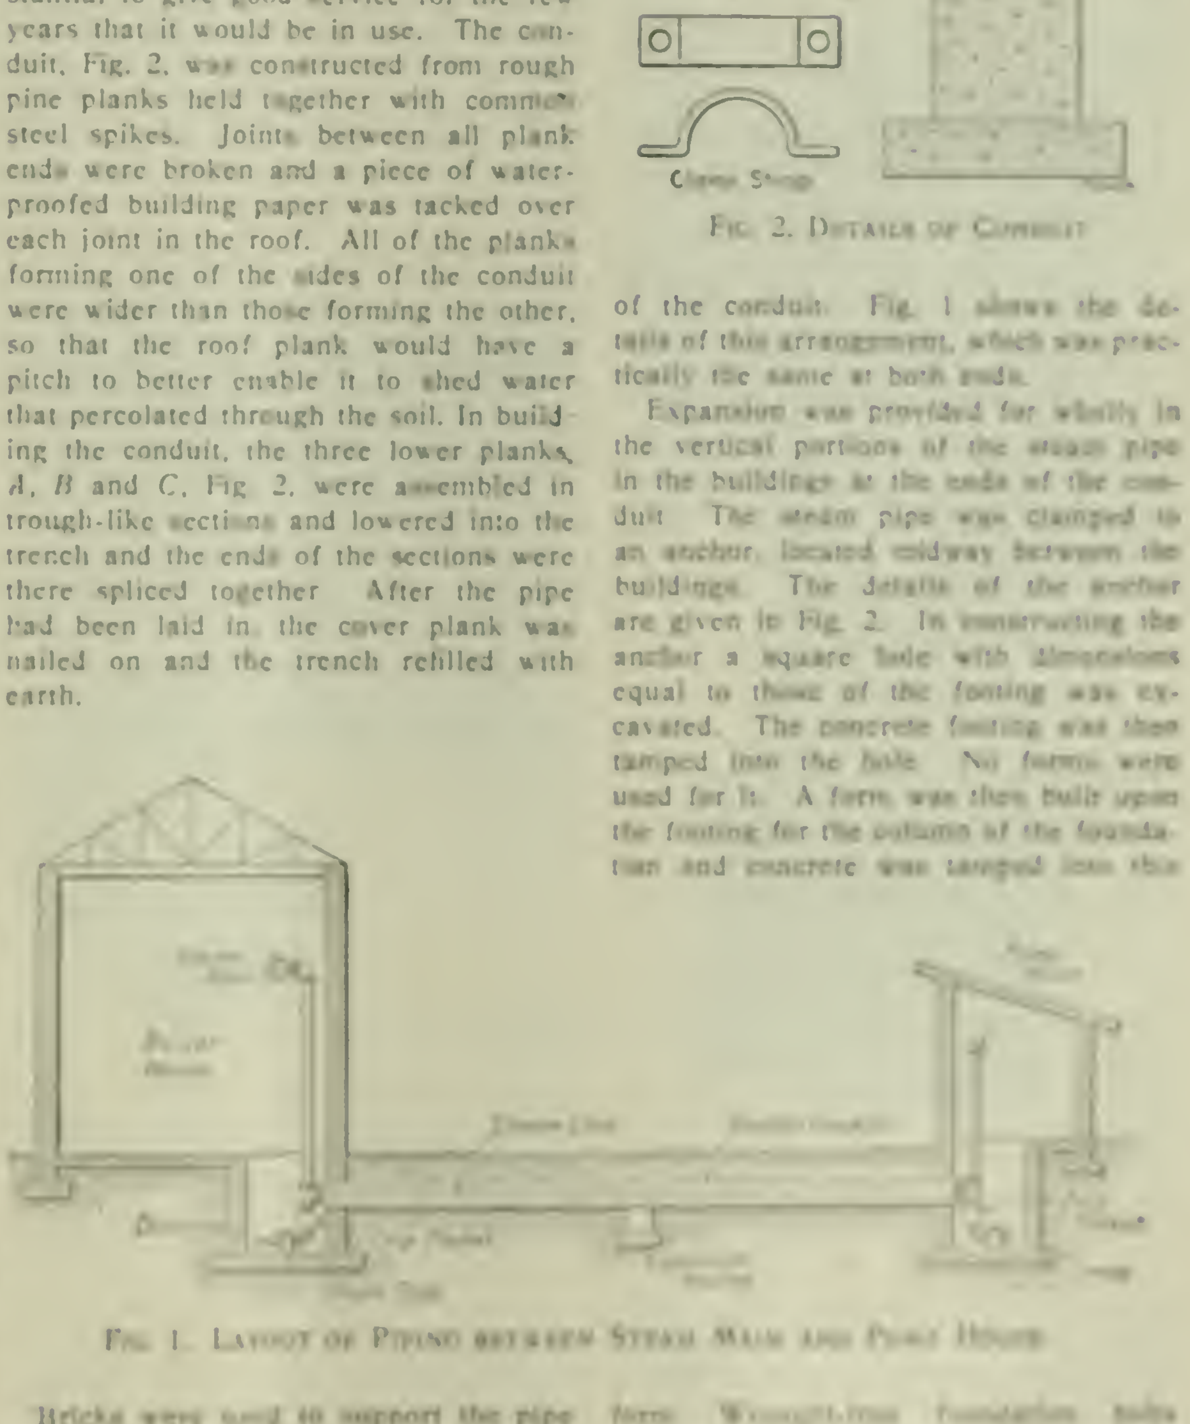

Fig. 1. Layout of Piping between Steam Main and Pump House

Bricks were used to support the pipe in the conduit. Supports of several other forms were considered, but all were abandoned in favor of the brick type because of its simplicity and low cost. Four bricks were used at each point of support, the distance between supports being about 10 feet. Two bricks (see Fig. 2), laid on their sides on the bottom plank of the conduit, prevented the pipe from touching it and two more bricks, each resting on its end, kept the pipe centered laterally. To prevent the bricks from shifting, due to the expansive and contractive movements of the pipe, several spikes were driven into the bottom planks around the bricks.

Although it is not shown in Fig. 1, the pipe line and conduit had a slight downward pitch toward the pump house, so that all condensation would flow with the steam that way. A drip pocket, drained by means of a steam trap of the bucket type, was provided at each end of the conduit. Fig. 1 shows the details of this arrangement, which was practically the same at both ends.

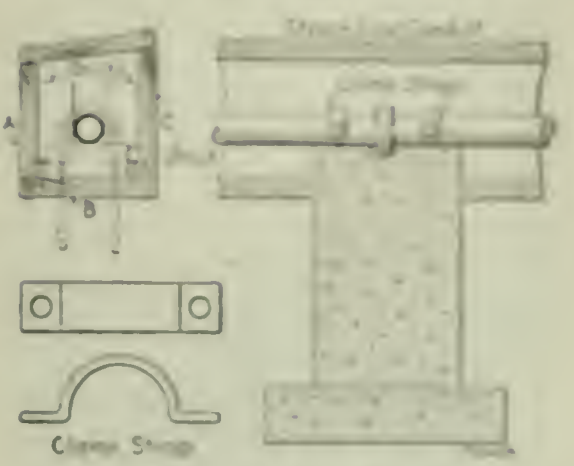

Fig. 2. Details of Conduit

Expansion was provided for wholly in the vertical portions of the steam pipe in the buildings at the ends of the conduit. The steam pipe was clamped to an anchor, located midway between the buildings. The details of the anchor are given in Fig. 2. In constructing the anchor a square hole with dimensions equal to those of the footing was excavated. The concrete footing was then tamped into the hole. No forms were used for it. A form was then built upon the footing for the column of the foundation and concrete was tamped into this form. Wrought-iron foundation bolts were cast in the concrete. Clamping straps, details of which are shown in Fig. 2, held the steam pipe firmly to the foundation and prevented any movement at that point. Ordinary nuts, turning on the foundation-bolt ends, secured the straps.

Automatic Starters for Induction Motors

By R. H. Fenkhausen

Automatic starters for induction motors are much more expensive than hand-operated starters, of course, but there are many installations where the saving in attendance or in other installation and maintenance costs will justify the extra first cost of automatic starters. For the control of a motor-driven pump deliver-

Fig. 1. Three-phase Starter for Squirrel-cage Motors

ing water into a tank in which the water level must be kept within certain limits, or for the control of a motor-driven compressor the receiver pressure of which must be maintained fairly constant, the automatic starter is almost indispensable.

Where motor attendants are unskilled or careless, automatic starters make it possible to limit the starting current and acceleration of each motor, because once the operator has closed the small switch in the control circuit, the starter automatically performs the several operations of starting the motor with a predetermined interval of time between each operation and the operator is powerless to shorten the starting period.

There are many cases where it is not practicable to install a motor near the

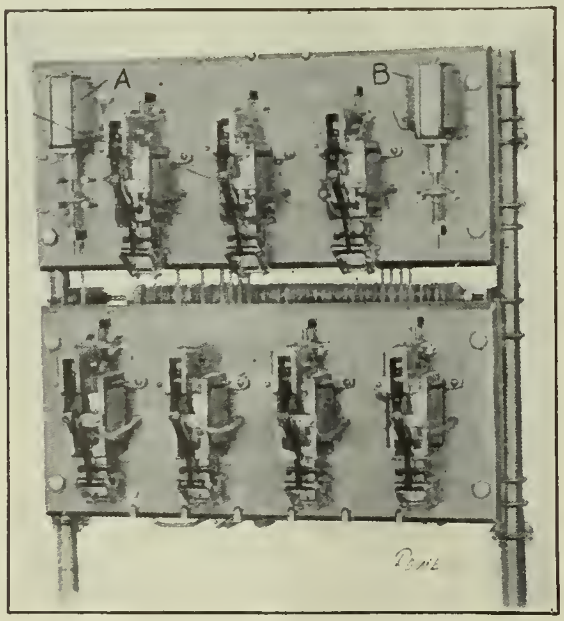

Fig. 2. Three-phase Starter for Wound-rotor Motors

place where it must be controlled and it often happens that the extra expense of an automatic starter is offset by the saving in wiring. When the automatic starter is used, it may be located close to the motor and the actual control accomplished by a small snap switch in the solenoid circuit of the starter. As two very small wires only are needed to connect the snap switch with the starter, there is a considerable saving in installation time and material over that required to carry the main wires from the motor to the control point.

If the distance from the motor to the point of control is very great, there is also a saving of energy due to the fact that there is less wire in the power circuit and therefore less loss due to resistance. This applies particularly to wound-rotor induction motors with external starting resistors, because, in addition to the line wires, these motors require three leads of large capacity from the controller to the collector rings and if the distance from the motor to the controller is very great, the loss due

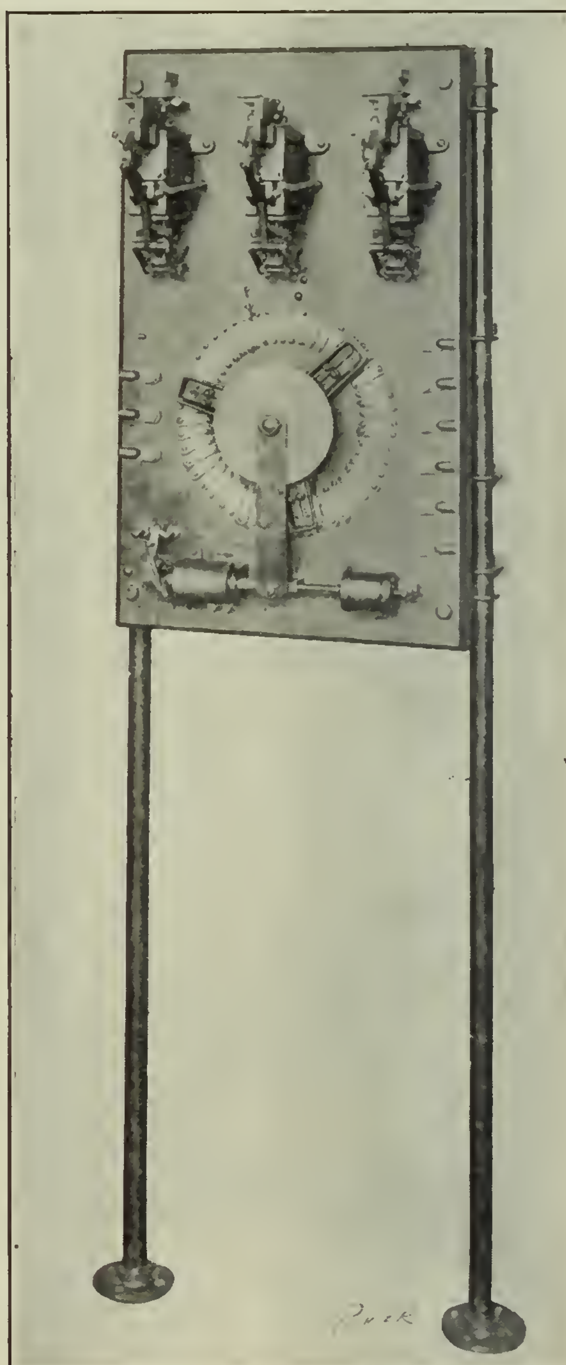

Fig. 3. Automatic Starter for Gradual Acceleration

to the drop in the secondary wiring will be excessive. The use of the automatic starter in such a case not only results in a marked reduction in installation costs but also improves the efficiency and speed regulation of the motor.

General Functions

Figs. 1, 2 and 3 show automatic starters which may be controlled in several ways. For remote hand control a snap switch is placed at the desired control point and connected in the main solenoid circuit of the starter.

Where automatic acceleration alone is required, the main solenoid circuit may be permanently closed and the motor started and stopped by a switch connected in the main motor circuit at any point between the motor and the entrance of the service wires, or the main circuit may be left closed and a pilot switch used as for remote control. The latter method is preferable unless the line switch is of the oil-break type, but the choice between the two methods will naturally be governed by the wiring layout. If the point of control is close to the run of the motor circuit one method is as good as the other, but if the control point is not located near any point on the supply circuit, the saving in wiring will make the use of the pilot switch advisable.

When automatic starters are controlled by float switches or pressure governors,

Fig. 4. Relay for Control by Pressure Changes

these are invariably connected in the main solenoid circuit, because their contacts are small and therefore not adapted for connection in the motor circuit where heavy currents must be controlled.

The pressure governor shown in Fig. 4 consists of a standard bourdon pressure-gage mechanism provided with two contact rings to which adjustable contacts may be clamped at any point. These contacts and the end of the gage pointer are silver tipped to prevent corrosion. The contacts are too small to carry even the main solenoid current of the starter, so a relay is interposed between the gage contacts and the solenoid circuit. When the pressure falls below the lower limit set, the end of the gage pointer makes contact with the sliding block on the inner ring and thereby closes the energizing circuit of the relay solenoid shown at the right, which raises its plunger, bringing the disks into contact with the two pairs of terminals above them; this closes the solenoid circuit of the automatic starter and short-circuits the contact made by the pointer and the inner ring. When the pressure rises to the upper limit, the gage pointer makes contact with the sliding block on the outer ring and short-circuits the relay magnet, which drops its core and opens the solenoid circuit of the starter at the lower disk contacts, shutting down the motor. The gage contacts never break any current, because the upper disk of the relay short-circuits the contact made by the pointer with the block on the inner ring; consequently, when the rising pressure moves the pointer away from the inner

Fig. 5. Complete Tank Switch, Float and Rod

contact, the circuit remains closed at the upper disk. The motor continues to run until stopped as described. (See also the relay connections in Fig. 8.)

Fig. 5 shows a float switch designed to be clamped on the edge of a tank. Adjustable collars on the float rod actuate the switch which controls the solenoid circuit of the automatic starter, and by setting the collars to operate the switch at the desired water levels the height of water in the tank may be kept within the limits of these levels. It is desirable that there be as great a difference as practical between the upper and lower levels in order that the pump and motor shall not be started and stopped too frequently. When it is not possible to locate the float switch at the edge of the tank, on account of exposure to the weather or other conditions tending to interfere with its operation, a float switch of the type shown in Fig. 6 may be used; this is operated by a rope passed over guide pulleys, with a counterweight on the end opposite to the float.

Starter Operation in Detail

Fig. 1 shows an automatic starter for squirrel-cage induction motors in which the various contacts are made and broken by "contactors," or electromagnet

Fig. 6. Float Switch for Operation by Rope

switches, under the control of relays. In the starter shown, the contactors are arranged for submersion in an oil tank for 2200-volt service, but for lower voltages the oil tank is omitted. The operation of this starter is as follows (see Fig. 7):

When the control circuit is closed, the relay A and the contactor magnets 1 to 5 are energized; the contactors connect the autotransformer coils across the line with the motor connected to the low-voltage taps. The relay A lifts its plunger against the retarding influence of a dashpot that is adjustable so as to vary the duration of the starting period of the motor. When the plunger reaches its limit of upward travel the control circuit of the contactors 1 to 5 is opened by means of the small switch shown above the relay in Fig. 1 and another circuit is closed which energizes the magnets of the contactors 6 to 8, which connect the motor directly to the line.

No-voltage protection is provided by the relay A and the contactors 6 to 8, which open on failure of the current sup-

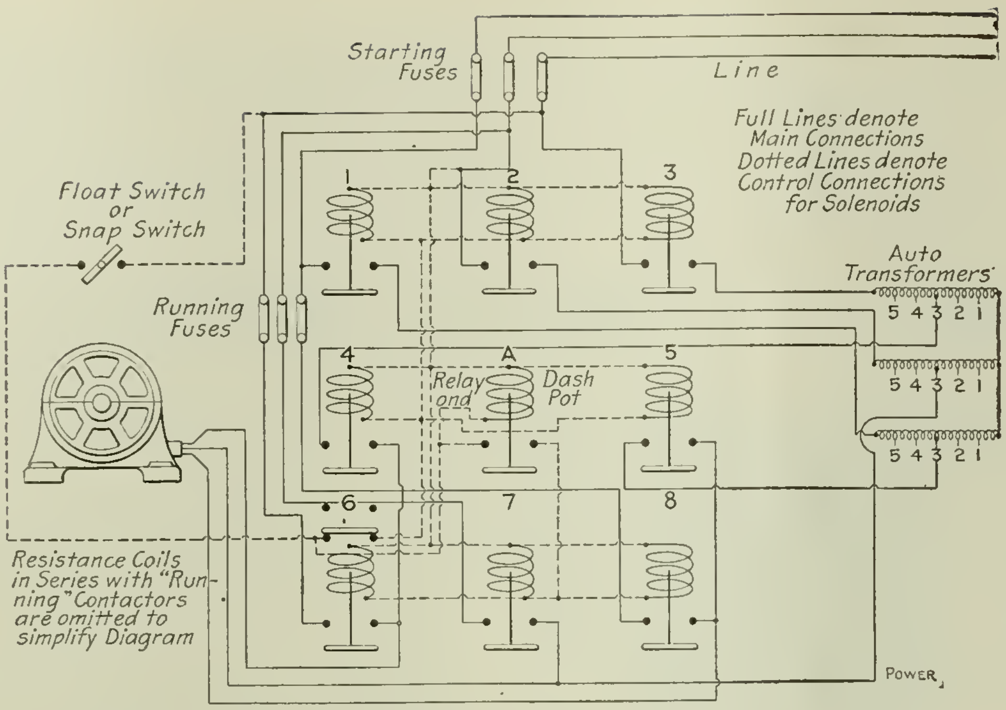

FIG. 7. DIAGRAM FOR STARTER IN FIG. 1 AND FLOAT SWITCH

ply, leaving the starter ready to start up again in the usual manner as soon as the current supply is resumed. The motor is stopped by opening the main control circuit.

The automatic starter shown in Fig. 2 is for use with induction motors of the wound-rotor type. Its construction is similar to that illustrated in Fig. 1, but two starting points are provided by variation of the resistance in the rotor circuit. The operation of this starter is as follows (see Fig. 8): When the control circuit is closed, the shunt coil of the compound-wound relay *A* lifts its plunger, which closes the magnet circuit of the contactors 1, 2 and 3; these connect the stator winding of the motor to the line, leaving all of the resistor in the rotor circuit. The contactor 1, in closing, also opens the shunt-coil circuit of the relay *A*, leaving its plunger held by the series coil. This series winding is proportioned so that as soon as the starting current of the motor falls below a certain value the coil will drop the plunger and close the operating circuit of the contactors 4 and 5; these cut out part of the rotor resistor and the contactor 4 also opens the shunt winding of the compound-wound relay *B*, leaving its plunger held by the series coil alone. When the starting current has fallen below the value for which the relay *B* is designed, this relay drops its plunger and closes the operating circuit of the contactors 6 and 7 which cut out the remainder of the rotor resistor and short-circuit the collector rings of the motor; the contactor 6 in closing also opens the operating circuit of the contactors 4 and 5, which therefore open their contacts. Overload during the starting period is prevented by the setting of the relays *A* and *B* and no-voltage protection is provided by the contactors 1, 2 and 3, which drop out and restore the starting conditions upon failure of the current supply.

The automatic starter shown in Fig. 3 is for use in service requiring a more even acceleration than is afforded by two starting points. A solenoid-operated ratchet switch of the dial form automatically cuts out the resistor in the rotor circuit little by little and the large number of contacts provided on the dial gives a very uniform rate of acceleration.

For small squirrel-cage motors, of less than 20 horsepower, the starter shown in Fig. 1 is often too costly and small self-contained starters of the types illustrated by Figs. 9 and 10 are applicable. The one shown in Fig. 9 is designed for operation by means of a rope connecting with a large float in a tank supplied by a motor-driven pump. The sheave around which the rope passes is loose on the starter shaft and its periphery is slotted through a large arc to permit a considerable movement of the sheave (due to change in water level) before moving the weight arm, which passes through this slot. When the water level falls, the rope attached to the float rotates the sheave in the clockwise direction until

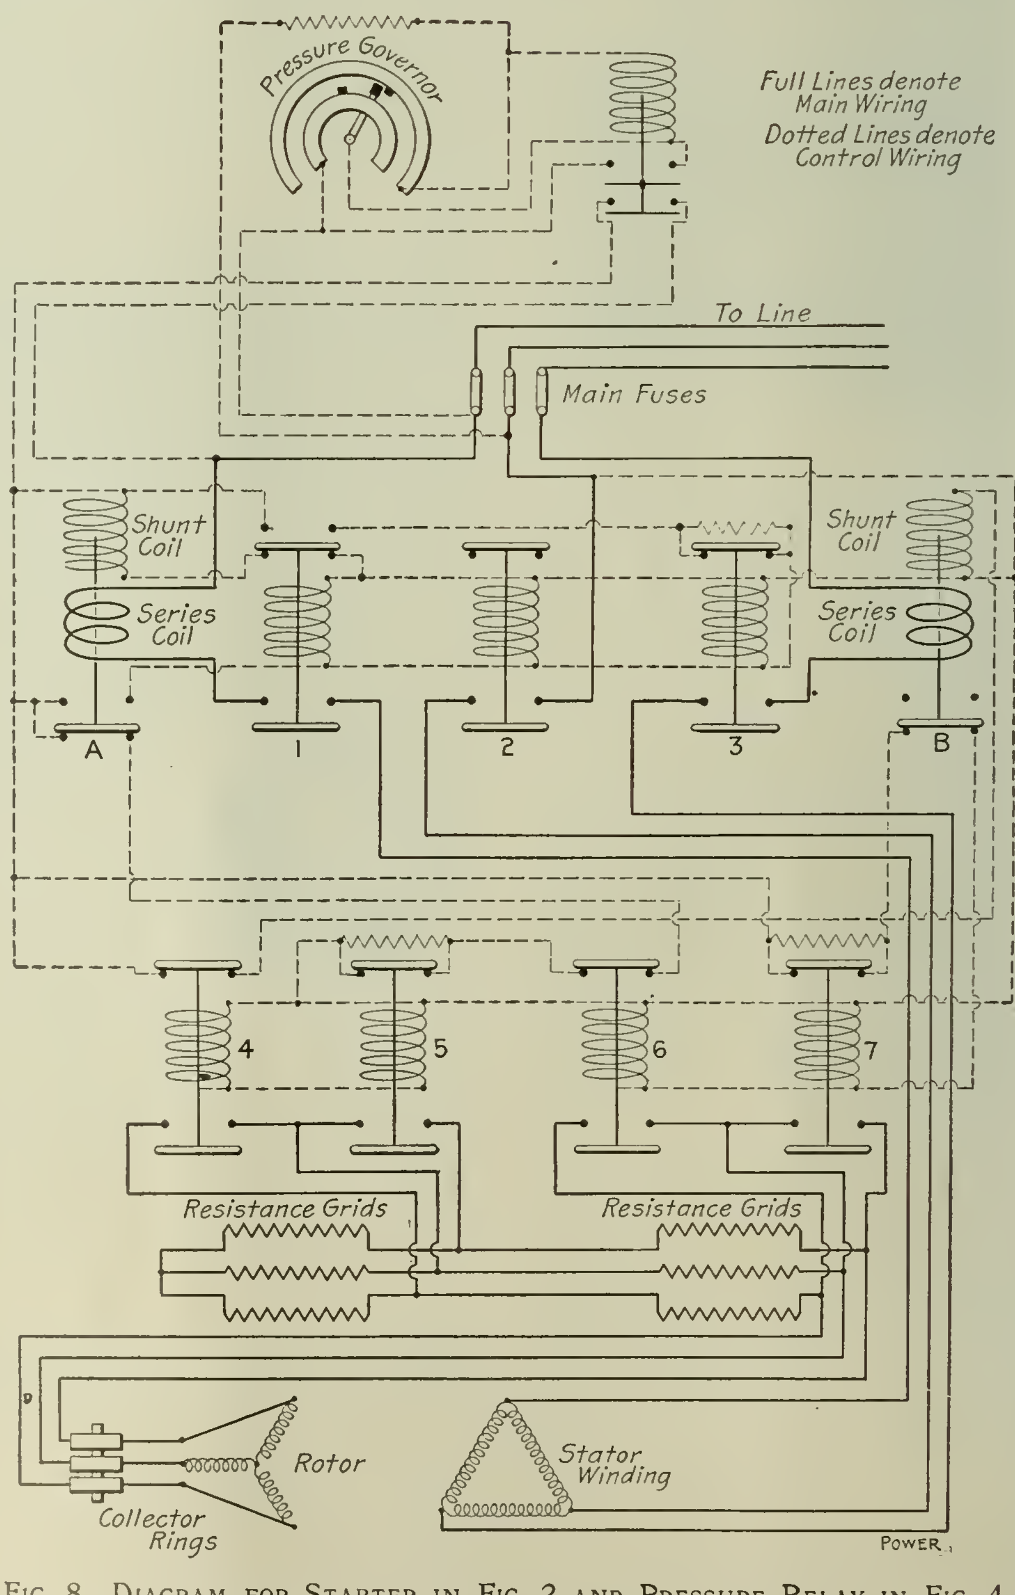

FIG. 8. DIAGRAM FOR STARTER IN FIG. 2 AND PRESSURE RELAY IN FIG. 4

the end of the slot engages the weight arm, which is flexibly connected to the drum switch within the case; continued drop in the water level allows the float to pull the sheave around farther and

FIG. 9. SMALL STARTER ACTUATED BY FLOAT AND ROPE

carry the weight arm over the top center, from which position it falls by gravity, retarded by a dashpot, and operates the starting switch, accelerating the motor at a rate determined by the dashpot adjustment. As the water level rises, the float is lifted, of course, and rotates the sheave in the opposite direction until the weight arm is carried over the top center, from which position it falls quickly, making a quick break at the main switch contacts and shutting down the motor.

FIG. 10. SMALL STARTER ACTUATED BY PRESSURE RELAY

The starter of Fig. 10 is equipped for operation by pressure variation under the control of a pressure governor. When the tank pressure falls below that for which the governor is set, pressure is admitted to the right-hand cylinder of the starter; the piston in that cylinder rises and operates the starter drum within the case, at the same time compressing a spring in the left-hand cylinder. The rate of acceleration of the motor is controlled by an adjustable dashpot in the left-hand cylinder which acts in opposition to the piston in the pressure cylinder. When the tank pressure exceeds that for which the governor is set, the pressure in the right-hand cylinder is relieved and the starter spindle is turned to the "off" position by the spring in the left-hand cylinders; the movement in this direction is very rapid, being unrestrained by the dashpot.

Each of these starters consists of a standard three-point autotransformer and drum switch, with the addition of the control device described. The connections are shown in Fig. 11. It will be noted that two sets of fuses are employed, one for starting and one for running, but there is no protection against failure of the current supply. If no-voltage protec-

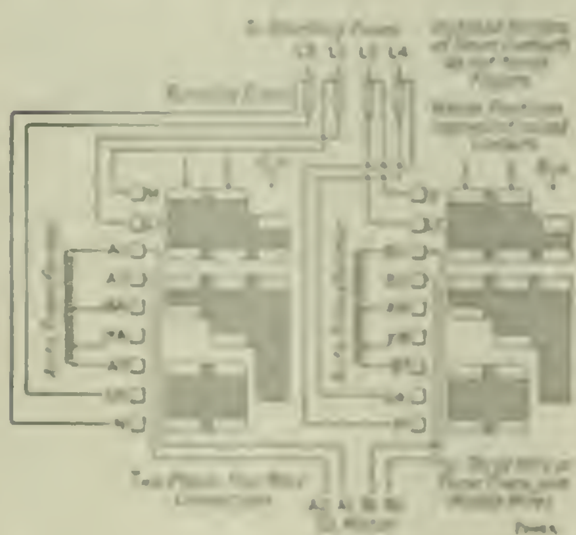

FIG. 11. DIAGRAM OF SMALL STARTERS IN FIGS. 9 AND 10

tion is desired, a circuit-breaker with a no-voltage trip coil, such as shown in Fig. 12, should be substituted for the running set of fuses.

SPECIAL CONTROL

All the automatic starters described in this article are built for constant-speed motors. Automatic control for multispeed motors is seldom used except for the larger sizes of motors. These starters are similar to the one described in connection with Fig. 2 except that the starting resistor is designed for continuous service and more starting points are provided. The contactors are under the control of a master switch by means of which those contactors giving the desired speed are held closed. The rate of acceleration and the starting current are out of the operator's control, however, because a relay set for a given starting current operates when the current reaches that value and opens the control circuit of the master switch, preventing any further reduction of the resistance in the rotor circuits until the starting current falls below the limit value.

An interesting example of automatic control as applied to wound-rotor induction motors is that employed in connec-

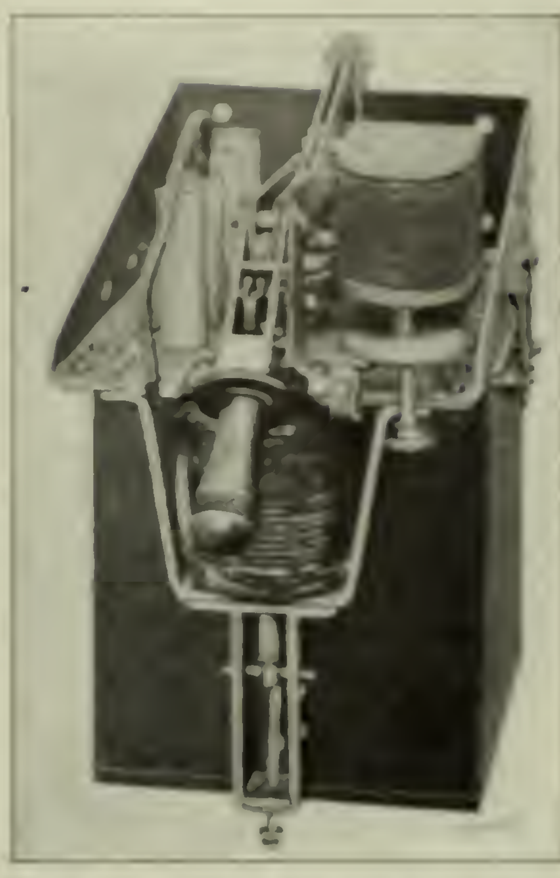

FIG. 12. CIRCUIT-BREAKER WITH NO-VOLTAGE COIL

tion with flywheel motor-generator sets. In order that the flywheel may deliver part of its stored energy to relieve the peak load on the motor, it is necessary that the motor shall "lie down" when the load becomes excessive. This is accomplished by the action of a relay set for a given rotor-current value. As soon as the current reaches the value for which the relay is set, its contacts close and energize a series of contactors which cut in resistance in the rotor circuit and reduce the speed of the motor enough to allow the flywheel to give up part of its energy.

The following instructions for raising steam were issued in the annual Memorandum of the Manchester Steam Users' Association: Before lighting the fires, see that there is sufficient water in the boiler, also watch the water gage while raising steam, for the blowoff valve or the feed-check valve may be so leaky as to pass water as soon as there is any pressure, that there is sufficient water in the boiler, may produce fractures or start leakages. If the boiler cannot be filled with warm water through the economizer, then the firing should proceed very slowly so that the bottom of the boiler may grow as warm as the top. If pressed for time, the boiler may be filled to the top of the water gauge, and when, with rapid firing, the top water has grown warm, discharge the cold bottom water and continue firing the boiler.

Everything worth while in the gas engine and producer industry will be treated here in a way that can be of use to practical men

Fitting Trunk Pistons for Gas Engines

BY OLAF OLAFSEN

The methods of fitting pistons to their cylinder bores, the allowances used, the methods of securing these allowances and the reasoning involved may be of value to some engineers who have occasion to do this kind of work or to check up the work of a repair shop. With

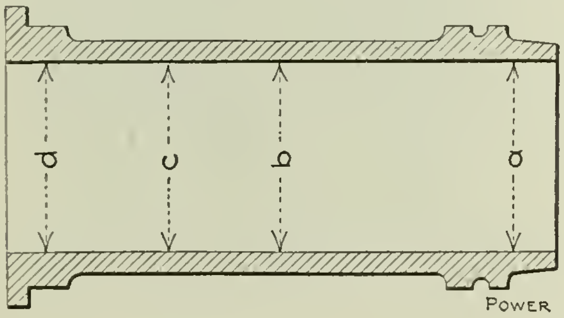

FIG. 1. REFERENCE DIAGRAM FOR CYLINDER TAPER

TABLE 1. CYLINDER TAPER.

Bore, Inches.	Minimum.	Maximum.
3¾ to 10¼	0.001	0.002
10½ to 14½	0.0015	0.003
14¾ to 19¾	0.002	0.003
20 to 26½	0.002	0.004

Referring to Fig. 1, measure the cylinder at the points *a*, 1¾ inches from the crank end: *b*, midway of the length; *d*, 1¾ inches from the head end; *c*, midway between *b* and *d*. The taper is the difference between *a* and *d*.

single-acting trunk pistons there are four sources of possible leakage of compression or of expanding gases: First, due to slight looseness of fit of the piston in a horizontal cylinder during the part of the compression stroke when the connecting-rod thrust is upward, the piston may be canted or cocked in the cylinder bore in such a manner as to disturb the proper bearing of the rings both on their edges and on their faces. Second, if there be a gap between the ends of each ring and if the lands between the rings be reduced too much in diameter, there is an easy passage for the escape of gases under pressure. Third, due to improper proportioning, machining or fitting, the rings may not bear properly over their entire peripheries. Fourth, due to improper machining or fitting they may not have a good bearing on their edges and may allow the gases under pressure to blow under them and out. As a rule, the engineer need consider only the first cause, as the others are due entirely to bad workmanship.

First, consider the expansion of the various parts under working conditions, without attempting to theorize upon the actual temperatures that may occur or the differences of temperature between the piston and the cylinder. It will readily be understood that the piston will be somewhat hotter than the cylinder under full-load conditions; therefore, a greater allowance for the running fit must be made than would be necessary were the piston and cylinder always at the same temperature. It is also evident that the head end of the piston will be much hotter than the other end and will therefore have to be turned somewhat smaller than the barrel. Most manufacturers now do not allow the lands between the rings to bear on the cylinder wall when the piston is at working temperature, although some few still adhere to that practice. It is a mistake to relieve the lands too much as it only adds to the tendency to leakage through the gaps at the ring joints.

Turn pistons to dimension *C* minus allowances as per schedule.

Pistons to be relieved on sides by throwing them out of center on a special turning or grinding fixture.

In estimating "play" of pistons in bore do not fail to consider cylinder taper.

There are two practices in turning the lands; some manufacturers turn them of different successive diameters, according to a schedule, and others, starting at the head and there reducing the diameter a specified amount less than the barrel diameter, taper the diameter for a specified distance toward the open end of the piston.

Obviously the breech end of the cylinder, where all the work is done, will be considerably hotter than the crank end if no special precautions are taken to prevent it. It is now common practice to introduce the jacket water under the seat of the exhaust valve or very close to it and discharge the water near the top of the cylinder head, whether the engine be vertical or horizontal; this allows the water to travel with considerable velocity around the hottest parts of the cylinder and to gravitate slowly toward the cooler ones. In some engines the water is first passed through under the exhaust valve, then through the cylinder-head jacket and finally to the cylinder-barrel jacket, thus supplying the latter with warm water and keeping the open end of the cylinder more nearly at the temperature of the breech end. Besides this, it is always the practice in boring cylinders, when reamers are not used, to start the finishing cut at the crank end; the wear of the tool, slight as it may be, almost always causes from a half to one and a half or two thousandths of an inch taper in the bore, depending on the size and the length of the cylinder. This will be found to be no serious fault; on the contrary, it is usually considered advantageous because the bore will be more nearly parallel when the engine is at working temperature. One manufacturer even goes so far as to scrape the crank ends of all cylinders with a long-handled scraper for a distance inward equal to about three-quarters of the length of the piston, increasing the diameter at the open end by about one-thousandth of an inch. Another builder heats the breech while reaming the bore, thereby making a tapered bore when the cylinder is cold and an approximately parallel one when the cylinder is hot.

Possibly the commonest practice in fitting pistons to cylinders is to turn or grind the pistons a certain schedule allowance less than the cylinder bore and "relieving" them slightly by filing on both sides about the piston pin to insure a bottom bearing of the piston when it receives the thrust of the connecting rod. A less rapid but, it seems to me, better method is to turn the piston one to three thousandths (according to its diameter) larger than desired for a running fit and to put the engine on the test block and run it with the maximum load that it is capable of carrying and at the regular working temperature, with copious lubrication. After a very short run the piston will be heard to "bump," as it is called, and no mechanic will ever mistake this sound for any other than a tight piston knock if he has once heard it. The piston is then removed and the high spots filed off. This process is repeated a number of times until the piston runs free, all "bump" having disappeared even when a full rush of cold water is turned on suddenly after the engine has operated for some time with a cylinder almost too hot for the hand to bear.

Great care and considerable skill are required to do this kind of fitting but if it is properly done a fine job is the result. There is really no occasion for anyone to "freeze" a piston in fitting it this way if he is careful and if the piston is turned to the proper size beforehand. The piston must be "relieved" very slightly on the sides about the piston-pin holes.

In fitting a piston in the manner just described the engine should be run on the fuel with which it is to be used in service because different fuels, producing different cylinder temperatures, will create different expansions. For example, the piston of a natural-gas engine needs greater allowance than that of a producer-gas engine and the piston of a gasolene engine may need a greater allowance than that of a city-gas engine. Engines to be run with gravity circulation of the cooling water should be especially free-running when hot, because they are liable to be run very hot for long periods where tanks are small, as is usually the case.

It is often the practice by mechanics to allow from a sixteenth to a sixty-fourth of an inch of clearance between the ends of piston rings when fitting them to the cylinder. This is unnecessary and only adds to the leakage. The rings will develop end clearance soon enough and I have found that there has never been the slightest trouble when rings are fitted so that they enter without any clearance at the joints.

Table 1 gives a list of cylinder tapers and directions for taking measurements for the piston diameter as practised by one European builder; Fig. 1 illustrates the instructions and Table 2 gives the schedule of allowances to be made in

NOTE—[illegible]

turning the piston. Fig. 2 is the reference diagram for Table 2. Fig. 3 and Table 3 present the practice of a well known American builder who anneals the pistons before finishing but never files them. For the repairman I would advise using Table 3 with the exception that it will be best to diminish the allowance in column *B* by one to three thousandths, according to size, leaving that amount for filing when the engine is started. Where the piston is very short it would be better also to diminish allowance *A*, as sometimes it is desirable to use the bearing between the rings under such conditions. For pistons two diameters long and over, it is advisable to follow Table 3 entirely. In every case, a piston which has not been annealed before finishing should be filed on the test stand as unexpected irregularities are developed when the casting is heated.

No attempt should be made in a repair shop to taper cylinders by a greater amount than that which is accidentally due to the wear of the boring tool, as special tools are required for this work and in most cases good results can be obtained without much taper. One repair man decided hastily that setting over the tailstock while boring with a bar between the centers of the lathe, the work being mounted on the carriage, would give a tapered bore. The result was an elliptical bore, of course.

Those makers who follow the practice of filing pistons are almost all builders of horizontal single-acting engines.

This article should not be considered as applying to automobile engines; the cylinders of such engines are so short that they are bored straight, with no allowances of the kind described.

Make and Break Ignition Troubles

By S. Kirl[illegible]

Trouble is frequently experienced with gas engines having the make-and-break system of ignition due to the contact points becoming corroded or worn down to such a degree that missing fire is frequent enough to cause irregular speed or even a complete shutdown of the engine. When missing is due to the contact points being worn down or corroded it can be quickly proved in the following manner without removing the igniter from the cylinder.

If the engine is small enough to be easily turned by hand, close the switch and hold the blade of a screwdriver or any other iron instrument near the end of the iron core of the spark coil while an assistant turns the engine. If the contact points in the cylinder are in good shape the iron instrument will be jerked to the iron core of the coil by the magnetism each time the engine is turned past the point where the ignition circuit is closed. If the screwdriver is not attracted to the core and if the wiring is in proper condition, it indicates that the trouble is due to the igniter contacts failing to come together, due to their being worn off too much or corroded to such an extent that the battery current cannot pass through them.

Trouble is also caused sometimes by the contact points remaining together due to the pin binding where it passes through the igniter body. This can be detected also by turning the engine over while holding an iron instrument near the coil core and noting whether or not it is jerked to the core each time the ignition point is passed. If it is continually held against the core during two revolutions of the engine, it shows that the ignition points are sticking together and failing to make the spark.

Trip Cutoff Kinks

The prevailing practice on engines handling the releasing-gear type of engine is to set the governor rods so that when starting up, both valves will be released at about the same time.

This method is incorrect, although I have seen engineers change the cutoff after the mean effective pressure had been equalized on both sides of the piston by means of the indicator.

The correct method of setting the cutoff on this type of engine when no indicator is available is as follows: Prop the governor up to where it stands at normal load and turn the engine over slowly until the crank-end trip lets go. Then measure the distance the crosshead has traveled on the backward stroke and turn the engine in the direction of rotation until the crosshead has traveled an equal distance on the forward stroke. Adjust the head-end trip to let go when in this position.

Cutoff will take place at the same part of the stroke, and, although it may not exactly divide the load, it is about the best we can do for cutoff without using an indicator.

Trouble with Steam Radiator

In reference to E. L. Morris' trouble with a heater as described in Power for January 17, I will say that in my opinion there are several causes for this heater not heating up properly. First, the pressure may be too low for the distance this heater is from the boiler; second, the heater may have become air bound; third, the pressure may be unequal and, by closing the valves down on the other two heaters to just a small opening, the trouble may be partially overcome.

I would suggest that a pet cock be placed on the end of the heater opposite to the inlet valve. This would release the air and help the situation, providing all connections are tight and the valve of the heater is open sufficiently wide.

There is but one thing needful to get the heater to warm up and that is circulation. I have had troubles of this sort and I have found most of them to be due to proper circulation failing to take place either from the fact that the heater was air bound or that it did not have sufficient steam pressure.

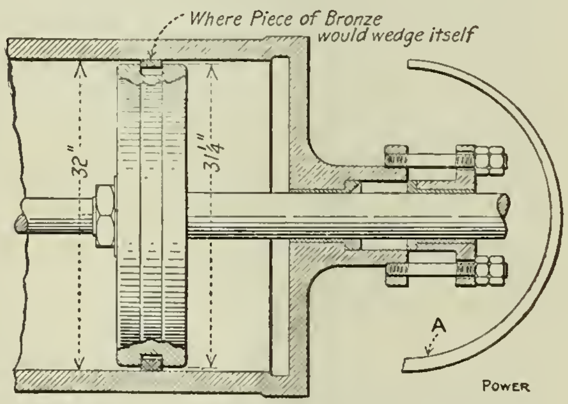
Bronze Piston Rings

Several years ago, I was employed in a large mill power plant in which there was a large simple steam engine. After the plant had been in operation for some time, the management decided to compound the engine and run condensing, therefore, a new cylinder was ordered from a different firm than had built the engine.

The cylinder and piston dimensions were as shown in the illustration. It will be noted that the cylinder is ¾ inch larger in diameter than the piston. When this cylinder was installed the piston was packed with a well-known type of sectional piston packing, and held out against the cylinder walls by springs.



Design of Piston and Piston Ring

After this packing had been in service for about a year, the engine began to give trouble. To overcome the difficulty the powers that be decided that cast iron was not the thing with which to pack a piston, and that there was but one intelligent method. They decided that a bronze ring of the snap type, cut eccentric, as shown at *A* was the proper ring. Having arrived at this conclusion, the bronze ring was ordered and in due time arrived and was at once put in place.

After very short service the cylinder began to have the time of its life, giving three cheers and a tiger at each revolution.

When the cylinder was opened up, a piece of the thin end of the bronze ring was found wedged between the piston and the cylinder wall. It will be seen that when the piston was centered in the cylinder but ¼ inch of the bronze ring was in the slot in the piston and, as bronze wears away very rapidly when in contact with cast iron, this ¼-inch leverage was very short lived. Consequently, the ring broke about 8 inches from the end and wedged itself as stated.

The "High Grand Mogul" decided "to fight it out along this line if it took all summer," so another bronze ring was put in which shortly proceeded to give a practical demonstration that bronze was bronze and again wedged the thin part of the ring between the cylinder wall and the piston. As there was no idea of giving up our military resolutions, another round of bronze was shot into that cylinder on five occasions, after which the cylinder was again fitted with cast-iron sectional rings.

Waterbury, Conn.

Boiler Inspection Law

Can any reader give a good reason why the legislature of the State of New York has failed to pass a good steam-boiler inspection law or an engineers' license law? True, there is a law in New York State that compels the inspection of locomotive boilers, and the enforcing of this law by the Public Service Commission has compelled the railroad corporations to keep their boilers in good condition.

A similar law should be passed that would make it compulsory to have all boilers used for power purposes examined semi-annually, once internally and once externally, and the boilers to be in charge of competent engineers.

The factory-inspection department sometimes calls for a report on steam boilers, but if it is compulsory to furnish them with a report, the law as enforced is a farce. The owner of a steam boiler can employ any person to make an inspection and send him a report of such inspection to be forwarded to the factory-inspection department, and it is accepted.

I know of many cases where men have made inspections of steam boilers, the reports have been accepted and boilers continued in use, but the men who made the examinations could not figure out the strength of a seam, strength of the braces or stays in the boilers and, in fact, if given all dimensions, they could not figure the steam pressure to be allowed. Certainly such a man could not be held responsible for any accident occurring after his inspection.

The factory-inspection department accepts the report of an examination made by a steam-boiler insurance company's inspector, but there are hundreds of boilers in the State of New York that are not insured. There are boilers in use that are from 20 to 30 years old, carrying the same steam pressure that was carried when they were first installed. Most of these boilers are of the horizontal return-tubular type, lap-seam construction and carry from 80 to 110 pounds steam pressure; they should be in the scrap heap. Some of these boilers are in charge of men who do not know the risk they are taking in carrying such pressures.

In one of the congested business districts in one of the large cities of the State of New York there is in daily use a battery of two boilers carrying a working pressure of 90 pounds that were practically condemned by an inspector several years ago. The boilers are about 60 inches in diameter by 14 feet long. The shell plates were originally 5/16 inch thick, the longitudinal seams are lap construction, double riveted, and the seam will not figure more than 65 per cent. of the strength of the solid plate. The opening in the shell under the dome is almost the full size of the dome and is not reinforced; the boilers are at least 25 years old. Figure what steam pressure these boilers would safely carry when new, and then imagine what is going to happen at this plant some day. The coroner's jury will, if the usual custom is followed, put the blame on the engineer or fireman, both of whom will doubtless have been killed. There are many plants being operated in worse condition.

There were more than 530 boiler explosions in the United States in 1910, and 280 persons were killed at the time of the explosion; there were also many persons scalded and otherwise injured who later died from the effect of their injuries. There were over 550 boiler explosions in 1909 and about 230 fatalities. The lap-seam boilers carried off the "honors" and, no doubt, the lap-seam engineers, referred to in a recent issue, had charge of the majority of these plants.

There should be a law, rigidly enforced, prohibiting the installation of lap-seam boilers and especially that type made up of two sheets with the longitudinal seams running from head to head. No extra expense is incurred in having the boiler built with butt joints. A triple-riveted joint properly proportioned will give from 84 to 87 per cent. strength of a joint and a quadruple-riveted seam from 92 to 94 per cent. There is no record, as far as known, of a boiler with this type of seam exploding.

Laying Pipe under Water

I recently saw a 10-inch wrought-iron pipe laid under water in a very simple manner. The pipe was to be used as an intake for a pump and extended into a shallow lake some 200 feet.

The method adopted was to connect the pipe lengths together, on skids, on the lake shore. A blind flange was put on one end and a foot valve on the other, the foot valve being fastened in a closed position by a wire. Then the pipe was rolled into the water, three men mounted it and with poles punted it into position. Then the foot valve was opened, allowing the whole to sink gradually onto the piers that had been made for it to rest upon.

Wood as a Fuel

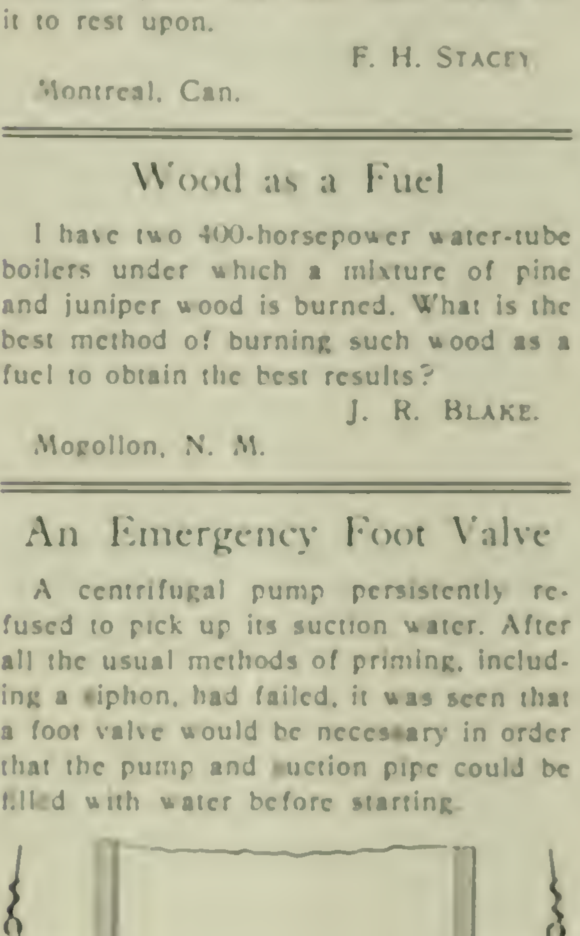
I have two 400-horsepower water-tube boilers under which a mixture of pine and juniper wood is burned. What is the best method of burning such wood as a fuel to obtain the best results?

J. R. BLAKE.

Mogollon, N. M.

An Emergency Foot Valve

A centrifugal pump persistently refused to pick up its suction water. After all the usual methods of priming, including a siphon, had failed, it was seen that a foot valve would be necessary in order that the pump and suction pipe could be filled with water before starting.



DETAILS OF FOOT VALVE

An ordinary galvanized water bucket was made into a foot valve, as shown in the sketch. A 6-inch hole was cut in its bottom and a valve was made from a piece of heavy rubber belting, cut 1 inch larger than the diameter of the hole in the pail. A ¼x1½-inch iron strap was bent to fit the bucket, as shown. A ½-inch thread was tapped in this iron strap to receive an ordinary ½-inch bolt to act as a valve stem.

The foot valve was placed over the bottom of the suction pipe and held in place by wires. It was a success.

Yazoo City, Miss.

Overloaded the Engine

In the southern part of Indiana a power plant, supplying power to a large cement factory, experienced considerable difficulty in keeping an exciting set in operation. The plant was of about 1500 kilowatts capacity. Two direct-coupled exciting units had been installed and the prime movers were twin-cylinder compound steam engines. One unit was of 75 kilowatts capacity, running at 350 revolutions per minute, and the other of 35 kilowatts capacity, at 520 revolutions per minute, which speeds are rather high.

Both exciters gave trouble continually and one or the other of them seemed to be down for repairs all the time. The 75-kilowatt unit was naturally used most, since the exciting load alone was about 35 kilowatts and the entire lighting load of about 20 kilowatts was taken from the exciter busbars also. The 35-kilowatt set was kept pretty busy when the 75-kilowatt set broke down.

For this reason duplicate parts for the larger unit were kept on hand so that the smaller unit need not be operated longer than was absolutely necessary. However, even though the small unit was operated but little, the tremendous overload when it was operated soon began to tell on the engine, and after three or four years this engine also became unreliable, but no duplicate parts were ordered for it.

One day the larger unit began to bump and rattle and, before the steam could be shut off, it had completely wrecked itself, everything within the four cylinders being smashed to bits; the 35-kilowatt unit was then started. Some of the repair parts had to be made, which would require a few weeks, and it looked very much as though there would be trouble before they could arrive.

While going over the works the day following the accident, I noticed a band wheel of some sort protruding from a pile of cement and rubbish behind one of the factory buildings, which proved to be a 9x14-inch Atlas side-valve engine that had been used during the building of the factory a few years before. This engine offered the only ray of hope in the solution of the pressing exciter problem, and I decided that it would be able to carry enough of the load to keep the works going nearly full blast day and night.

I knew that these engines were designed for 125 pounds pressure so that perhaps the full boiler pressure of 100 pounds could be withstood if the load demanded such. My greatest fear was that the pressure plate would deflect and bind the valve if a pressure of much over 125 pounds was used.

Timbers were placed in position near the small exciter and the Atlas engine mounted on them in such a way that, should the exciter engine break down, a short shaft could be bolted to the generator shaft by means of a flange coupling and the generator driven by a belt. This arrangement was completed none to soon, for the overloaded exciter engine showed signs of failure a day or two later and had to be stopped.

The shafting was speedily put in place, the belt tightener screwed down and the Atlas engine started on what proved to be a long run. It pounded a great deal and ran hot, and after a half hour's run ordinary lubrication was insufficient so water pipes were arranged to keep streams of water playing on all the bearings. The belt used was of sewed canvas, 8 inches wide.

This outfit ran six weeks, during which time two sets of main bearing parts, three sets of connecting-rod brasses and two belts were used up; crank and wristpins were badly scarred, as were also the main journals. Otherwise the engine as a whole was little harmed. Nothing broke and apparently the cylinder and valve were not touched. The cylinder was lubricated perfectly. The generator was unharmed except that the commutator was slightly burned.

A long shutdown was avoided, contracts were met, and now an exciting set of large size carries the load so easily that one can scarcely realize the supreme effort required by the small 9x14-inch engine to do about 80 horsepower of work.

Lafayette, Ind.

Boiler Insurance

A matter connected with boiler insurance recently came to my notice, that is of more than passing interest.

The superintendent of a power plant, after reading a recent discussion relative to boiler insurance, looked up his own policy to see how it was worded. He discovered that his policy allowed him to carry 110 pounds steam pressure on his boilers, but they were carrying 120 pounds. In case of an explosion the policy would probably have been worthless.

On investigation he found that a former superintendent had increased the pressure 10 pounds without consulting the insurance people and, as a consequence, the policy had never been changed.

This condition had existed fully a year and the insurance-company inspectors had inspected the boilers several times since the change had been made, and presumably had noted the pressure carried. They had not, however, reported the matter to the officials of the power-plant company.

Is it possible that the inspectors had passed in their report without the increased pressure being mentioned, had the increased pressure not been detected or had the insurance company wilfully failed to notify the company, knowing that they could not be held in case of an explosion? It would also be of interest to know if under the above circumstances any insurance could have been collected. The boilers were in first-class condition, designed for 150 pounds steam pressure per square inch, and the insurance people readily changed the policy when their attention was called to the increased pressure carried.

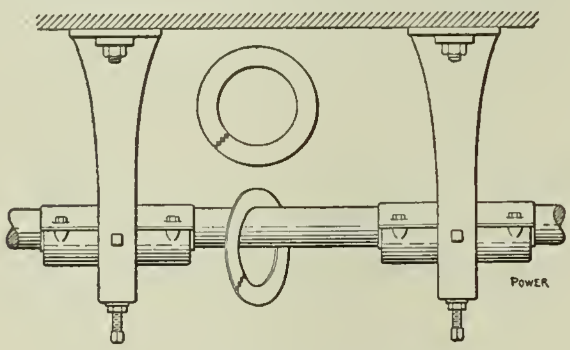
Ring Shaft Cleaner

My little kink, while old, may be of use to some engineer who is obliged to keep his line shafting clean and free from dust and oil.

Make several large rings out of belting, leatherboard or some such sub-



Ring Cleaner on Shaft

stance, having a hole about twice the diameter of the shaft, and the outside diameter about 2 inches larger than the inside diameter.

The ring is cut diagonal on one side, put on the shaft, after which the ends are sewed together with fine wire. The ring will travel from one hanger to the other so long as the shaft revolves.

Thus, the shaft will be kept free of dirt and it will eventually take on a bright polish.

Boston, Mass.

Flushing Pump Valves

Trouble is often experienced with foreign matter getting under the valves of feed pumps.

It is a simple matter to place a barrel at some elevated place, connect it with the suction pipe of the pump and provide a pipe and valve to the discharge line for filling purposes.

When the pump valves hang up, close the valve in the suction line and open the valve in the pipe leading from the barrel which is kept filled with water. This flushes the pump and saves a lot of trouble, time and temper.

Sheboygan, Wis.

Unsafe Pulleys

Some days ago, I visited a small sawmill and, while looking over the plant, the manager pointed to a pile of cast iron that had once been a pulley 7 feet in diameter. He said it had burst a few days before and killed the sawyer. I did a little figuring and found that the rim speed of the pulley had been 9560 feet per minute.

To my surprise the new pulley was a duplicate of the one that had exploded and was running at the same speed.

I told him that the high rim speed at which the new pulley was running was liable to burst it, but he said the salesman who sold it said that the old pulley had burst on account of a flaw and that he supposed the one he was now running was perfectly safe. I do not know whether he has killed another sawyer yet or not.

H. T. Fryant.

Adjustment of Crank Pin Brasses

While talking with the superintendent of the company where I am employed a few days ago, our conversation turned to bearings, and I remarked that the crank was running cool, although the brasses were only 0.004 of an inch slack.

"How do you know that?" he inquired.

"Well," I answered, "the wedge tapers 1/8 inch to each inch in length, and the adjusting bolt has eight threads to the inch; therefore, each turn of the bolt will move the brasses 1/64 inch or practically 0.016 inch, so that 1/16 turn of the adjusting bolt will equal a movement of 0.001 inch of the brasses. As the wedge was drawn up so that the brasses were snug against the pin and then slacked back 1/4 turn on the bolt, there is not far from 0.004 inch clearance between the pin and the brasses."

Roy W. Lyman.

Ware, Mass.

Return System

I would be glad to get some information on the following: The drips from the steam main, separators, reheating coils and four engines are collected in a manifold located in the basement. This manifold is 20 feet below the water line in the boiler. The steam pressure in the boiler is 160 pounds. The difference in pressure between the boiler and the manifold is 10.5 pounds.

Is it possible and practicable to return the condensation to the boiler by means of the Holly system? If so, to what hight will it be necessary to carry the return riser? Also, what should the size of the riser be?

At present I am using steam traps, but they do not give satisfaction.

William Bopp.

Washington, D. C.

Questions Before the House

Comment, criticism, suggestions and debate upon various articles, letters and editorials which have appeared in previous issues

Water Hammer and Other Phenomena

In reply to J. W. Payler's inquiries in the March 7 issue under the heading, "Topics for Discussion" the following are my opinions on the topics which he presents:

There appears to be a marked difference between water hammer and the contraction and expansion of a steam line when steam is turned on. When steam is turned into a line of piping slowly, the steam coming in contact with the cold pipe is condensed. The condensation collects on the bottom of the pipe. The incoming steam eventually heats the pipe to a temperature practically the same as its own, but during the first part of the process the water lying along the bottom of the pipe causes unequal expansion to take place, the condensed water acting as a heat insulator.

I would account for the origin of water hammer in the following way: First, there must be a collection of water in a pocket or at some point in the line. Under normal conditions the steam passes over this water. But, when suddenly a demand for more steam arises, the steam picks up the water in passing. The water then attains the same velocity as the steam and when the water strikes a turn or other point where change in direction is necessary, the result is water hammer.

Steam entering a pipe pushes whatever air the pipe may contain along until the air is compressed to the same pressure as that of the entering steam. Very little or no interchange of heat takes place between the steam and air. This is illustrated when air becomes trapped in a radiator; until the air is removed the radiator remains cold almost indefinitely.

The water next to the plates or tubes in a boiler is turned into vapor bubbles. The vapor being lighter than the water rushes to the surface. It is this rising of the vapor that causes the agitation of the water. It will be seen, therefore, that steam is generated at the heating surface.

To demonstrate how a large body of water contained in a boiler is turned into steam when a rupture takes place, the following example is submitted. Assume a boiler in which the steam pressure is 160 pounds gage to contain 20,000 pounds of water. The temperature due to the pressure is 371 degrees. The water in the boiler contains, then, about 3,180,000 B.t.u. above 212 degrees. The latent heat of steam at atmospheric pressure is 970.4 B.t.u. Then the sudden reduction in pressure resulting from the rupture of the boiler would cause the instantaneous evaporation of about

$$\frac{3,180,000}{970.4} = 3280 \textit{ pounds of water}$$

Montreal, Quebec.

Binding "Power"

In the March 7 issue there is an article on filing data after they have been cut from the magazine. This method of preserving data is theoretically perfect, but for practical purposes it seems to me that it could be improved upon. It embraces the necessity of alphabetical indexing, which is a study in itself, and also the problem of what to save.

In a magazine of the scope of Power the matter of the index is in the hands of a specialist. My substitute for filing away individual articles is a scheme for binding the magazines exclusive of their advertisements. It was suggested to me by my boss, C. L. Patch, chief of the estimating division of the hull department of the Boston navy yard.

Fig. 1. Volume Clamped for Drilling Holes

I cut a narrow board to the length of the magazine and mark it for holes. The holes are then drilled from the marked side. Then several magazines are held between this board and a plain unmarked board by a clamp in the manner shown in Fig. 1. Next, the holes are drilled with a breast drill of 7/64 inch diameter. The holes are made about ½ inch from the back of the magazine. When the holes are drilled, all the leaves of one volume are sewed together with ordinary wrapping twine and a sailors' needle. For covers several leaves from the advertising section are sewed on in front and at the back and the whole covered by a paper or cloth covering. By the use of mucilage between the several leaves, front and back, the effect of a flexible cover is secured. The outside covering of cloth or paper hides the stitches and gives a finished appearance. The cost of the whole is only a few minutes in time and a few cents in money. The only expense is for the outside covering. By treating the magazines in this way a handy record is kept, not only of what you thought you might want to use, but also a vast amount of matter which you just glanced at, never thinking you would need it until the occasion suddenly arose.

J. F. Wentworth.

Quincy, Mass.

I have noticed several men's ideas for preserving back numbers or interesting articles. I think that it is a poor policy to attempt to outdo the publishers in the matter of indexing—time is too valuable—a particularly useful article can be referred to in a card index or checked in the regular index. The idea of preserving only what seems at the present time to be the useful parts of each issue is a poor one, for one can never tell what will come next, providing he is in a live part of the world and what today is a waste of time to read may be of permanent value tomorrow or next year.

Fig. 2. Volume Ready for Cover

I do not make a practice of reading everything in each issue, but I save all articles which are apt to be of value till such time as I can get the issues bound with the complete index. Then when any question arises I have a very useful library at my disposal which is broader in scope on any subject covered than most of the engineering books published. The cost of binding is usually from $1.50 per volume, up.

C. W. Bell.

Taylor, Penn.

Stress in Boiler Sheets

Regarding the editorial under the above heading in the February 28 issue, it seems to me that a confusion has been made about the line of least resistance. However, the question brought up will make a large number of readers do some thinking, and for that reason it will be valuable.

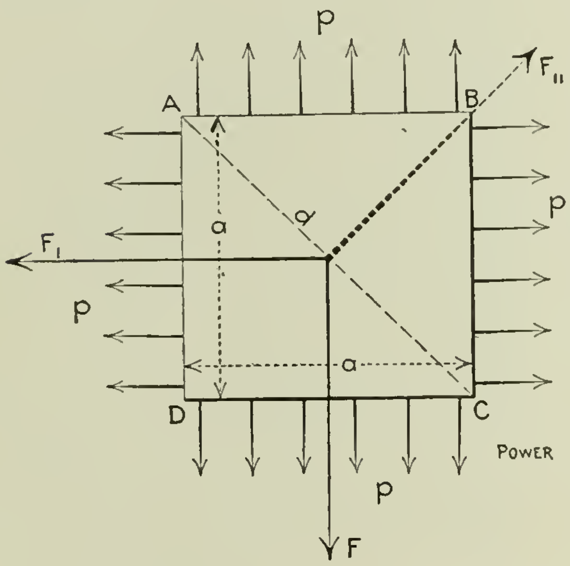

Diagram for Specific Solution

In the first place, the fact should be noted that when testing cylinderical shells by bursting them, the rupture invariably takes place lengthwise of the cylinder. The reason for the split being lengthwise and not either circumferentially or slantwise is because the least resistance is along this line, least resistance because there is the least material to withstand the stress. Thus, the stress per unit length on the line A of Fig. 1 is $\frac{PD}{2}$

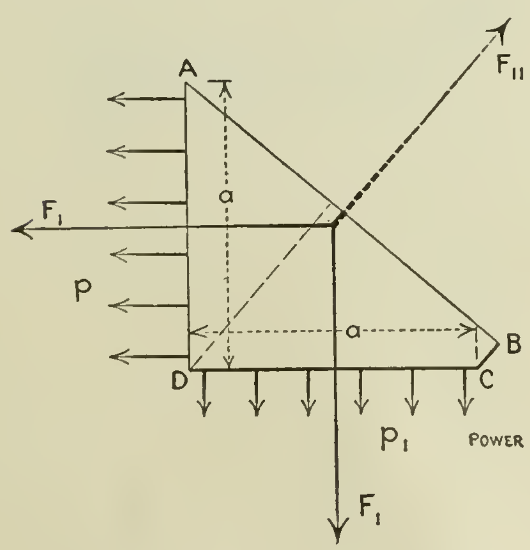

Diagram for General Solution

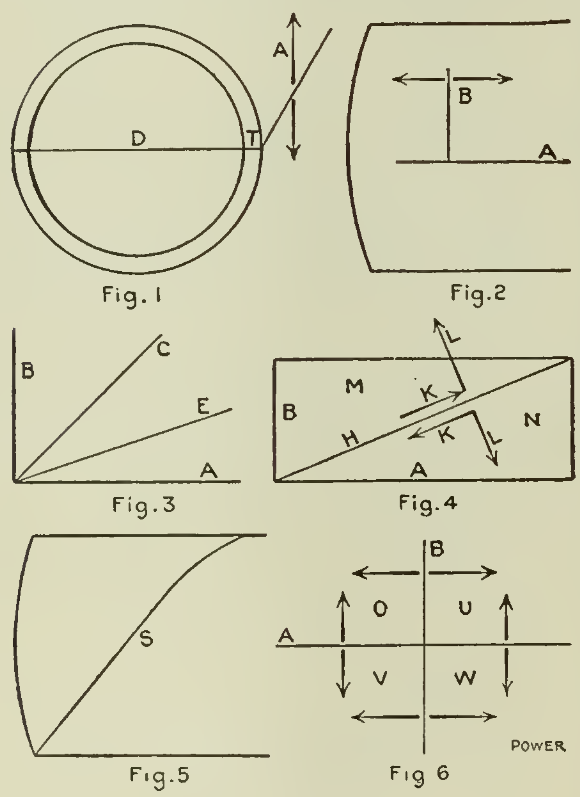
and the material to withstand this stress is T. At right angles to the stress on the line A of Fig 1. the stress tending to tear the plate along the line B of Fig. 2 is $\frac{P\pi D^2}{4}$, and the material to withstand it is $\pi D T$. As, based on the thickness alone, the stress in Fig. 2 is

$$\frac{P\pi D^2}{4} \div \pi D = \frac{PD}{4}$$

being half as much as in Fig. 1; on the other basis, there is twice as much material to withstand the stress in Fig. 2 as there is in Fig. 1; hence, the section in Fig. 2 is stronger and less liable to split. It follows then, that at any other locations, C and E, Fig. 3, between these two lines A and B of minimum and maximum strength, the strength will be less than at B and greater than at A.

It can be shown by an elaborate mathematical demonstration how that two stresses, one half the other, acting at right angles, will give a resultant diagonal H, Fig. 4; and, further, how some of this stress K is lengthwise of H and some L at right angles to it. The action of K is to shear the plate into two triangles M and N, while that of L is to tear them apart. This mathematical treatise will give any engineer good mental exercise. It will lead him, though, providing he does not get lost in the thicket of figures and symbols, to the same station



that the experimental facts have long since located. Rupture does not take place along the helical seam S, Fig. 5, nor does the plate separate into four rectangles O, U, V, W, Fig. 6.

F. Webster.

Scranton, Penn.

Blowoff Pipe Protection

I noticed in the issue of March 21 an account of the bursting of a cast-iron elbow in the blowoff of a 135-horsepower boiler. No cause was given for the failure of the elbow.

I was once called to take charge of a steam plant in which the blowoff pipe of the boiler was screwed into the front head of the boiler alongside of the handhole and a hole was drilled in the boiler front, through which the pipe passed just far enough to screw on a valve, short nipple and an elbow. The blowoff then passed through the wall of the boiler house and connected with a blowoff tank in the yard. The boiler-house wall was used for the side wall of the boiler setting. Where the blowoff went through the wall it was bricked in solid. I consider this very unsafe as I contend that all blowoff pipes should be left free so as not to be affected by expansion or by any settling that may take place.

Edward Hamilton.

Ridgefield Park, N. J.

Slipping Latch Blocks

In Power for February 28 and March 28 are letters on the subject of "Slipping Latch Blocks," giving useful instructions as to what to do to prevent or overcome trouble from this source.

The design of the valve gear has a great deal to do with the amount of this trouble and in selecting an engine care should be taken to select a design of gear that will give the least trouble.

We had an engine that gave us a great deal of trouble in this respect, the latch blocks having to be turned once in two or three weeks. After running for several years the gear became so badly worn that it was replaced with a gear of different design. Since that time we have had to change the blocks only about once a year. The difference is not in the blocks, for we tried several different steels with the old gear and made the blocks as hard as it was possible to make them, but even the hardest would slip in a short time.

Bristol, Conn.

Central Station versus Isolated Plant

The editorials in the issue of March 28 entitled, "Will an Isolated Plant Pay" and "The Marginal Principle," strike the nail squarely on the head and put the matter in the plainest possible way. I wish they could be read by every power user. The fanciful and exaggerated charges saddled upon the steam plant when the central-station man is swelling his list to show the awful waste only go to show his desperation in working for business that he sees slipping from him. Could this be any better illustrated than in Mr. Parker's paper on "The Cost of Industrial Power," reported in Power for March 21? Conceive, if you can, a plant of 150 kilowatts capacity with a $12,000 manager, devoting one-twelfth of his entire time to the power equipment! And, this not being enough, the cost is still further padded to the extent of $150 per year for one hour daily clerical work. This generosity is not shown in the purchased-power table, where the wear and tear on the manager and clerks, due to the heating plant, is fixed at $25 per year, surely low enough in comparison.

Again, in this paper the "emergency service" is given at $936 per year. This is based on four days' shutdown per month. Does anyone know of a power plant, working under ordinary conditions, that is shut down on an average of four working days per month? If so, will the engineer please stand up and, if it is not a worn-out, obsolete plant, tell us how long he expects to hold his job? A charge for emergency service is, of course, proper if, as is usually the case, the power user wishes to retain the central-station connections for such use, but there is a lack of fairness in placing it at an extravagant cost, merely to make the right kind of a showing. If this cost were correct, emergency current would be a highly profitable part of the central station's business, inasmuch as it is at a rate nearly three times the amount per kilowatt-hour of the regularly furnished current in the other table, which figures out 2.47 cents. It would be equitable to credit back the coal that is not used during the 48 days per year that the plant is supposed to be out of business, but no such credit appears.

It appears that in the isolated plant 300 horsepower is installed for a demand load of 140 kilowatts, fully 25 per cent. more than necessary, but this makes the estimate item of supplies and repairs higher, and all goes to swell the total cost.

It is to be regretted that comparisons of this kind, figured out by central-station representatives, can only be made with a view of obtaining patronage, for it would certainly seem that they are not made with a desire to arrive at true and correct results. There is plenty of business for the central stations in public lighting, railways, etc., as well as in many isolated plants where exhaust steam has little or no value, especially in small units where the labor item is a very large percentage of the whole. But, no amount of argument can prove that purchased power is cheaper than that furnished by the isolated plant in the majority of cases where use can be made of all or a considerable portion of the exhaust steam, which is a most valuable byproduct. This means with every legitimate item of cost figured in, but not the "amortization" of the manager and his clerks, unless we also estimate, on the other hand, how much his monthly quarrel with the central station over the current bills shortens his life. Nor will we include a charge for the amount of money the cost of the power plant *might* have earned if he played the stock market and struck it right, which is just as consistent as the item of "profit rates."

In the city of Buffalo, within 20 miles of the much touted Niagara Falls power, steam plants are in use by the hundreds and new ones going in constantly, where careful investigations have shown the lower cost for power in the isolated plant. And, in this connection, it may not be generally known that at least one power-equipment company is installing steam plants in whole or in part, and taking its pay in the saving made over the cost of purchased power. I know of several plants that have been purchased in this way, and all are making good. One of these is a $20,000 plant that paid for itself inside of two years. When an engineering company is willing to take business on these terms, we can hardly wonder that the central-station companies work up the kind of papers that are read before engineering societies, biased as these papers are in favor of purchased power.

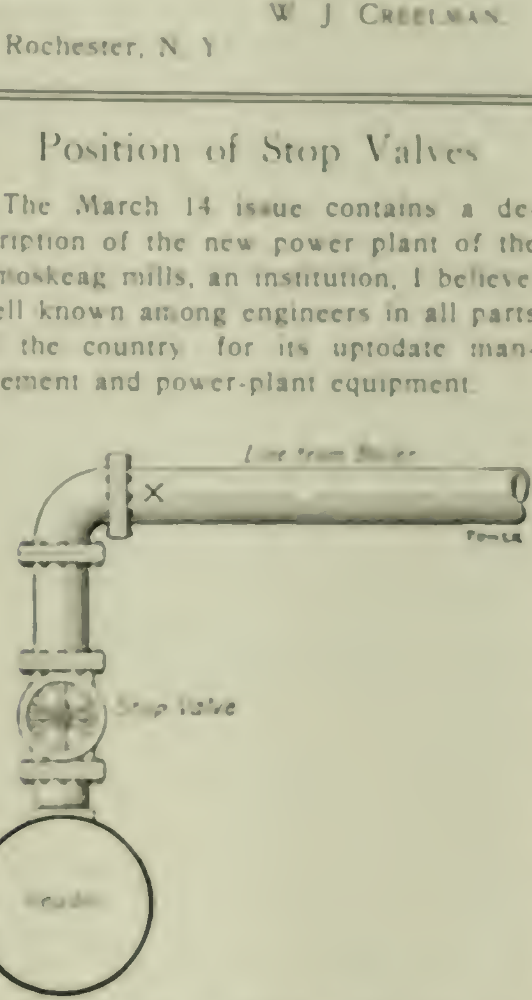
Rochester, N. Y.

Position of Stop Valves

The March 14 issue contains a description of the new power plant of the Amoskeag mills, an institution, I believe, well known among engineers in all parts of the country for its uptodate management and power-plant equipment.



Present and Proposed Positions of Valve

I may have been asleep while some new things in steam piping were being promulgated but, never having been shown differently, I must still hold the opinion that the proper place for a stop valve would be in the horizontal pipe, as at X, instead of in the vertical connection. With the valve at point X the possibility of a slug of water lying above the valve and the necessity of a drain pipe above the valve are eliminated. But, as it is inconceivable that an institution of such reputation should make such an installation without every detail being "exactly right," there must be some very good reasons why the stop valves were placed in their present positions. I would like very much to be enlightened.

F. C. Holly.

Yazoo City, Miss.

The Benefit of Organization

I have read Mr. Goldstein's letter in the March 14 issue and would say that what he has said with reference to engineers' wages is a fact that we cannot get away from. The solution does not rest upon forming an organization with a resolve to stick together, but rather on the basis that an organization be formed with a view to raising the individual standard along educational lines in order to be able to present the matter to the owners of plants in such a way that they cannot refuse an increased wage when it is requested.

We have at the present time any number of engineers' organizations but each has its own ideas of doing things.

I venture to say that it would be far better and more beneficial to all concerned if they would all come together under one name and for one purpose, and that purpose to be the uplifting of the men who are running the very heart of the great industries of today. After all said and done, what would an office building, factory, mill, hospital or apartment house be without a competent man to operate intelligently the machinery that is necessary to run its elevators, supply its light, water, etc.?

The time is now ripe for the men in this most important branch of industry to look around them and wake up to the fact that something is slipping away from them, get busy and start a movement that will make it necessary for the central-station solicitors do some mighty hard work before they can earn their salaries.

H. H. B[illegible].

Brooklyn, N. Y.

Reduced Grate Area at Light Loads

I have just read the editorial, "Reduced Grate Area at Light Loads," which appeared in the issue of March 21, and feel moved to write of a recent experience of my own along these lines.

Two of my friends, owners of the local steam laundry, sought my advice as to the possibility of reducing the coal consumption in their plant.

On visiting the plant I found a 50-horsepower return-tubular boiler, very much underloaded, the engineer's chief difficulty being to prevent the safety valve from popping. This was accomplished by a damper in the stack and by the occasional opening of the firing door.

I had the grate surface reduced by bricking off [illegible] inches on each side of the firebox, and as a result the coal consumption was reduced from four and a half to three tons per week.

This is perhaps an extreme case, but it illustrates a possibility which is often overlooked.

[illegible]

McCook, Neb.

Interest and Sinking Fund

In the issue of March 21 in an editorial under the above caption a line of reasoning is followed from which I venture to dissent.

Referring to the discussion of the subject, "The Cost of Industrial Power," which took place at the recent joint meeting of the American Institute of Electrical Engineers and the American Society of Mechanical Engineers, the editorial contains the statement that "one of the central-station solicitors maintained that it was not right to reduce the sinking-fund charges because inquiry upon his part had revealed the fact that nobody invested the money thus charged annually to the plant at compound interest," and the writer of the editorial then proceeded to show why, in his opinion, a sinking-fund charge based upon compound interest is justifiable.

The accumulation of a sinking fund with the assistance of the accretions due to compound interest appears attractive upon its face, but it is not in accordance with established methods of finance. The fiscal considerations which are involved in present-day commercial activities are confined—so far as the profit and loss account is concerned—to the limits of a single year or, in some cases, to a period of even shorter duration. If this were not so, or if the compound-interest theory were applied—as it logically could be—to all expenditures, a decidedly involved condition of affairs would result. For example, suppose that a man should view his personal expenditures from the compound-interest point of view and, instead of striking a yearly or monthly balance between his income and his expenses, he should look upon the expenditure required for a cigar or for a drink, not as the sum directly involved, but as the amount which the expenditure would amount to at compound interest at the end of a certain number of years. A few calculations of this nature would doubtless cure many of the smoking habit, and would tend to make the "water wagon" more attractive to many than it is at present.

There is another point of view from which, in the writer's opinion, the compound-interest theory is untenable. If we consider that the natural function of money—or capital—is to bring a yearly return to its owner, and that when it is not so doing a direct loss results to its possessor, equal in amount to the interest which could have been obtained (not necessarily the highest rate of return which could have been obtained, but a fair average rate), it is evident that the accretions to a sinking fund in the form of interest are as much of a burden upon the person who is accumulating the fund as contributions of equal amount paid directly into the fund. In the one case a direct payment of, say, a comparatively small amount is made yearly to the fund and the interest for the preceding year upon the accumulated portion of the fund is added. This interest, therefore, cannot be withdrawn (inasmuch as "one cannot eat his cake and have it too") and, in this sense, it is lost to the owner of the fund, thereby making the final result no different than if the owner had withdrawn his yearly interest (a normal condition, the reverse of which only signifies a loss) and then paid an equal amount directly into the fund. On the other hand, under straight-line depreciation, with equal and larger amounts paid yearly into the sinking fund, the owner may withdraw his yearly interest and the equal yearly amounts paid into the fund become his only burden. In either case, the final result is the same: at the termination of the estimated life of the equipment the owner will have paid (in one case partly in the form of lost interest) an amount equal to the original value of the equipment.

New York City.

Feed Water Treatment

In regard to Mr. Utz's letter in the January 31 issue and Charles H. Taylor's well grounded letter in Power for December 6, 1910, relative to feeding solvents to steam boilers, the opinions contained therein certainly make an interesting contrast. Each of them, from the standpoint of a practical critic, if it be possile to assume such a rôle, deviates considerably from the straight and narrow path which practical experimenting has blazoned through the dense forest of obstacles confronting users of "solvents," or "boiler solvents." In a great many cases the latter term is not a misnomer, for certainly the most significant point in Mr. Utz's argument is that he has been using a "boiler solvent" instead of a treatment to neutralize the troublesome elements carried in his boiler-feed water. Most certainly if the solvent he is using scores the pump lining and rods and destroys the packing, it will continue its havoc through the entire feed-water system and, consequently, in the boiler where pitting and corrosion must naturally result; and this, if continued, is not only a financial loss, but tends to intensify the dangers naturally prevalent in steam-generating sets.

It has been my experience that in order to use a treatment for boiler-feed water, it is necessary first to ascertain the mineral contents of the water used. Not having the apparatus for this purpose, we have always sent a representative sample of the water to a well known Chicago firm which makes this matter a specialty. It then selects from one of its numerous formulas (if necessary, it will specially prepare one) a compound that will neutralize the salts, etc., carried in the water. I have used one of its formulas for a number of years, introducing the compound into the boilers by placing a solution of it in a tank placed above the discharge section of the hotwell and allowing it to drop continuously into a ½-inch pipe leading down and looking into the feed-pump suction. In this way the compound is thoroughly mixed with the water and passes through the pump. We have never experienced the least ill effect from the use of this compound, which has always been fed through the feed pumps.

A. Lee.

Honolulu, T. H.

Dashpot Troubles

Referring to Mr. Green's article under the above caption in the March 21 issue, I have found that the greatest trouble, as Mr. Green has mentioned, is given by Corliss valves of the multiported type equipped with the combination vacuum cushion dashpots. After they become slightly worn the trouble begins and is manifested mostly by the engine racing when suddenly it loses the load. The indicator diagrams show a constant reaching of the governor or a hunting for the point of equilibrium and the average engineer looks for a slipping governor belt and a poorly working gagpot as the cause, without suspecting the real trouble. Most of these double-ported valves have very little or no lap and require careful adjustment else they will admit steam at the back edge when they are supposed to be closed.

There are many kinds of dashpots, and each has advantages and disadvantages peculiar to its type and the engines upon which it is used. The vacuum-cushion dashpot used on some types of engine consists of a central vacuum chamber surrounding the piston or plunger, in which are the valves of the cushion chamber. The cylinder of the vacuum chamber is in the center of the cushion piston and is, therefore, hard to keep lubricated. The outlet-air valve of the vacuum chamber is on the upper end of the cylinder above the cushion piston.

The following is a case from my experience. For some reason the dashpot would bounce and continue to bounce as the engine increased in speed. After placing my foot on the dashpot and forcing it shut with my weight, I removed the cover and put engine oil on the air valve of the vacuum chamber. There was a sharp hiss as the air passed through this valve, and the dashpot operated normally for about two hours. Then the treatment had to be repeated. At the end of the day's run I removed the gummed oil and dirt from the small holes in this valve seat and found that the seat and valve disk were worn enough to admit air to the vacuum chamber which was so dry that it also drew air in from the cushion chamber past the piston, thus forming a cushion in the vacuum chamber. As a result of the 1/16-inch holes being almost entirely stopped up, there was not enough opening through which this larger volume of air could escape. Adding this cushion to that of the cushion chamber it required but little to make the piston bounce. Placing some quartz under the disk on the seat and putting a bit-brace screwdriver into a breast drill, I ground the valve in and smoothed the roughness off with pumice stone until the valve was air tight. I then cleaned out the four 1/16-inch holes, and smearing the vacuum plunger with oil, reassembled the dashpot, and it gave no further trouble except when the vacuum plunger ceased to get the oil at the bottom to keep it air tight.

Mr. Green spoke of connecting the vacuum chamber to the condenser. This would insure a more perfect vacuum and positive cutoff, but on heavy loads when the dashpots lifted to the full hight it would be apt to cause much pounding on the cushion valves which, if made of leather, would soon give out. Then, too, the greater the vacuum the harder it would be to open the steam valves, thus bringing more load on the eccentric which would be apt to heat.

R. A. Cultra.

Cambridge, Mass.

Proper Use of Tools

In a recent issue I came across an article by H. A. Greene showing how to use a pipe wrench without crushing the pipe. He could have added lots more to his article.

It is certainly interesting to hear a steamfitter tell how an engineer should be "fired" for using a monkey wrench as a hammer, while he on one side and his helper on the other of a piece of 2½-inch pipe are yanking and jerking a new cutter (of the one-wheel kind) backward and forward over about one-half the circumference of the pipe, tightening the cutter at each jerk and then forcing it over the remainder of the circumference of the pipe that is not yet cut. After several pipe lengths have been cut in this manner, the engineer finds his new pipe cutter strained or twisted out of shape and really unfit for further use.

While on the subject of tools, a point that I would like to mention is that of wrench handles. Why are they not longer? Considering the way in which the majority of men use a wrench, it seems to me that it is high time for manufacturers to change the lengths of pipe-wrench handles. For instance, the present 18-inch wrench might have its handle lengthened to 36 inches, and the handles of other sizes of wrench might be changed in a like manner. This certainly would save an enormous amount of time for it would be unnecessary to stop to look for a piece of pipe of the right size and length to go over the wrench handle.

Just a few days ago I saw a new 48-inch pipe wrench ruined by a chief engineer (who is usually very particular). He got three heavy men to swing on a piece of pipe 6 feet long on the end of the wrench. Pipe wrenches 48 inches in size cost money.

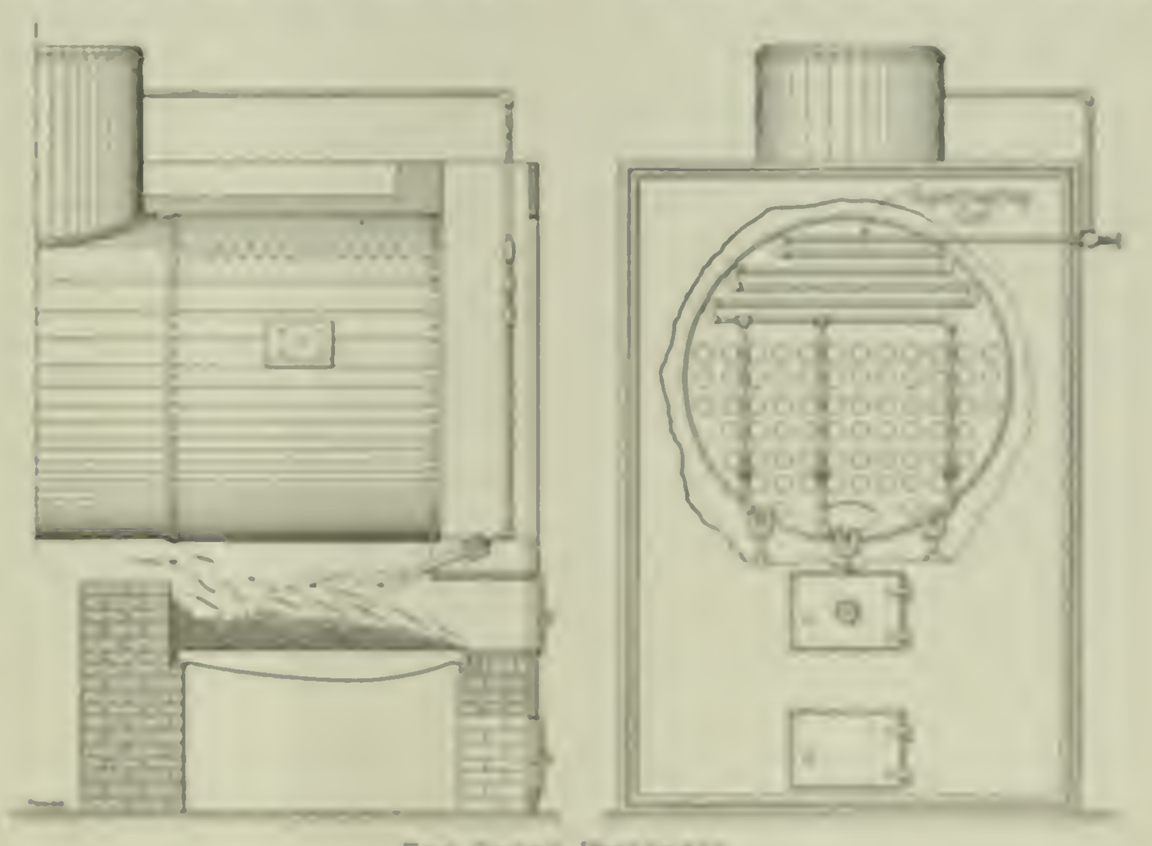
Roman S. Wilhelm.

Indianapolis, Ind.

Furnace for Bituminous Coal

Referring to Mr. De Motte's letter in the March 21 issue, I would advise him to install a smoke preventer similar to the one described in the January 10 number. I have one in use and can say that it accomplishes results very satisfactorily.

Of course, to give good results the device must be properly adjusted. In the installation which I made, the pipe from the boiler to the superheating coils is ½ inch in size. The outlets from the coil to the nozzles are of ½-inch pipe. The castings for the nozzles are 4 inches in size each way and open on two sides, as shown in the figure. One side of each casting was drilled and tapped for a piece of a 1¼-inch pipe which was cut



The Smoke Preventer

long enough to extend over the fire about 2½ inches. Opposite this pipe a ½-inch pipe drawn down so as to have a 1/16-inch opening was screwed into the casting. The tip of the latter pipe comes within ½ of an inch of the 1¼-inch pipe.

The boiler under which I use this device is 60 inches in diameter and 18 feet long. With a 72-inch or larger boiler it might be well to use four nozzles instead of three. I find that when the steam inlet valve is opened only about one third of a turn, enough steam is admitted to secure good results. A little experimenting will enable Mr. De Motte to decide what the necessary quantity of steam is and to regulate the inlet accordingly.

Fred Smith.

Port Clinton, O.

Effect of Discharge Pipe Size on Motor Load

Referring to Mr. Lee's letter in the March 14 issue, probably the reason why the 3-inch bushing was put in the discharge pipe was to produce a greater velocity in the discharge pipe. A pump having the suction and the discharge pipe equal in size will work successfully only in low-pressure systems.

Mr. Lee should have given both the suction and the discharge head so that a more accurate analysis of his problem could be made.

J. E. Stephens.

Yuma, Ariz.

Change of Cutoff

H. Jones has a letter under the above heading in the March 21 number. I think that he is mistaken in the directions which he gives for changing the cutoff on a Brown engine.

The point of cutoff may be changed by changing the boiler pressure, the back pressure, or the load on the engine. The cutoff is controlled by the governor which regulates the volume of steam according to requirements. If the cutoff is uneven between the ends it may be evened by adjusting the clipper pin or the nurl screw at the head end.

The question looks to me as though it might have been asked at an engineers' examination to determine whether the applicant fully realized that the governor controls the amount of steam admitted.

West Fitchburg, Mass.

Questions Before the House

Comment, criticism, suggestions and debate upon various articles, letters and editorials which have appeared in previous issues

Clogged Gage Pipe

Two recording-pressure gages are connected to the same water main, but they do not record the same pressure. I have been told that the pipe of one is clogged which prevents it from giving the true pressure. How can I find out if this is a fact?

P. C. G.

One of the gages is incorrect and perhaps both are. They should be tested by comparison with a gage known to be correct. No amount of clogging in the gage pipe unless it stopped it entirely would affect the reading unless there is flow through the stricture. The gages must, of course, be at the same hight so that the effect of the columns of water in the pipes leading to them will be equal.

Weakest Part of Boiler

Where is the weakest part of a vertical fire-tube boiler, and why?

W. P. B.

The weakest part of any tubular boiler is the longitudinal seam. It is not possible to make a joint as strong as the sheet and the stress tending to pull the metal apart along its length is only one-half that which is exerted to separate it circumferentially.

Cooling Hot Bearings

I have an engine bearing that frequently goes hot at short notice and without any apparent cause, and I have to stop until the bearing is cool. Is there any preparation that will cool a hot bearing while running?

H. C. B.

Before the days of graphite a mixture of lard oil and flour of sulphur was the standard remedy for hot boxes. Graphite and good lubricating oil in proportions of ten parts of oil to one of graphite will usually reduce the friction of a troublesome bearing until it will run cool.

Pitch of Steam Pipe

Should the steam pipe incline toward the engine or toward the boiler, and why?

P. S. P.

It is better to have the pipe incline toward the engine. Then any water which condenses in it goes along with the steam and is passed off a little at a time. If the inclination is in the other direction, the flowing water is opposed by the current of steam and may accumulate into a large volume which will go over all at once.

Low Speed in a Motor

A shunt-wound variable-speed motor rated at 1350 revolutions per minute, maximum, will not run faster than 1000 revolutions per minute. What is the probable cause, and can the speed be increased by adding to the resistance in the starting box?

E. C.

The voltage may be low or the field section of the speed regulator may be partly short-circuited. The speed can be increased by increasing the resistance in the field section of the controller, not in the starting section, which is in the armature circuit.

Net Diameter of Bolts

How much greater is the diameter at the root of the United States standard thread than in the case of a V or sharp thread of the same pitch?

R. E.

In the standard thread the diameter of the bolt at the bottom of the thread is ¼ the hight of the thread greater than in the case of the V or sharp thread.

The diameter of a bolt at the bottom of the standard thread, in inches, is

$$\textit{Dia. of bolt} - \frac{1.299}{\textit{Number of threads per inch}}$$

For the sharp thread the diameter is

$$\textit{Dia. of bolt} - \frac{1.733}{\textit{Number of threads per inch}}$$

Indicator Springs for Given Boiler Pressure

What number of spring should be used in an indicator for 100 pounds boiler pressure?

E. A. S.

For ordinary conditions a spring which will make a diagram 1¾ inches high will be found satisfactory. With 100 pounds boiler pressure a 50 spring will give approximately the desired hight, as the pressure in the cylinder never equals that in the boiler.

High Temperatures in Gas Engine Cylinders

Will it injure a gas-engine cylinder to run it very hot, provided the maximum temperature is not high enough to decompose the lubricating oil?

F. E. W.

Probably not, but the advantages due to high temperatures are not worth the risk of experimenting in that direction. The temperature of the cooling water at the jacket outlet should not be more than 100 degrees (Fahrenheit) higher than the temperature of the entering water.

Rotor Current of an Induction Motor

a. What is the usual ratio between the stator and rotor currents of an induction motor?

b. What would be the probable rotor current of a 75-horsepower 240-volt three-phase motor?

L. J. G.

a. There is no definite relation between the stator and rotor currents. The rotor current depends only on the rotor slip, the field strength and the resistance of the rotor circuit.

b. About 180 amperes, regardless of primary voltage and phases.

Air Compressor Capacity

What is the free air capacity of a compressor?

R. E. M.

The cubic feet of free air it can handle per minute, hour or other unit of time. That is equal to the piston displacement in cubic feet multiplied by the number of piston strokes per minute or hour or other period. "Free" air is air at atmospheric pressure and temperature.

Three-phase Power Measurement

Can the power in a three-phase circuit be figured from the switchboard instruments without a wattmeter?

R. E. M.

Yes; if you have a power-factor indicator and the circuit is balanced. Multiply the voltage by the amperes per phase; multiply the product by the power factor and that product by 1.732; the final result will be the watts in the circuit. Example: Volts, 2300; amperes per phase, 50; power factor, 80 per cent. Watts $= 2300 \times 50 \times 0.8 \times 1.732 = 159{,}344$. If the circuit is not balanced, add the currents in the three legs and divide the sum by 3; take the result as the current per phase. This is approximately correct.

Governmental Control of Water Power

The conservation movement as applied to water powers, and which is now receiving so much attention, may be summed up as follows:

The development of high-tension transmission has made possible the utilization of water powers which, owing to their remote location far from any market for power, have heretofore been unavailable. The promoters, knowing that more or less risk is involved in the development of most water powers, wish to obtain the privileges upon practically their own terms. On the other hand, the people, having more than once been the victims of monopolistic control, have called a halt until they can see their way clear to grant the use of these water powers upon equitable terms.

One fact is agreed upon by all parties concerned; this is that the present laws regarding the point at issue are inadequate, being for the most part cumbersome and involving a division of authority. This is especially true where the rights of several States are jointly involved. In view of this it would seem desirable to centralize the authority and simplify the laws, at the same time making them flexible enough to fit each particular case.

The main point of difference between public opinion and the views of those promoting water-power developments seems to center about two points: First, whether the Government shall be paid for the use of the water; second, whether it shall be limited or unlimited tenure. Regarding the first point, the promoters argue that the public will receive power at cheaper rates if the power company does not have to pay a tax upon the use of the water; furthermore, that due to uncertain conditions of flow, as well as uncertain markets for power, it is often impossible to reap a fair return upon the capital invested; therefore they should not be taxed upon this investment. The former contention will probably be found to have very little effect upon the selling price of power unless the rates are controlled by the people as through a public-service commission, and the latter is well founded. Obviously, it would not be fair for a power company to pay a tax based upon the maximum development of fifty thousand horsepower when six months out of the year they were deriving only twenty thousand horsepower from this source. However, one way out of this difficulty would be to base the tax upon the actual power developed.

As regards limited or unlimited tenure, the power interests claim that it is hard to finance a project involving a limited tenure, and that limited tenure also necessitates an additional amortization charge. It is hard to see why this contention should hold true if proper provisions are made for safeguarding the property at the expiration of the franchise. J. G. White, at the recent conference held under the auspices of the National Electric Light Association remarked that he had yet to learn of a single case in which the right of revocation had been exercised where the business had been carried on in good faith. From the viewpoint of the public, conditions are constantly changing; hence, why should we tie the hands of future generations by granting unlimited tenures?

The recent conference undoubtedly accomplished much toward a better understanding of both sides of the question, although perhaps still more would have been gained had the papers been less general and more specific in character.

Recording Instruments

"Knowledge is power."

In steam engineering and in other branches of industrial endeavor this truism may be revised to "Knowledge is more power," in which the term power is used in the literal sense. In the "good old days" this was not so well and widely known as it is now. Even in these improved times it is not as thoroughly understood as might be desired.

Only a few decades ago pig iron was manufactured by the crudest of hit-or-miss methods. The proportions of ore, limestone and coke or charcoal were determined entirely by personal judgment based on the experience of the operator. When an "off cast" or a batch of bad iron was made, which occurred with distressing frequency, the operator would blaspheme his luck and hope for better things.

The condition of the furnace was guessed at; the operator would hold his hand over its top and take a look through a peek hole or two, and by the degree of heat that he felt and light that he saw, would decide that "she" needed another charge, more "wind" or something else, as the case might be.

Competition grew keen. The more progressive iron makers began to study their business in a thorough and scientific manner. Chemists were employed to investigate the chemical phases of the problem of refining iron cheaply and with control over the quality. The influences of the temperature and the air supply in the furnace were determined with exactness.

With the acquisition of exact knowledge came the necessity of and, consequently, the demand for means of accurately measuring the variable factors in furnace operation, such as the blast pressure and temperature, the top-gas temperature and the quantity of the air supply.

It has been alleged that "Necessity is the mother of invention." It proved so to be in the present instance, for closely following the demand came the supply of suitable recording pyrometers, recording pressure gages and engine-speed recorders. By the aid of such equipment, the furnace man can tell at what temperature, in what quantities and under what pressure the air supply is going into the furnace. Further, he can compare today's conditions with those of yesterday or a year ago, for he has the records.

In the power plant education and competition are fast creating conditions similar to these in the iron-refining business. Success demands that accurate and complete knowledge be acquired of what is going on in the boiler and the engine room.

Although this is truest of the operations in the boiler room, progress there has been slowest.

How idiotic it would seem to attempt to operate a boiler today not equipped with a steam-pressure gage and a water column. Yet, there was a time when such was "all the fashion"—in the days of "haystack" boilers. A platform encircled the boiler at a convenient hight and when the fireman wanted to gratify a curiosity as to where the water level stood he would mount said platform and give the boiler sundry kicks amidships which, by the process of elimination, eventually established the point in question. When the steam pressure rose too much the safety valve rectified conditions—when it fell too far, the engine served notice and the fireman did the rest.

It is not improbable that the time will come when it will seem similarly foolish to operate a boiler plant without such things as feed-water meters, automatic fuel weighers, recording draft gages and thermometers, CO_2 records, etc.

In many quarters a demand already exists for accurate recording devices. When the manufacturer places on the market instruments that are reasonably low in first cost and upkeep, simple and substantial in construction and accurate and reliable in operation, he will lend a great aid to the right kind of progress in steam engineering. Great possibilities lie in this field.

Not A Rival

From the public utterances of a number of prominent members of the National Association of Stationary Engineers, it would seem that the Institute of Operating Engineers is regarded as a rival organization, the growth of which is to be discouraged. This is a misconception. The Institute is a school for the systematic education of engineers and machinery operators and is no more a rival of the National Association than any other educational movement. It proposes to do in a thorough and orderly way that which fraternal organizations can only handle in an incomplete and desultory manner.

The fireman and his helper, the oiler, and all other power-plant employees, however ambitious and able, are denied membership in the fraternal organizations of the aristocrats of the vocation, while the doors of the Institute are open to all, and the future standing of any member will depend entirely upon his mental and manual attainments. Instead of being a rival, the Institute will become a source of membership of the highest quality to the fraternal bodies.

Indexing Engineering Literature

The literature committee of the Institute of Operating Engineers is sending to the members of that society digests of articles in the leading engineering papers. The digests are classified by subjects, three of the articles upon boilers being abstracted as follows:

BOILERS

Boilers and Piping of Wieboldt Building. Osborn Monnett. Giving some very good ideas on piping layout as to size, showing clearly that a much smaller pipe can be used for the run by placing a good-sized receiver at throttle on engine.
1½ pp. 5 ills Power, Feb. 7, 1911

Modern Boiler Plant of Holyoke, Mass. Warren O. Rogers Illustrating how a great saving was made by building a central station to do the work formerly done by several plants. Method of coal conveying and handling, damper regulation, feed water measuring, results of boiler tests, etc.
6½ pp. 15 ills. Power, Feb. 14, 1911

Firing Boiler with Pulverized Coal. W S. Worth. Giving the performance of a 300 h. p. boiler fitted with the Blake system of pulverizing for period of 200 days, with full details of how a proper mixture of air is attained.
5 pp. 3 ills. Power, Feb. 14, 1911

The above is a reduction, the original size being such that it may be pasted upon a regular 3x5-inch index card and these cards filed either alphabetically or by subjects as the user may prefer. The persistent following of this system would result in a card index which would point to where the latest information upon power-plant subjects could be obtained, and if the articles are filed or the papers containing them saved and the index card is made to point to their location, a veritable encyclopedia of the business would in time result.

A Record Breaking Turbine Test

The reported performance of a Brown, Boveri turbine at Newcastle-upon-Tyne, particulars of which will be found upon page 599, beats the record so far as we know of published actual accomplishment in British thermal units per kilowatt-hour referred to the total work done by the turbine with an overall efficiency of ninety per cent. There are turbines which have made records under other conditions of pressure, superheat and vacuum which, could they be reduced to these better conditions, would better this performance, but for actual accomplishment this is the best so far reported.

The United States Supreme Court has sustained the commodity clause in the Hepburn rate bill, forbidding coal-carrying railroads from owning coal mines. Just notice how much difference this will make in the price of coal.

There are some engineers who are "old fashioned" enough to believe that the more simple a power plant is in design the more economical it is in operation. They have no use for frills and at that some of them are getting results.

Have you seen helpers who could not, or would not, learn the lesson of obedience? They consider it degrading to a free-born white man to take and obey orders.

An engineer cannot expect to accomplish much unless he has self-confidence.

Some managers employ cheap help and use cheap material, and are surprised that they get poor results.

Have you noticed that some engineers keep an open tin filled with cylinder oil in a warm spot so that dust from the coal, ashes and sweepings can readily settle into it?

When a power-plant owner is losing money and does not know it, it does not worry him.

It isn't so much what you do as the way you do it that counts toward success.

Do it now; tomorrow may be too late—too late even to be sorry.

Have you ever taken the trouble to personally examine the inside and outside of the boilers in the plant where you are chief?

Activity is contagious. Therefore, a lazy chief engineer cannot blame his assistants if they follow his example.

An honest man is respected by all; a grafter by none.

Government Control of Water Powers

The conference was held at the United Engineering Societies building in New York City on April 8. Walter L. Fisher, Secretary of the Interior, and a large number of prominent engineers and water-power men from various parts of the country were present. Chairman H. L. Doherty opened the meeting with the following remarks:

A summary of the papers presented at a public conference on "The proper attitude of the National and State Governments Toward the Development and Utilization of Water Powers," held under the auspices of the power transmission section of the National Electric Light Association.

The National Electric Light Association is an organization of corporations and individuals engaged in the electric-light and power business, which now exceeds 7000 members and represents over 80 per cent. of the money invested in the electric-light and power business in this country. It was organized to encourage the development of electric service from central-station plants along broad and comprehensive lines, which will bring benefit to the members of the organization and to the public.

According to the last census there is 37,000,000 horsepower available in the United States in water power which can be developed at a cost comparing favorably with that of steam. Of this amount about 1,600,000 horsepower has already been developed electrically and approximately 1,900,000 horsepower has been developed for industrial purposes through means other than electrical, leaving approximately 33,500,000 horsepower still available. To develop even the smaller amount of power named would require over $7,000,000,000.

It is interesting to note that the undeveloped water powers of this country exceed the total amount of power now generated by all known means. However, the bulk of these powers is located in mountainous regions, while the great bulk of all the power now generated is along the populous sea coast and plains districts and often far away from these water powers. The question of electric transmission of power is purely one of economy and reliability. Given enough money for the equipment, it would be possible to transmit power from San Francisco to New York with no greater loss of energy than now occurs on many ten-mile transmission lines. Power is already being successfully transmitted over distances of more than 200 miles.

At present over $200,000,000 worth of fuel is being consumed annually which might be saved by the development of our water powers. In the movement toward the conservation of our natural resources it must be evident to all that the resource which is greatest in danger of exhaustion, and which should be conserved, is the fuel supply. It is interesting to note that under the teachings of this so called "conservation" movement the National, and to a large extent the State governments, have assumed an attitude which has almost completely discouraged the development of water power and is causing every day an unnecessary and flagrant waste of the fuel supply. The development of our waterpowers represents an enormous source of available wealth to the community as a whole, but it does not promise the reward to the promoters and backers of these enterprises equivalent to that which is promised in almost every ordinary line of business.

The Government cannot give title to a water-power site that would warrant the erection of a $600 miner's hut. Undertakings requiring millions of dollars are expected to accept such a title to the property which is to be improved, and yet the title can be revoked at will, even on caprice of a governmental agent. The National Government has committed itself to a policy of limited tenure of grant, which is contrary to the opinion of all of the advanced thinkers in the school of economics, and a policy which is wrong in principle.

It has been suggested that this controversy may be partially due to an unrecognized difference in the fundamental premises which have been unconsciously assumed without careful analysis. By this is meant that one class, taught by the more recent and impractical school, assumes that the public lands are the absolute property of the Government, intended only to enrich the treasury of the Government without regard to other considerations; while the older and more practical school assumes that these lands are held in the nature of a trust and should be used for the settlement and development of the territory where they are situated, and thus contribute to the development of the entire country. The latter school is in accord with the precedents which actuated the Government through many decades, and although precedent alone should not govern in matters of this sort, there is a consideration which precedent in this case has reflected, and which is of prime national importance. The Government has from time to time dealt out vast areas of these public lands under the guidance and advice of the early statesmen of this country, selling or giving away these lands for a mere fraction of what their ultimate value would prove to be, believing that the benefit of quick settlement would bring about by earlier use vastly more in the development and prosperity of the country than to permit these lands and opportunities to lie unproductive for many years.

This policy had the support of all the great statesmen of all parties from the country's birth until in the last few years, but it may be that the men we reverence who formulated and executed these policies lacked the wisdom of our later-day magazine-made-hero statesmen, but in spite of this later-day wisdom why does not fair play demand that the public lands and opportunities of Oregon, Washington and Colorado be utilized to develop these sections rather than to have the public lands of these and other States treated as public property, owned in fee simple by the Federal Government and used to enrich those States that have already had distribution of their public lands according to the policies of the old school.

Conservation of Water Powers and Their Development for the Public Good

By Sidney Z. Mitchell

The real conservation of water power means its use. The only methods of producing this power are (a) through the consumption of coal, oil, gas, wood and other fuels which exist in limited quantities and cannot be replaced, and which are being consumed and exhausted at a rapid rate; and (b) through the use of water powers.

Under the first method, natural resources which cannot be replaced are consumed. It has been estimated that there are now being annually used in the United States more than four hundred and eighty million tons of coal, worth, on an average, $2 per ton, or a total of about $960,000,000 annually, to say nothing of the annual consumption, in addition, of millions of dollars' worth of oil, natural gas and wood. In many places entire forests are being denuded to obtain the fuel supply for local uses when the same purpose could be better served by the development of hydroelectric power from nearby streams.

By the second method, that is, by the use of water power, this frightful wassumption of coal, wood and other fuels can be minimized and in many cases wholly obviated, and in that way the natural resources, which are limited in quantity and which are now being so rapidly exhausted, will be conserved.

The distinction between water powers operated for private purposes and those operated for public purposes seems to me so logical and so important that it must be recognized in future legislation. Too much emphasis cannot be laid upon the radical difference between the pulp mill or factory type of water power used entirely in a private business and the water power used for the generation and distribution of light, heat and power. The latter is the servant of a widely scattered public, serving, without distinction, all the people, including manufacturers, domestic consumers, traction lines and municipalities. In the truest sense of the word it a public-service business, and as such there can be no doubt of the power of the Government to exercise over its service and charges the most minute and continuous supervision and control. The only restriction upon this power is that there must not be confiscation of the property in which capital has been invested.

There has been a great deal of discussion as to the relative legal rights of the Federal and State governments as bearing on water powers. These I will not attempt to discuss. So far as I have been able to ascertain, the majority of investors have no particular preference in the matter; but are vitally interested in having their public-service investments regulated by only one authority. And it seems to me that the possibility of having one government passing laws that the officers of a corporation shall conduct a business in a certain way and in no other, and another equally potent government passing laws requiring these same officers to conduct the public-service company's business in a different way, and in no other, needs only to be stated to show that such conflict of laws would be fatal.

Contrary to the general belief the charges which the Government, State or Federal, may make for the privilege of using the water powers is not a matter of material importance to the power companies, so long as such charges are not so great as to make it impracticable for the power company to compete with steam- or gas-producer plants, or with other water-power companies exempt from such special tax. It may seem desirable to the Government that an annual charge be made. To my mind this is merely one of the methods of providing State or Federal revenues at the expense of the particular community served. I believe that so long as the charges are not so high as to prevent the substitution of water power for fuel-consuming power, the matter is entirely one of equitable taxation, in which the only interested parties are the Government and the local community paying the tax. For, if made, such charge must be taken into account in the regulation of rates, and will proportionately raise the limit below which prices to the consumer cannot constitutionally be reduced.

It is important also to bear in mind some of the undesirable complications which may grow out of this method of taxation where the power developer is forced to construct and donate to the Government expensive locks at the rapids of so called navigable streams. This large initial investment is in effect a lump sum tax upon the particular community served. It must necessarily be paid at the outset by way of construction costs. Without being unduly burdensome, however, it cannot be shifted upon the consumer in a short period. To minimize the sinking fund or amortization charges necessitated by this unusual and to my mind unwise expense, it is necessary to spread it over a long series of years. And to the extent that the spreading out of the charge is made impossible by the short tenures imposed by Congress in authorizing the building of the dams, to the same extent will these amortizations bear harshly upon the consumers of power and often prevent the substitution of water power for fuel-consuming power apparatus. In many cases this lump-sum method of tax is undoubtedly too much for a new industry to bear, and thus defeats the desire that all these water powers should be built.

Many of the largest and best unused water powers today are upon the so called navigable streams. An investor is asked by the local people to join in providing capital to develop such powers. He is at once confronted by the necessity of securing an act of Congress authorizing the construction of a dam across the rapids of the so called navigable stream, rapids over which in many cases no boat has ever passed, nor probably ever will pass until locks are constructed. In demanding that the power developer shall construct and present to the Government an elaborate system of locks as part of the construction of the dam, the Government overlooks the fact, not only that such construction must ultimately be paid for by the community served by the power company, but also that the very building of the dam across such rapids will relieve the Government of the great expense of creating the necessary pond over the rapids. If it should thereafter desire to make the rapids navigable it need pay only the then much smaller cost of building locks sufficient merely to put the boats into the pond created at the expense of the power builders. As a rule, water powers of this character involve the handling of large quantities of water at low head. This of itself makes development expensive and in many cases more or less unreliable, unless supplemented for short periods by steam, owing to the fact that extreme high and low water affects such development more seriously than high-head developments. These great burdens to the investor are increased many fold in most cases by arbitrary legislation, restrictions and limitations. These restrictions and harsh requirements, from a navigation standpoint wholly unnecessary, are today holding back the development of hundreds of thousands of horsepower, the operation of which would save millions of dollars' worth of fuel which is being consumed each year.

In some of the Eastern, Southern and Middle Western districts where coal is cheap, it is frequently difficult for engineers to decide whether it is more economical to develop water power or use the ever-improving steam and gas-producer power apparatus. Waterwheel construction has so advanced that it is not possible to materially increase the water efficiency. On the other hand, the efficiency of steam and gas-producer apparatus has been wonderfully improved in the past two decades, and will undoubtedly be further improved from year to year.

Where there is this close competition between the relative economies of water-power and fuel-consuming apparatus, and where the adoption of steam, oil or gas means a large unnecessary consumption of nonreplaceable fuels, is it not a pity that every possible power at the command of the Government, Federal, State and local, is not exerted to the utmost to secure the adoption of the water-power system and thus save the fuels? Very frequently the omission of all Governmental restraints (other than the power of regulation and those necessary to protect navigation) or a small difference of cost amounting to not more than the value of one or two years' fuel consumption by the equivalent steam or gas-producer plant, will turn the balance in favor of the water power.

The investor of today knows that his property on Government lands is inadequately protected. He demands permanent, tangible and specific rights; the mere shifting and changing permits now in effect scare off all but the most speculative class. At present the rights of the hydroelectric companies in the Forest Reserves, for instance, are subordinated to operators under the mining laws. If I am correctly informed, it is possible for a mining company to start placer or other mining operations, at the very dam or canal intake of the hydroelectric company, and to so interfere with the company's structures as to render the operating plant inoperative and, therefore, useless.

Moreover, under the present law, there is a question whether the Federal officials have power to grant or sell to the hydroelectric companies any rights as against subsequent homesteaders, scrip locators or other entrymen, who may obtain title at any later time when the lands involved are thrown open to settlement. If there is no such authority, then any future scrip locaters, homesteaders or other entrymen on such lands have the right to take possession thereof as if the plant and property of the hydroelectric company had never existed. And in States which do not give hydroelectric companies the right of eminent domain, there would be no way to protect such investments against the arbitrary action or unreasonable demands of the subsequent scrip locaters, homesteaders or other entrymen, who would thus have the absolute power to eject the hydroelectric developer from the premises and thereby render inoperative his entire plant and investment.

Limited tenures may be well enough in the case of the development of a water power in connection with a private business which the Government has no right to regulate; but advanced thinkers on the subject, I believe, all agree that, next to revocable permits, limited tenures are the most fallacious and harmful of all the present-day popular notions, when applied to a water power, or any other development made for the public benefit.

A power developer may have three or four times as large an investment in his distributing system (entirely off the Government domain) as in the generating station on the Government domain. The whole distributing system would necessarily be made inoperative and useless by the failure to secure a renewal of the original limited tenure for the generating station, and is thus unduly jeopardized by the mere possibility that some Government official, actuated by political exigencies of the day, may fix the renewal terms on such an onerous basis as in effect to confiscate the power system as a whole. There is always the theory that these limited tenures will be renewed on some terms, but what these terms will be, what is the significance of the so called but very indefinite "preference right" of renewal, and, in fact, what is to become of the entire generating and distributing property at the end of the 50 years, no one seems to know.

We know that population and general business, particularly in the western sections, are growing by leaps and bounds. The requirements of the people both as to quantity and quality of service, including new uses of electricity, are daily increasing. Consequently, capital investment must be increased from day to day and from year to year if a corporation is to do its duty properly as a public servant and as the law requires. Who ever heard of a public-service corporation in the West, or even in the East, needing less plant and equipment and less facilities for serving the people from year to year as time goes on?

Why should any of our local communities be taxed with high rates from month to month in order to create a large amortization fund to pay for and present to the Federal Government at the end of 50 years or other limited tenure its local power developments? Why should the present generation be forced to pay exorbitant charges for service, to create this amortization fund, so that the property may in two or three generations revert to someone else?

If an amortization charge at the rate of so many cents per kilowatt-hour and so many dollars per horsepower-year for the entire plant capacity is necessary for the money invested during the first year of the 50-year tenure, then what must this rate be on every additional million dollars invested during, say, the twentieth year and during the thirtieth or fortieth year? And how it is possible for the consumer to pay a high enough rate in, say, the forty-fifth, forty-ninth and fiftieth years of the tenure, to return the investor at the end of the 50-year period all of his capital put in during these last few years and devoted to serving the people? Unless the investor receives positive and satisfactory assurance on this point, is he likely to come forward, particularly toward the end of the tenure, with the cash to provide the equipment and plant necessary for proper service of the people?

In the water-power business, without providing anything by way of an amortization fund, it usually takes, over a term of years, from $5 to $10 actual cash investment in plant and distributing system to get $1 per year gross revenue at such normal service rates as will provide a reasonable return on the investment and be commercially obtainable in competition with steam. Evidently, therefore, it is not only impracticable, but I can tell you from experience it is absolutely impossible, to charge only normal and reasonable rates for service, and devote all the earnings to providing for the growth, not unusual in the West, of 15 per cent. and upward per year, and at the same time have anything whatever left for interest and dividends. The cash required to provide facilities for such growth will, over a term of years, more than absorb the entire net earnings. How much more impossible, then, does the problem become if additional money put into the property toward the end of an expiring tenure must be gotten back through the creation of an amortization fund by raising the rates to the consumers?

All of us who have lived in the West, and who have had dealings with the farmers in the arid communities, have had forcibly brought to our notice still another fatal feature of the limited tenure theory. There are in the West many millions of acres of arid land which is the most fertile in the world when properly irrigated, but which is worthless without an adequate and reliable source of water supply. The lower levels of land are being supplied from Government or other irrigation canals, but fully as many acres of land on the higher levels can be commercially irrigated only through the use of hydroelectric power, the bulk of which is being furnished by public-service corporations in connection with their general light and power business. This arid land would be of no use without an unfailing water supply. But how is it possible for the power company to agree to furnish water in perpetuity for irrigating these lands, if there is the slightest chance of its source of supply being arbitrarily cut off under the present revocable-use agreement or limited tenure systems? Will there not inevitably be recurring periods of expiring tenures to cause complete stagnation of all productive effort dependent upon water power, disastrous alike to the community and to the power developer?

To my mind the only way this water-power question can be promptly and correctly solved, as a fuel conservation problem or otherwise, is by so educating the people on every phase of the subject that they will not only support and approve, but will insist upon the adequate and sane legislation now so much needed. The objects of this association are largely educational, and I know of no way in which it can better serve the people, including its members, than by taking a leading part in this educational campaign for true conservation.

Discussion

Several other papers and discussions of a more or less general nature were presented before the meeting. Space is not available in this issue even to give a summary of much of this material. Some of it, however, not included in the following, will be given attention in a later issue.

Walter L. Fisher, Secretary of the Interior: Fundamentally there is no conflict between the State and Nation in this matter, but no correct solution of the subject will be reached until all possibility of real conflict, justifiable conflict, has been removed. I believe that the State and Nation should be coördinated in a solution of this problem, and that they can be and will be when the correct solution is reached.

The expression has crept into the remarks of the chairman that there is existing a Governmental policy which seems to be subject to some criticism, or at least some dissatisfaction. I think that is a fundamental mistake. As I understand the existing situation, there is no Governmental policy, and that is the chief fault of the existing situation. What the Government has been doing, as I understand it, is merely to maintain the existing status until a policy can be developed.

To my mind, the most essential thing in this whole matter is that we do get together, that we do try to understand each other, and then that we act. The time has come when discussion is useful as a basis only for forward action, and I welcome this meeting as one of the first steps in that direction.

J. G. White: It seems to me, from the ordinary business point of view, that conservation properly means "saving what is otherwise going to waste," and that would necessarily mean utilizing the water powers instead of throwing hindrances which either prevent or divert such utilization. Every hour that any particular stream on which water power could be developed is allowed to go without such development, a certain amount of energy is being wasted, and being wasted beyond recovery. On the other hand, the coal which may be used from time to time to develop the energy, in place of the water power, might rest in the ground for a decade, or a century, or any time, with little or no deterioration. If the Government officials could all, as most of them do really, think of it as a fundamental proposition, from a practical and businesslike point of view, and then see how they could help to enlighten members of Congress on the subject, seeking to arouse their interest in a study of the subject, and others who perhaps for the sake of currying favor with the political elements, or whatever their object may be, could be gotten to take a businesslike point of view on this proposition, and then all work together to the end of arousing the interest of the Government officers in charge to look at it from a business point of view, I have no doubt that most of these problems could be settled along sane lines.

While the so called water-power privileges might be given in the shape of Government permits, with the right to revoke such permits, I do not believe, unless there should be a wholesale change in the tenor of affairs, that that authority would be used to the detriment of the people who had invested their money in good faith; but in spite of that, it is my thought that there should be a clear and businesslike appreciation of this general problem, and it would seem to me that some resolutions, either advocating the appointment of committees to give special consideration to the problem, and to make a report to Congress, or having a report from the Government engineers to Congress, for the consideration of Congress, looking toward legislation which would be along business lines, should be advocated by this body.

John H. Finney: A policy that makes for continued nonuse does not fit the true definition of conservation, which is wise use, and for much of this the power companies are themselves to blame, just as the railways have been to blame for radical legislation directed against themselves. The time for the "public be damned" attitude, for frenzied finance, for secrecy of operation, for extravagant profits, for unrestricted perpetual rights and franchises, is past. The time is here and now for the exact analysis of all these things; the sooner it is recognized by capital and exploiters, the sooner will we get that better understanding that will make wise use and fair dealing possible. I am no prophet, but it seems to me that it is clearly possible that fair dealing and wise use may in time rest not on the Government control of navigation, which is now wrongly considered by the Government as the paramount use of water, but on the broader public-welfare clause of the constitution, which will consider the larger and more important and valuable water power, made possible by a well considered and coördinated plan of river development, as the important thing concerning which the people require education—I do not know anything upon which Congress would require more expert knowledge than in dealing with these matters, and the function of this body should be wisely directed toward the education of Congress to the importance of water power now, and the supreme importance of water power in the future.

Charles F. Scott: The relations of the public to water powers, the rights of the public in water powers, it seems to me is something that changes from time to time. It has been pointed out that the rights in early days, when there was no use of water except along the banks of a stream, were such that the rights were granted entirely to those who occupied the borders of the stream; and later, when water began to be useful for irrigation at a distance of a mile or so from the banks of the stream, then the people occupying the adjacent country were found to have rights in the stream because they were found to have a use for the stream which never existed before. Likewise, when people fifty miles away have use for the power which the stream can develop, then rights, generally moral rights, and later legal rights, are created which did not before exist; and it is to meet new conditions of that kind, for which our laws are obviously inadequate—not that there has been a fault in the past, for it would be as impossible for the legal machinery of our Government to have anticipated these conditions twenty years ago, and provide for them, as it would have been for the electrical engineers of that day to have laid out the power plants of the present day—it is a matter of normal evolution, brought about through these new scientific and engineering developments.

If we were in a few words to state what is the real problem, the general problem now before us, it seems to me it would be this: To formulate a constructive policy by which water powers may be made available to the public at fair and equitable rates. I think when we consider for a moment the various phases of the questions that have come up, that all of them resolve themselves finally down to that simple proposition—how can this power be made available in the most efficient way to the public at fair and equitable rates? The great public cry, I believe, is against "interests" getting hold of water powers in such way that they may extract an undue profit. If, therefore, we can insure by Governmental control that that power shall be made available to the public at fair rates, we have accomplished the purpose which we want to accomplish.

D. B. Rushmore: My feeling toward the Government is that it is not an opposing force—it is fighting for us, it represents us, it is ourselves, and we want the Government to help us, the people, to carry out these enterprises. A sudden brake has been put on, partly because people do not understand, and they wanted to stop it until they got the thing right.

Very few individuals now question the right or desirability of public supervision and public regulation, but they want it in a fair-minded way, and engineers ask that it be done in an understandable way. Now, when a supervising body states that on a certain system the current and the voltage must be kept at a constant value, twenty-four hours in the day, it appears absolutely ridiculous, and we know at once that the men, with the best of intentions, making these rules, do not know what they are talking about. The result of conferences like this, and future conferences for interchange of opinion, will be that the people who will have the control and supervision of these enterprises, will be able to exercise this control and supervision in an understanding way.

Resolution Adopted

At the close of the meeting the following resolution was read and adopted by the society:

Resolved, That it is the sense of this meeting convened at the instance of the power-transmission section of the national body, that the National Electric Light Association should offer its coöperation with the legislative and executive branches of the National and State governments for the formulation of a definite constructive policy which will encourage the prompt and fullest development of our water powers in the public interest; and

Be It Further Resolved, That to this end it is recommended that the officers of the National Electric Light Association appoint a committee or committees, with power to act in the premises, and to invite the coöperation of such engineering, commercial and other bodies as they may deem expedient.

New Power House Equipment

What the inventor and the manufacturer are doing to save time and money in the engine room and power house. Engine room news

Indicator Spring Tester

This apparatus, which is made by the Schaeffer & Budenberg Manufacturing Company, Kent and De Kalb avenues, Brooklyn, N. Y., consists essentially of a closed vessel made of cast iron, capable of resisting internal steam pressures up to 200 pounds per square inch. The steam pressure in the vessel is measured by a gage of special construction consisting of a piston, of ½ square inch area, which is free to move in a cylinder.

The lower portion of the piston is pointed and rests in a yoke which is suspended on the knife-edge of a pair of scales mounted on top of the closed vessel. If the scales are previously balanced, before admitting steam into the vessel, it is evident that the reading of the scales will give the pressure acting on each element of the vessel equal in area to that of the piston. The scales are graduated to fiftieths of a pound, which permits very close readings. The device is shown in Fig. 1.

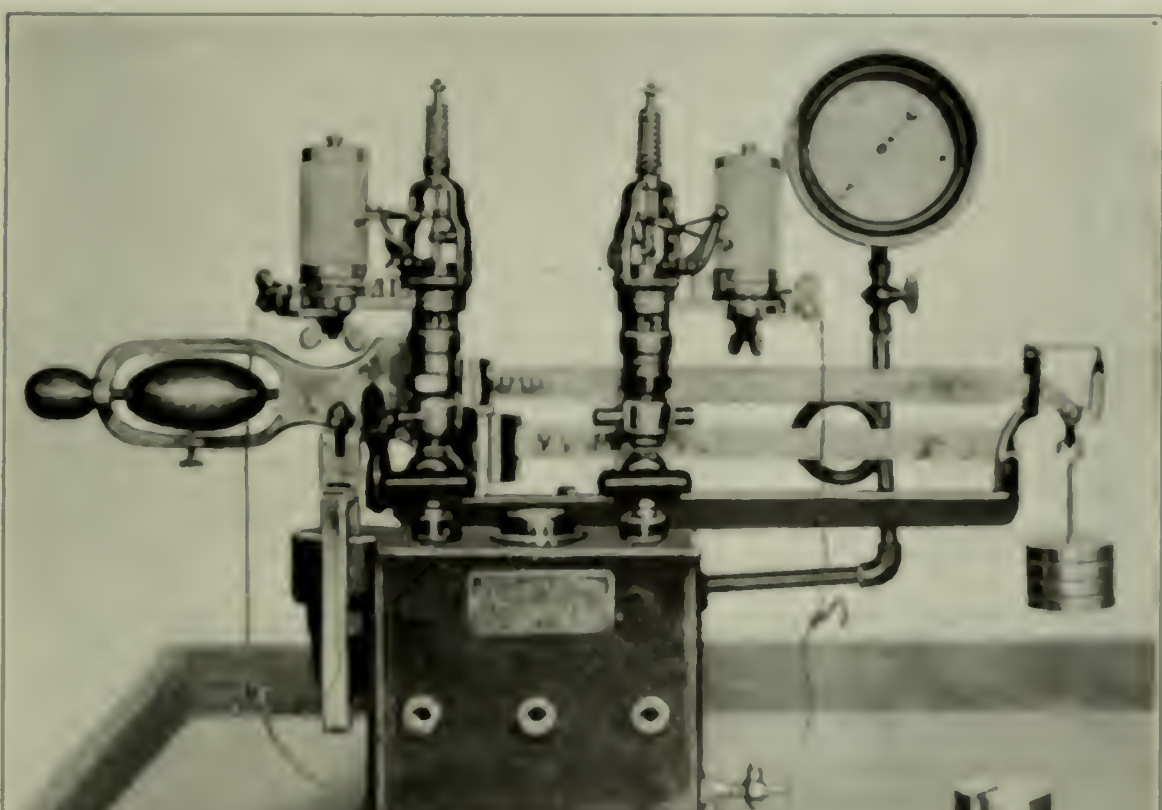

Fig. 1. Indicator Spring Tester

In testing indicator springs, steam is turned into the vessel to gradually warm it and is allowed to blow through the connections and indicator cocks to remove any particles of dust or grit which may have accumulated therein. Steam is then shut off and the indicator put in its place and paper put on the indicator drum, on which paper two vertical lines are ruled as shown at the lines *A B* and *C D* in Fig. 2.

The indicator pencil is pressed against the drum and a horizontal line *Q Q* drawn at the point thus marked. The poise of the scale is set at say 5 pounds, and steam is admitted to the vessel, gradually rising in pressure until the scale floats. When the pressure is exact, the line *R R* is drawn, and so on for successive pressures of 5 pounds until the limit of the scale is reached. During this operation the motion of the indicator pencil is continuously kept upward and if at any moment the pressure rises too high it is lowered by manipulating the valve below the required amount and then gradually raised to the desired point.

When the indicator pencil has reached its highest position the steam pressure is allowed to fall gradually and a series of similar lines, as *W W*, *X X*, *Y Y* and *Z Z*, are drawn during the descent of the piston, the motion being continuously downward. The distance between any two of these lines, as *Z R*, *Y S*, indicates the loss due to the friction of the indicator.

This testing apparatus also serves for testing pressure gages which can be connected to the three openings in the front side of the vessel provided for that purpose. The readings are verified by the indications on the scales and the test gage shown in Fig. 1.

Fig. 2. Lines Showing Loss Due to Friction

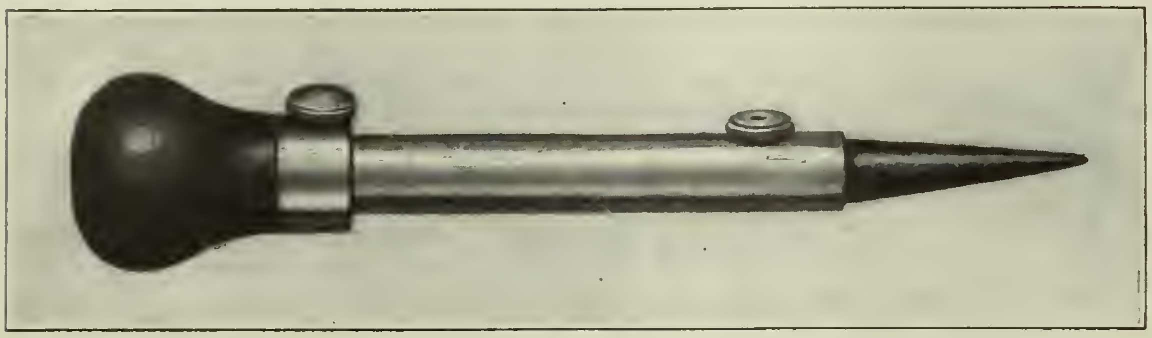
Belt Lace and Leather Cutting Tool

This tool is 7 inches long and has a body ½ inch in diameter. It consists of an adjustable knife blade for cutting belts and belt lacing. On one end of the body an adjustable gage can be attached for cutting lacing of various widths from rawhide skins.

The opposite end of the knife is made in the shape of a half-round reamer, pointed at the outer end. This serves the purpose of cutting about 40 different-sized holes in a belt and is extremely useful when lacing wide belts.

In starting a hole in a belt with the reamer, it is turned to the right and left with a gradual pressure exerted on the handle until the reamer has been pushed through the belt. Then a full turn is made until the desired size of hole is obtained.

The reamer or knife can be used by reversing the detachable handle, which is held in place by a thumb screw. This device is manufactured by the Kane & Christie Manufacturing Company, 118 Greene street, New York City.



Belt Lace and Leather-cutting Tool

"Model B" Rochester Lubricator

This force-feed lubricator is built substantially the same as the standard Rochester lubricator, the difference being in the arrangement of the driving gear. The stock size of the "Model B" lubricator holds three pints but other sizes having capacities of from ½ pint to 2 gallons can be furnished. It is designed for high-speed engines running from 200 up to 400 revolutions per minute.

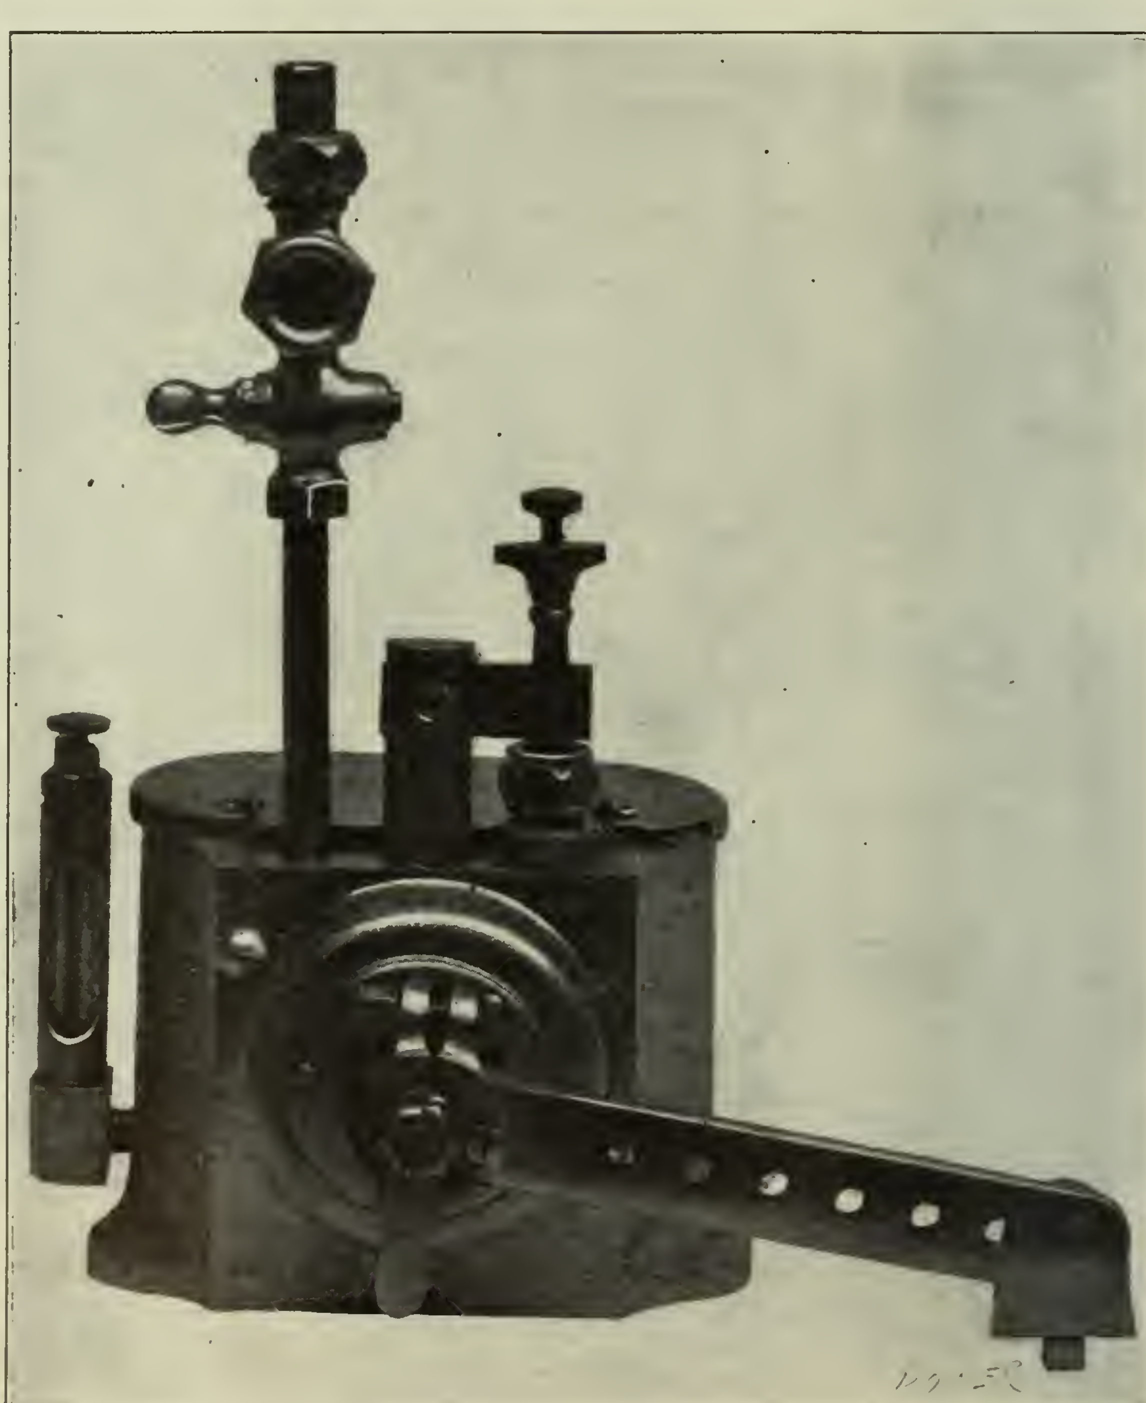
The oil reservoir is fitted with a gage glass to indicate the hight of the oil, which is drawn from the main reservoir and forced to the steam pipe leading to the engine by means of a small plunger pump that is actuated by an arm attached to a vertical shaft. This shaft receives its motion from a cam that is driven by means of two hardened-steel ratchet wheels, which are cammed together and cammed apart by the action of the actuating arm. These ratchet wheels operate a series of cog wheels which in turn operate the main shaft of the lubricator.

By means of these cog wheels the outside ratchet gear revolves 10 times to one revolution of the cam driving the pump plunger. This feature makes the lubricator capable of doing good work on high-speed engines. A special advantage is that the reduction of wear and tear in the lubricator is greatly reduced over what it would be with the standard arrangement, operating at high speed.

The driving mechanism is inclosed in a dust-proof steel cover. The motion to the ratchet gears is obtained from the lever which is connected to a reciprocating part of the engine.

There are three methods of adjusting the amount of oil fed to the engine. One is by changing the position of the adjusting arm, which is made by loosening the bolt in the actuating arm and moving the arm to the right or left as desired. This causes more or less lost motion between the cam on the lever and the ratchet gear; therefore the teeth of the ratchet wheels are engaged for a greater or less portion of the stroke.

Another adjustment is accomplished by a screw in the top of the plunger, shown in the accompanying illustration, and a third adjustment is made by changing the position of the rod connection on the actuating arm, for which purpose holes are provided.



View of "Model B" Rochester Lubricator

By changing the inner ratchet wheel and substituting one that is not filled with cog gears a "Type A" lubricator can be had, the difference between the two types being that the plunger of the latter makes one stroke for each revolution of the ratchet gear. In other respects the "Model A" is identically the same as that of the "Model B" lubricator.

These lubricators are manufactured by Greene, Tweed & Co., 109 Duane street, New York City.

The H. and B. Steam Drier

The H. and B. steam drier, manufactured by Edward C. Garratt & Co., 25 South Clinton street, Chicago, Ill., is designed to separate excessive moisture from steam before it leaves the boiler, and the water, thus separated, remains in the boiler and permits the steam to pass into the steam piping in a dry state.

The accompanying diagram, Fig. 1, is a partial sectional view of this steam drier, as installed in the dome of a boiler; it is placed directly under the main stop-valve connection, where the steam must pass through it when leaving the boiler.

Steam passes through the drier as follows: Entering at the top, it travels

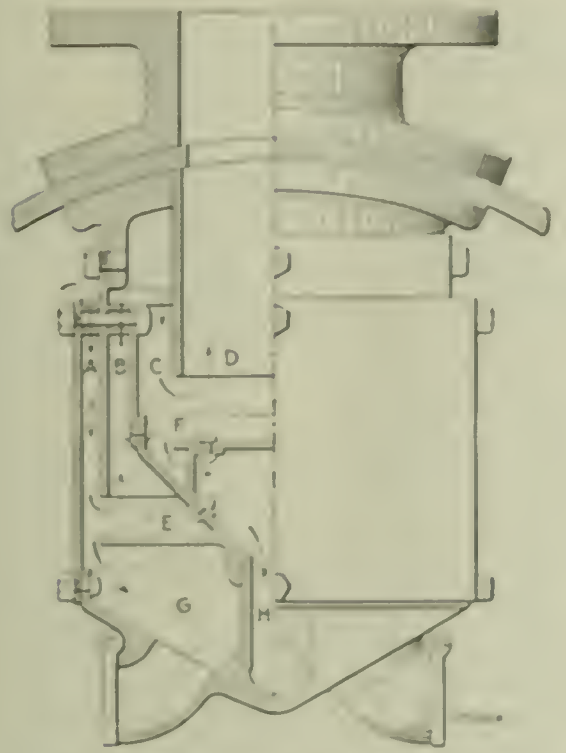


FIG. 1. SECTIONAL VIEW OF DRIER

downward through the passage *A*, as shown by the arrow, traveling at the same velocity as it rises, thus separating some of the excessive water that has been

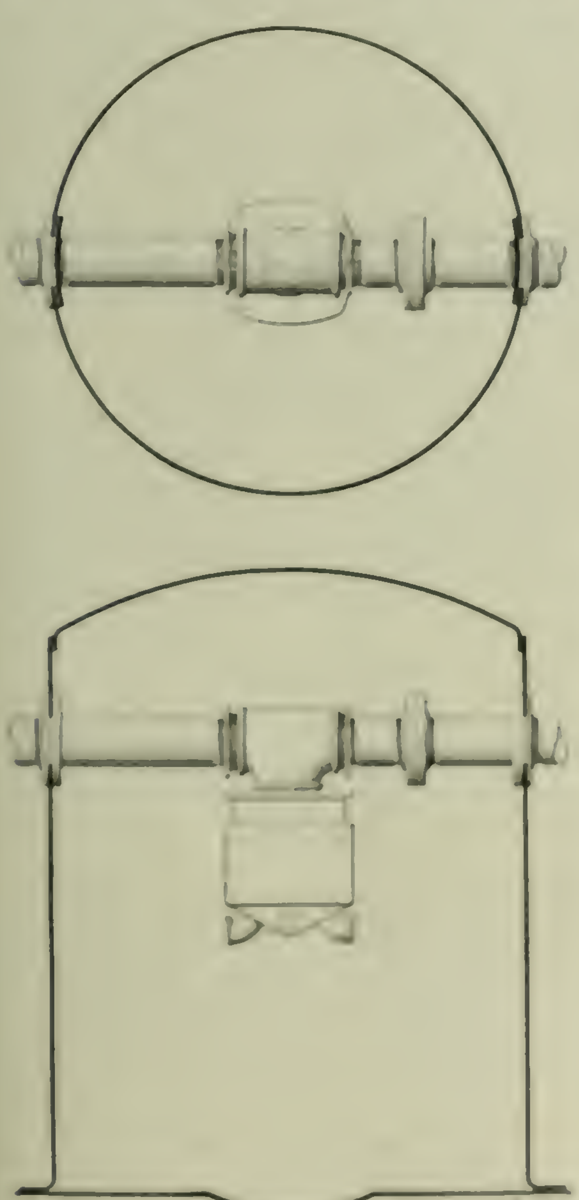

FIG. 2. DRIER CONNECTED TO STEAM PIPE

drawn in by the steam and throwing it under the baffle plate *E* causes it to return to the water level through the drains *G*. The steam passes through a similar process at *C* and *D* and baffle plate *F*, where any moisture that might have passed *E* is expelled through the smaller drain *H*.

The manner of installation varies according to the design or type of boiler.

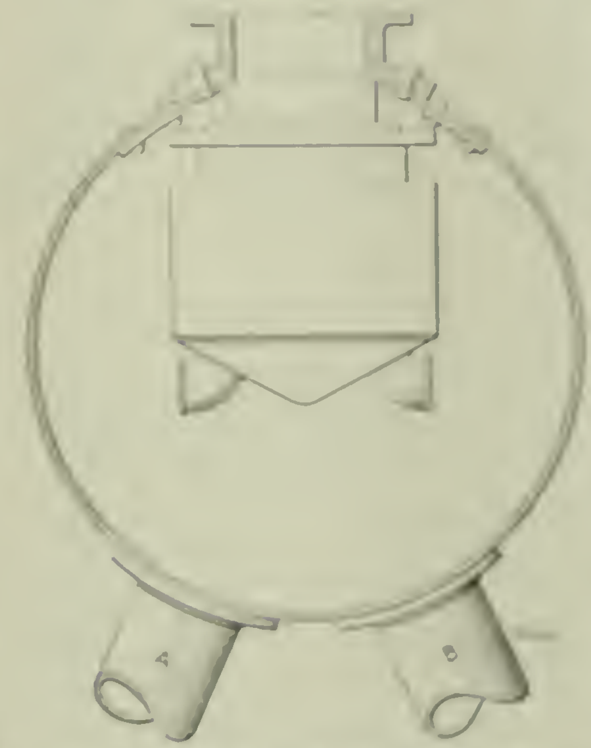

FIG. 3. DRIER PLACED IN A RECEIVER

In some cases the drier is connected direct to the piping, as shown in Fig. 2, and all of the steam used from the boiler, either to the main engine or auxiliaries, passes through the drier.

Fig. 3 shows a drier installed in a drum that acts as a common receiver for two boilers and takes care of the moisture in the steam passing through the two supply pipes *A* and *B* from the boiler.

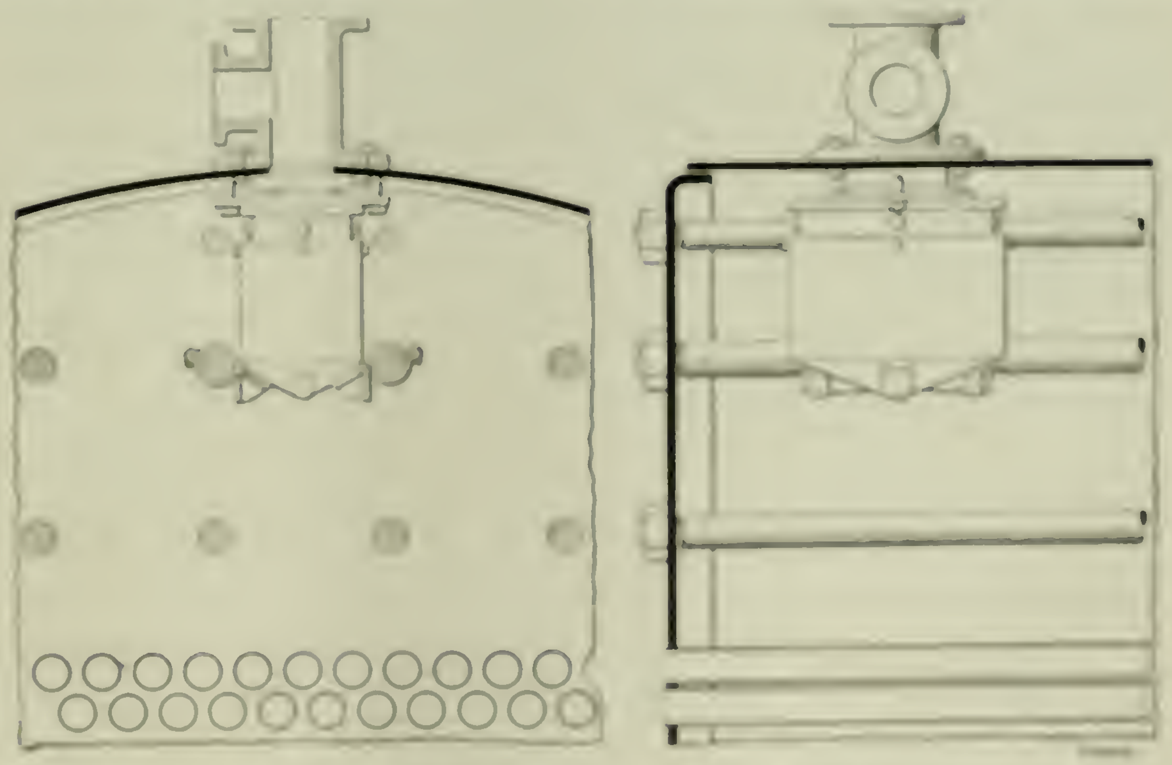

FIG. 4. DRIER INSTALLED IN SCOTCH BOILER

Fig. 4 shows the drier installed in a Scotch marine boiler. In case the longitudinal stays in the boiler are close together, the drier can be built oblong in shape to get the required areas; sufficient areas are always allowed, in the various steam passages of the drier, to prevent the steam from being wiredrawn.

Atlantic Mills at Providence Enlarge Plant

With the object of concentrating their power plant and eventually operating all their machinery by electricity, the Atlantic Mills of Providence, R. I., have just completed a large addition to their boiler house. Eight new boilers, 200 horsepower each, of the Manning type, built by the Dillon Steam Boiler Company, of Fitchburg, Mass., have been installed within the past year, four being used for the first time two weeks ago, and it is planned to add eight more, with an additional turbine. The scheme is to derive power from two turbines, one condensing and the other noncondensing, using the exhaust steam from the noncondensing unit for heating and manufacturing purposes.

The company believes that by centralizing the plant and using turbines they will save money and labor, occupy less space and also save exhaust steam.

At present the mills are being operated from three power houses, one containing a 1500-horsepower Corliss cross-compound engine with a 32-foot gear driving the jack shaft instead of belting. This engine is run by seven boilers of 200 horsepower each. In the second there are two belt-driven generators of 800 and 350 kilovolt-amperes capacity. In the station where all the units are to be assembled, there is a 1500-kilovolt-ampere Westinghouse Parsons noncondensing turbine.

A new 175-foot radial-brick chimney, built by the M. W. Kellogg Company, of New York, has been erected to serve the additional boilers.

Boiler Explosion at Mt. Washington, Kentucky

One person was instantly killed and four others were hurt, two probably fatally, when a boiler of a traction engine operating the sawmill of Brumley & Jones exploded on Thursday, April 6, at 10:15 a.m.

The accident occurred in the woods, on the farm of John Cornell, on Drake branch a mile below Whitfield in Bullitt county. The explosion was heard for miles around and caused much excitement. The injured members of the party summoned assistance from the nearest farm houses and physicians hastened to the scene. The young man who was killed was standing beside the engine, of which his brother, who was the engineer, had charge, when the boiler let go. His body was literally torn to pieces.

The engineer was scalded about the face and internally injured. It is feared that his eyesight will be permanently effected.

A laborer employed in carrying lumber from the mill was frightfully scalded and it is thought that his injuries will prove fatal.

The boiler let go without the slightest warning and caught the crew entirely unaware of the impending danger. Pieces of the wreck were picked up hundreds of yards from where the accident occurred. It is said that the engine was comparatively new and the cause of the explosion remains unexplained.

Joint Meeting of Machinery Dealers and Manufacturers

With an attendance of nearly 600 the annual triple convention of the Southern and National Supply and Machinery Dealers' Associations and the American Supply and Machinery Manufacturers' Association was held at the Seelbach hotel, Louisville, Ky., April 3, 4 and 5.

Opening addresses were made by Gov. Augustus E. Willson, William Heyburn and Pendleton C. Beckley upon behalf of Kentucky and Louisville, while Edward C. Hinman, W. M. Patterson and S. P. Browning responded for the associations.

Executive sessions occupied most of the daylight hours, during which were discussed important matters connected with the business end of the various manufacturing establishments represented.

Entertainment of the most hospitable kind was not lacking and all the visitors will be heartily in favor of Louisville as the scene of another annual convention in the not far distant future.

On Thursday the convention left in a body for a visit to Mammoth Cave, this trip constituting one of the most enjoyable social features of the meeting.

Officers were elected as follows: For the American Supply and Manufacturers' Association, Willard Parker, president, Spring City, Penn.; N. A. Gladding, first vice-president, Indianapolis, Ind.; D. K. Swartwout, second vice-president, Cleveland, O.; C. H. Jenkins, third vice-president, Louisville, Ky.

Officers for the Southern Supply and Machinery Dealers' Association: W. P. Simpson, president, New Orleans; S. M. Price, first vice-president, Norfolk, Va.; I. F. Young, second vice-president, Birmingham, Ala.; Alvin M. Smith, secretary and treasurer, Richmond, Va., reëlected.

For the National Supply and Machinery Dealers' Association: W. L. Rogers, first vice-president, New York City; J. O. Herron, second vice-president, San Francisco; Thomas A. Fernly, secretary and treasurer, Philadelphia, Penn.

Representatives of Norfolk, Va.; Asheville, N. C.; Dallas, Tex., and other cities presented invitations for the joint triple convention to meet with them next year. Complimentary references were made to all of these cities. The selection of a meeting place, however, will not come up until later. Asheville seems to have a shade the better of the argument, judging by the expression of the delegates.

PERSONAL

Frank T. Clarke, M. E., who has been located at Los Angeles, Cal., has opened an office as consulting engineer at Honolulu.

C. M. French has been transferred from the Deane Steam Pump Company, at Holyoke, Mass., to the Cleveland office of the International Steam Pump Company.

C. H. Pearson, formerly with the Noera Manufacturing Company, of Waterbury, Conn., has accepted a position in the hoist department of the Yale & Towne Manufacturing Company. Mr. Pearson's field of operation will be in the West.

On Monday evening, April 4, twenty-five of the officers and members of Colorado No. 1, National Association of Stationary Engineers, tendered James Merrick a surprise and farewell banquet in the Albany hotel in Denver. Mr. Merrick has filled practically every office in the association during the last five years with credit to himself and honor to the fraternity. He was this year filling the office of vice-president of No. 1, which he has resigned, as well as his position as chief engineer of the Denver Gas and Electric building, to accept a position on the sales force of the Dearborn Drug and Chemical Company, taking charge of the Salt Lake City office.

OBITUARY

James C. Bradford, who built the boiler for the "Monitor" during the Civil War, and who has been engaged in other lines of the business since that time, died at his home in West Medford, Mass., on April 10. He was 82 years old. Mr. Bradford was in charge of the Rhode Island Locomotive Company's plant for several years and was master mechanic of the Providence-Springfield Railroad Company during the period of its building.

He was a direct descendant of Governor Bradford, who came over in the "Mayflower" and headed the Plymouth colony. He was born in Taunton, where he received his education. He learned the machinists' trade in Boston in the Old Colony Railroad shops. He left this company to take charge of the building and development of the Fairhaven-Boston Railroad.

Just prior to the Civil War he started a boiler business in New Bedford, Mass., and continued in it for nearly 15 years. While there he built the boiler that was used in the "cheesebox on a raft"—the "Monitor"—and did much other Government work during the war. From New Bedford he went to Providence, R. I., to take charge of the Rhode Island Locomotive Company's plant, and remained there until he took a position as master mechanic of the Providence-Springfield railroad, which was absorbed by the New York, New Haven & Hartford Company.

SOCIETY NOTES

The eighteenth annual convention of the Oil Mill Superintendents Association will convene in Galveston, Tex., May 25, 26 and 27.

At Philadelphia on April 22 a meeting of the American Society of Mechanical Engineers will be held at the Engineers' Club. The subject for discussion will be "The Recent Work of the United States Fuel Testing Plant."

On April 21 the Boston sections of the American Society of Mechanical Engineers and the American Institute of Electrical Engineers and the Boston Society of Civil Engineers will hold a joint meeting at which a paper will be presented by B. R. T. Collins, with the Stone & Webster Corporation, Boston, on "Oil Fuel for Steam Boilers." The paper deals with the possible use of oil fuel for steam-generating purposes in the Atlantic coast States, its safety and permanency of supply, as well as conditions under which it may have special advantages over coal.

POWER

NEW YORK, APRIL 25, 1911

THERE is probably more attention, intelligent and otherwise, being given to the boiler room of the modern power plant today than to any other one department.

In the production of power the cost of the fuel is in most cases the largest single item in the expense account, and any percentage of reduction in this means more than an equivalent saving made in any other way.

Power plants are operated for the profit there is in the business, and any plan or suggestion that seems to point toward a possibility of increase in profits will be given more or less consideration by the man or men most directly interested.

It, however, seems strange that men who use good business judgment in every other department of their business are so indifferent to the results obtained in the burning of fuel.

In chemical industries certain materials are changed from one form to another. Measured quantities of different substances are mixed or treated with known weights or measures of still other materials for the purpose of enhancing their value to mankind. The results are accurately observed and any departure from uniformity is made the subject of special investigation.

Untrained and careless men are not given responsible positions in such industries because it does not pay to employ men who are potentially wasteful. The product costs money and carelessness or ignorance on the part of one man may possibly waste the wages of many in inferior product or restricted production.

The burning of coal, wood, gas, oil or any other fuel in a boiler furnace is a chemical process on a commercial scale. It is industrial chemistry.

Air, carbon and hydrocarbons are mixed and the product goes up the chimney. But the fact that the product is wasted and that the provisions for wasting the product mean an investment does not lessen the importance of knowing the ratios of the elements in this waste to each other, nor the value of the ability to keep this ratio constant and at its best.

Too much air cools the furnace; too little wastes the fuel by poor combustion; too thick a fire restricts the draft and hinders combustion, and too thin a fire may have holes and will pass too much air anyway.

What is wanted is such a mixture of air and burning fuel that the highest possible percentage of carbonic acid gas will be held in the gases which go up the chimney.

Expert firemen are industrial chemists of no small degree of skill, and the plant manager who fails to recognize this and secure the best in preference to ordinary unskilled labor, whatever may be the difference in labor market rates, is standing in his own light.

What is wasted by an untrained, careless fireman will, if saved, in most plants more than pay the wages of the highest priced man about the establishment.

The Coal Problem Analyzed

By A. Bement

In which attention is given to the proper usage of significant coal terms, the analysis of coal, its size, the ash content, and features over which the producer has control. A number of illustrations of trouble frequently met with in the burning of coal are also given.

Under this title an attempt will be made to discuss certain features of coal and its utilization, and it is believed that the following may be of assistance toward a better understanding of a difficult and complicated problem.

Attention will be first directed to the matter of definition of words and terms, as there is no agreement in the use of them, neither is there a sufficient accepted vocabulary to enable one to give clear and definite expression to his meanings. This leads to various people using the same word or term in a variety of ways and for the purpose of indicating things of different character. Therefore, in the following, attention is directed to certain terms which have special significance.

Terms of Special Significance

Coal: There is no definite agreement as to what is implied by the use of this word, whether it refers to the coal itself or to the fuel mixture. According to the best defined meaning, coal is a solid fuel and it is something which enters combustion and produces heat. Therefore, none of its components can be ash or moisture, because neither of these take part in the combustion process nor do they develop heat. It therefore follows that coal is that part of the fuel minus ash and moisture, sometimes known as ash- and moisture-free coal, for which the term pure coal has been devised. Thus the first equation of Table 1 illustrates the

TABLE 1. ULTIMATE COMPOSITION OF COAL.

Pure coal = (Carbon, Hydrogen, Sulphur) + (Water of Combination, Nitrogen).
Dry Coal = Pure Coal + Ash.
Moist Coal = Dry Coal + Moisture.

composition of coal proper, in other words, pure coal, and the second and third portions show the dry and moist fuel mixtures. It is, of course, true that only carbon, hydrogen and sulphur take part in the combustion process developing heat, so it might appear that water of combination and nitrogen are not constituents of the coal. But there should be no conception of coal, strictly speaking, other than in its chemical aggregate, thus nitrogen and water of combination cannot be considered independent from the coal without implying a destruction of its chemical aggregate. The view that coal fuel is composed of an aggregate of coal, ash and moisture is a definite one, having undisputed application in practice, for it is known that the moisture is immediately evaporated from the mixture because this fact is observed in the laboratory. It is also a fact that the ash is found on the fire grate or in the ashpit after the coal has been burned. Therefore, it is desirable to consider that coal, according to a strict definition, is that portion of the fuel which is neither moisture nor ash. Thus, it is well, in making use of the word coal to avoid misapplication. In certain instances it must necessarily be used to a great extent as a general term, but when a specific statement is involved it is desirable to adopt a more exact definition. The matter is further illustrated by Table 2.

TABLE 2. PROXIMATE COMPOSITION OF COAL.

Pure Coal = Combustible Elements + Noncombustible Elements.
Dry Coal = Pure Coal + Mineral Matter.
Moist Coal = Dry Coal + Water.

Pure Coal: This is a convenient term which has been quite extensively used to denote that portion of the fuel mixture which is coal, as discussed above. It means the same thing as ash- and moisture-free, but is a more convenient expression.

Fuel Mixture: By this is meant the aggregation of coal, ash and moisture. The acceptance of such a definition is desirable because it tends to avoid confusion and misunderstanding. For illustration, assume that two different lots of fuel are derived from a single coal seam, from the same coal mine, if you will. One is carefully prepared, low in ash; it may be referred to as good coal. Another lot, high in ash and dirty, will be referred to as bad coal, when, as a matter of fact, the coal in each case is absolutely the same. The trouble is entirely apart from the coal and one which concerns the fuel mixture. Yet, the impression conveyed is that the coal itself is of poor quality, not realizing that the trouble is with the larger amount of ash which makes an unsatisfactory fuel mixture. The equations of Table 3 serve to illustrate this feature.

Clean Coal: Properly prepared lump coal, for example, consisting of fuel in which there is no visible ash, or, in other words, consisting of clean, black pieces, accompanied by no slate or other dirt, is very often referred to as pure coal, the inference being that there are no visible impurities with it. This, however, is not a good definition, because ash, although not visible, is one of the components of the lumps. Therefore, the coal is not pure. It contains ash combined in the structure, notwithstanding the fact that it may not be accompanied by pieces of rock or slate. Thus, the expression, clean coal, is a more definite and exact one.

Dirty Coal: An expression often used to denote a fuel mixture containing a large amount of fine fuel, as "slack" or "duff." But is not accurate because these very small pieces of coal are coal to just the same extent as the larger pieces. This term should only be used as applying to a fuel mixture containing foreign matter such as rock, slate, fire clay, etc.

Size: Is, with some fuel, a feature which requires more recognition than it receives, because the size of the pieces have an important influence on the value of fuel coal, as will later appear.

Kind of Coal: This expression is often used with no definite application. The following examples will serve to suggest appropriate application: Anthracite, semi-anthracite, bituminous, semi-bituminous, subbituminous, lignite, coking coal, gas coal, blacksmith's coal, gas-producer coal, pure coal, unit coal, dry coal and moist coal.

Grade of Coal: Thus, it appears from the foregoing that anthracite or bituminous, for example, are not grades, but kinds. The application of the term grade is shown by the following examples: Mine-run, lump, egg, range, nut, buck-

Dry Fuel Mixture = Coal + Ash.
Moist Fuel Mixture = Dry Fuel Mixture + Water.

wheat, raw screenings, slack, washed coal, washed screenings, washed slack and washed nut.

Interpretation of the Analysis

This is a feature of the coal problem in which there is confusion, not only of understanding but of expression. In the usual laboratory treatment, coal is considered as an unknown substance to be analyzed, and the results reported in the terms of the entire weight of the sample, in other words, in terms of the moist-fuel mixture. Thus, for example, a chemist may report the percentage of volatile matter as being less in one sample than in another, the inference being that the two samples, as far as the coal itself (the pure coal), is concerned, differ, when in fact the coal in each sample may be identical, the difference on the moist-coal basis being due to a greater or less percentage of ash or moisture in the fuel mixture. Thus for the quantitative analysis of the constituents of the pure coal, or, in other words, the real coal, to be comparable one with another, they should be stated on a pure-coal basis.

TABLE 4. CLASSIFICATION OF COMPONENT PARTS OF AN ASSUMED COAL FUEL MIXTURE

Combustible Elements in Coal		Noncombustible Constituents Chemically Combined with Coal		Noncombustible Constituents in a Physical Combination with Coal	
Carbon	61.0	Water of			
Hydrogen	3.[illegible]	composition	5.2	Moisture	12.0
Sulphur	3.0	Nitrogen	1.1	Ash	11.3
Totals	67.[illegible]		6.3		2[illegible].3

Combustibles	67.[illegible]
Chemical noncombustibles	6.3
Physical noncombustibles	2[illegible].3
Total	100.0

This reasoning applies to the ash constituent of the fuel mixture, because, if expressed on a moist-fuel basis, it will appear as a variable depending on the amount of moisture present. For this reason the amount of the dry, not the moist ash, is the significant quantity. Thus it is necessary to consider the object required. It is true, of course, that the proper measure of heating value of coal, as bought and sold in commerce, is expressed on a moist-coal basis, because it is the moist-coal fuel mixture that is bought and sold. No mine produces dry or pure coal. Ash and dirt, as well as moisture, always accompany it, but if it is desirable to know whether the ash content of one fuel mixture is greater or less than another, the values must be reduced to a dry-coal basis, and if desirable to make comparison between the coal of two or more fuel mixtures, heat value must be given in terms of the pure coal.

TABLE 5. RELATIVE COMPOSITION OF AN ASSUMED FUEL MIXTURE

Constituents	Chemical Symbol	Per Cent.	Character
Carbon	C	61.0	[illegible]
Hydrogen	H	3.4	[illegible]
Sulphur	S	3.0	[illegible]
Moisture	H_2O	12.0	[illegible]
Water of composition	H_2O	5.2	[illegible]
Nitrogen	N	1.1	[illegible]
Ash		11.3	[illegible]
Total		100.0	

In the application of the analytical data to the use of fuel in connection with its combustion, in fires under boilers, for example, it is an assistance to consider the matter from its actual relation to the process. In this connection, Tables 4, 5, 6 and 7, will be of service.

Table 4 presents the fuel mixture in three groups, illustrating the relation of the combustible and noncombustible elements. In Table 5 is shown a quantitative classification of constituents. Table 6 illustrates the combustion process and disposal of the products of combustion.

In applying analytical data to problems in practice, it is desirable to simplify the matter as much as possible. Thus in the foregoing, it appears that the entire hydrogen content is not treated as combustible, yet it is so given in the results of practically all ultimate analyses which have been reported up to the present time. But, according to our conception of the matter, oxygen must necessarily be chemically combined with some other element, and the assumption that this combination is with hydrogen, is the most reasonable one. Therefore, all of the oxygen of the coal is combined with hydrogen, as it must enter the combustion process as H_2O and leaves it in the same condition. For this reason, in calculating a heat balance, it is not only undesirable to consider this water as separate elements of hydrogen and oxygen, but doing so leads to confusion if the standard code for steam-boiler trials of

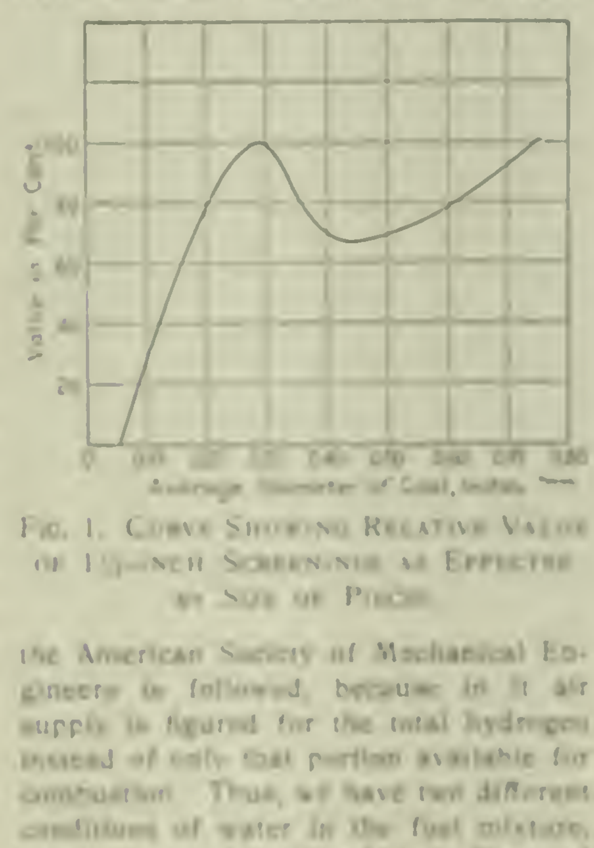

FIG. 1. CURVE SHOWING RELATIVE VALUE OF 1¼-INCH SCREENINGS AS AFFECTED BY SIZE OF PIECES

the American Society of Mechanical Engineers is followed, because in it air supply is figured for the total hydrogen instead of only that portion available for combustion. Thus, we have two different conditions of water in the fuel mixture, one in the coal itself, which is liberated by the combustion process, and the other in a free condition, which is dispelled as soon as the coal is heated and before combustion begins.

CONSIDERATION OF THE SIZE

To the present time fuel coal has been valued entirely upon the basis of its chemical analysis and price. It has, however, been observed that there are two other very significant features which may have even greater influence than that of chemical composition. One of these is size of the pieces, the other the ash content. For example, assuming that best coal fuel has a heat value of 15,000 B.t.u. and the poorest 9000, the ratios are as one is to 1.66. It has been found, however, that in practical conditions of operation, coal may be of so small size as to give a zero result in use, in other words, to have no value whatever, or again, of such large size, that the practical value of the fuel is largely reduced, yet the results of analyses might be the same in each instance.

This matter is illustrated by Fig. 1,

TABLE 6. COMBUSTION PROCESS

As Entering Combustion	Result of Combustion	Character and Disposal of Products
Carbon	CO_2	Gas to chimney
Hydrogen	H_2O	Steam to chimney
Sulphur	SO_2	Gas to chimney
Moisture (H_2O)	H_2O	Steam to chimney
Water of composition (H_2O)	H_2O	Steam to chimney
Nitrogen	N	Gas to chimney
Ash	Ash and clinker	Ash and clinker to the ashpit

showing the value of stoker fuel for steam boilers. It shows very plainly that the feature of size is one of great significance. An explanation for the formation of the curve is that, as the average diameter of the pieces increases, a point is reached at about 0.28 inch where the amount of dust and small pieces is just sufficient to properly fill the spaces between the larger pieces, after which time the decreasing percentage of small size causes enlargement of the vacant spaces in the fuel bed, with a result that the value decreases rapidly until at about size 0.43 where the average diameter of the pieces has become great enough to insure that in a measure they fit together in harmonious compact. As the average diameter still increases this condition develops, so that at size 0.75 it has again attained maximum value. In other words, the uniformity in size approaches that of nut coal, forming a desirable fuel bed, although if absolutely uniform, the fuel would have a much greater value than illustrated by the curve of the diagram, which is confined to 1¼-

TABLE 7. FORMS OF ULTIMATE ANALYSIS OF AN ASSUMED COMPOSITION

	As Usually Stated	As Proposed in Practice
Carbon	[illegible]	[illegible]
Hydrogen	[illegible]	
Available hydrogen		[illegible]
Oxygen	[illegible]	
Water of composition		[illegible]
Nitrogen	[illegible]	[illegible]
Sulphur	[illegible]	[illegible]
Total	100.00	100.00

inch screenings. The value assumed as 100 per cent. illustrates the best element from 1¼-inch screenings. Upon this basis it is apparent that factors may be devised by the use of which the value of fuel may be determined by calculation. For example, if the average diameter should be 0.10 inch, multiplying the heat value by 0.25 would give the actual value, or if the size is 0.30 inch, multiplying the heat value by 1 would leave it unchanged.

Variations in thickness of fire with lowchanical stokers is a matter which in itself has an important influence, and values such as those shown by the curve would be more or less modified by adjustment of the fire-bed thickness, or, should hand firing prevail, the result may be influenced through a wide range, by skilful hand manipulation. Thus, fine dust, which would not make a useful fire with a stoker, could be placed in a hand-operated fire, either by sprinkling it lightly over the surface or by allowing it to become coked and then broken up. The tests from which the curve is plotted were all made with one thickness of fire, and uniformity of conditions, except that of the fuel itself. Thus the foregoing shows that the feature of size is of greatest significance as affecting value, especially so, if auxiliary influences, such as hand manipulation, are not employed.

Consideration of the Ash

According to the conception that coal fuel is composed of an aggregate of coal proper (pure coal), ash and moisture, it is found that the coal may differ in quality, due to a greater or less amount of water of combination, sulphur or nitro-

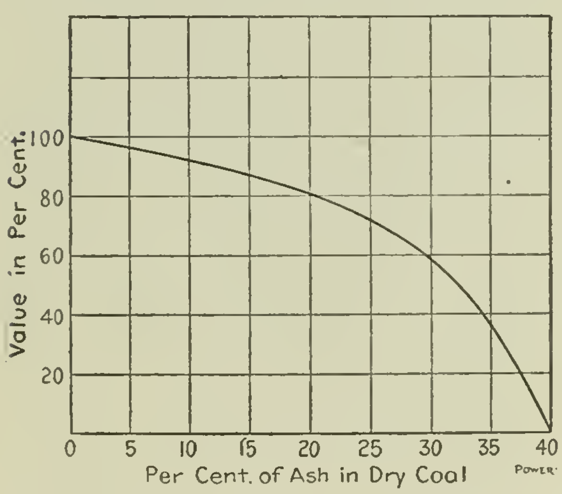

Fig. 2. Value of Coal as Effected by Ash Content

gen. These influence its heat value and in slight measure the loss of heat in the chimney gases, but do not affect or interfere with the combustion process. Neither does the presence of the moisture affect combustion except to cause a lower initial temperature and to increase loss in the escaping gases. Thus the water of combination and the moisture pass freely to the chimney and in no way obstruct action of the fire. With the ash, however, the case is quite different, as it remains as a solid residue, which does obstruct combustion to a very serious extent, as shown by Fig. 2, which, according to best present knowledge, illustrates the effect of ash content for any kind or grade of fuel. From this curve it is possible to devise a set of factors which will compensate for various ash content. Thus, if ash percentage is 20, multiplying the heat value by 0.79 determines the actual value.

A definite and clear conception of the ash with its relation to the fuel mixture is useful. To this end Table 8 gives ash content in three groups.

Referring to the first group, it is known that when a lump of clean black coal, having no visible evidence of ash associated with it, is burned, a residue al-

TABLE 8. ASH GROUPS IN COAL FUEL.

1. Ash in the coal itself.
2. Ash in the coal seam distinct from that in the clean coal.
3. Ash associated with the fuel which becomes mixed with it during mining, but not derived from the seam.

ways remains. This is the ash in the clean coal. In all coal seams distinct stratas of rock, slate, pyrites, etc., prevail to a greater or less extent, as well as impurities, in other than stratified form. These impurities of the seam are distinct from the impurities actually associated with the coal itself. In addition to the impurities of the second division, there are others which emanate from a source entirely outside of and distinct from the seam, such as from the roof and floor of the mine, in the form of fire clay, rock, etc., the matter being further illustrated by the equations of Table 9.

It will be observed in the foregoing that ash is considered as being only the residue remaining after combustion. It is a fact that certain ingredients of the ash mixture, such as fire clay, for example, contain volatile components, as water of combination. Thus, the true ash is the residual quantity, plus the volatile amount. This is true as far as it affects the displacement of pure coal in the fuel mixture. It, however, has no application in practice because it is the residue only which interferes with and affects the combustion process.

Upon the basis of values as displayed by Figs. 1 and 2, Table 10 has been prepared showing values in 1¼-inch coal screenings for maximum ranges of size and ash content. It is, however, not implied that 1¼-inch screenings may be as small as an average diameter of 0.06 inch, but the range has been carried thus far for purposes of illustration.

Relation of the Producer and Coal Users to the Problem

Within recent years it has become customary to purchase coal under specification, with an agreement as to quality, with bonus or penalty in case the fuel delivered is superior or inferior to the requirements. Many difficulties, however, have been encountered owing to the complications involved. Probably the matter may be illustrated by quoting what somebody is supposed to have said, "that it is not so bad to be ignorant, as it is to know so many things which are not true." This very aptly illustrates the position of the coal consumer. On the other hand there exists an equal lack of positive knowledge on the part of the coal producer and dealer. The relation of producer and consumer to the problem will be better understood when the manner is explained by which the producer may fail to furnish proper fuel. When the matter has been analyzed, it appears that the features over which the producer has control as affecting the quality of the fuel, are as follows:

Features over Which Coal Producer Has Control

1. Locality and seam from which the fuel is taken.
2. Size of the pieces of the fuel.
3. Amount of the ash content.

It may appear strange that the producers' power is so limited when many specifications give much prominence to volatile matter, sulphur, fixed carbon, heat value, etc. But when the matter is duly considered, the facts become apparent; for example, it is now well known that a particular coal seam or definite locality in a seam is of a constant and uniform quality, as far as the coal itself is concerned. Therefore, this being true, it follows that fixed carbon, volatile matter, sulphur or other components are constants and need only be determined once. It also follows that the composition would be the same from any mine.

TABLE 9. DETAIL GROUPING OF ASH CONTENT.

Group.	
No. 1.	= Ash in clean coal.
No. 2.	= Ash of group No. 1 + the distinct impurities derived from the seam.
No. 3.	= Ash of group No. 2 + dirt and rock.

Thus, if the coal is taken from the proper locality or seam, the requirements are automatically satisfied.

The size of the pieces in which the fuel is produced is a matter of great importance in certain coal districts. In others where only mine-run coal, owing to its friable nature, is produced, the consideration of size is entirely eliminated, as all of the fuel as hoisted out of the mine is loaded directly into railway cars. With the fuel, however, which is graded into various sizes, a more or less elaborate screening process is employed. Thus the producer has control over the sizes furnished.

The amount of ash content in the fuel is dependent largely upon the care exercised in mining, which consists in removing dirt and pieces of rock from the fuel mixture and in provision to prevent dirt becoming mixed with the coal. This is one of the important features of the preparation of fuel.

Other features which are often considered by coal consumers as something over which the producer has control, but which he really is unable to exercise any influence, are as follows:

Features over Which the Coal Producer Has No Control

(1) Moisture content, (2) heat value, (3) fixed carbon, (4) volatile matter, (5) sulphur, (6) evaporative perform-

ance secured in use of the fuel, (7) amount of smoke that may be produced, (8) suitability.

Referring to these features in detail, the moisture content, for example, is a constant of the coal seam and is the result of natural processes, extending over ages, during the time the coal was formed. The coal miner cannot afford to dry the coal by artificial means before shipment, neither would it be profitable as a general practice to add water to it, thus moisture is constant until changed by weather conditions, or time in transit. The heat value, fixed carbon, volatile matter and sulphur are likewise constants of the coal which cannot be changed. For illustration, it would be impracticable for a coal producer to make a change in the sulphur content. There is no method by which it may be reduced and it would not be profitable to add sulphur as an adulterant because it costs very much more than coal.

If a purchaser or consumer should demand coal from a prescribed locality, specifying heat value of the fuel mixture, and the heat value of the coal delivered did not meet the specifications, it would either be caused by excessive ash content, substitution from some other locality, or that the specification of heat value did not apply. It would not be because the producer did anything to alter the heat value and the same is true of any constituent of the pure coal.

The matter of the amount of water which may be evaporated when coal is burned under boilers is a matter around which more confusion, trouble and uncertainty has centered than probably anything else. This is because there are so many factors having influence that it is impossible usually to know whether the result was due to the fuel, the character of manipulation it received, or to the efficiency of the steam-generating apparatus in which it was employed.

Under the heading of what is designated as suitability a large variety of demands are made regarding the performance of fuel which have no reasonable application, as will be shown in the following six examples of cases which have actually occurred. These cases are quoted as illustrating troubles as they often appear when the causes are not well understood.

Coal of Too Large Size in Hand Firing

An important power producer had successfully operated a down-draft type of furnace for a number of years, but one day some new coal was received with which it seemed impossible to maintain the usual steam pressures. When the trouble was investigated, the engineer stated that the coal "appeared to be all right but that there was no heat in it." Screenings were the fuel which had been regularly employed, but owing to an emergency, it was necessary to accept anything obtainable, which happened to be some very high-quality lump coal; in fact a very much superior fuel to that which had before been satisfactorily employed.

The trouble was that a sufficiently deep fuel bed was not maintained. With the screenings, being of a small size, a comparatively thin bed was sufficient to exclude excessive air supply. But with the lump coal, the fireman followed previous practice as to thickness of fuel bed, with a result that so much air flowed between the pieces of the burning coal that the heat generated was almost entirely expended in heating this air and for this reason there was very little left to make steam in the boilers, or, in other words, nearly all of the heat went up the chimney. This fact, however, not being realized, it was thought the trouble was due to some mysterious characteristic of the coal.

Thin Fuel Bed

Complaint in a certain instance was made of a high quality of washed nut coal being used on a mechanical stoker. The report was that the coal would not burn. The coal company supplying the fuel sent its trouble man to investigate. He returned with the statement that the coal looked all right; it was clean, bright and accurate as to size, but that it would not burn. He had watched the performance himself. The only explanation offered was that, for some unknown reason, the particular lot of coal was of such peculiar chemical quality that it could not be ignited. The fact was that the fuel bed on the stoker grate was too thin, allowing such a great excess of air to flow through, that the temperature was not high enough to ignite the incoming coal.

Coal of Too Large Size with Stokers

A large coal company had a case of serious trouble with an important customer. The question was one of quality of screenings. Two mines were involved, which may be designated as *A* and *B*. Mine *A* was located upon what may be called the Central Railway, while *B* was upon this railway and also connected with what may be designated as the Western Railway, both of which roads terminated in the city where the coal was used. It appears that shipments had been from mine *A*, but owing to lack of orders for lump coal on the Central Railway, this screening order was transferred to mine *B*, because there were lump-coal orders which could be shipped over the rails of what is called the Western Line. When this transfer was made, the customer immediately complained, claiming that the coal from mine *B* was of an inferior character and not at all suited to the purpose, which was steam production in boilers served with a certain type of stoker. These two mines were located about ten miles apart and operated in the same coal seam. As far as chemical analysis and physical conditions are concerned, the seam at both places is exactly the same, and from this standpoint it would be difficult to find, in the quality of the coal itself, the reason for the trouble. But the screenings from mine *A* had been delivered in steel cars, bearing the imprint of the Central Railway, while the coal shipped from mine *B* came in wooden cars, bearing the imprint of the Western Railway. This in itself was an apparent evidence to the purchaser that the coal was different, which belief was confirmed when it was placed in the stoker and failed to produce as good a fire as had the former screenings. The facts, however, were that mine *A* was equipped with a perforated screen having 1¼-inch round openings, while mine *B* had a bar screen, set somewhat farther apart; the size of the openings, instead of being limited by the width, were the full length of the screen. The result was that the screenings produced by *B* were of a considerably larger size than those produced at mine *A*, because larger pieces passed through the bar screen. In fact, from the standpoint of the coal business, it was a superior fuel, because the size was larger; also from an analytical standpoint, because owing to the presence of a greater percentage of large pieces, the ash content was lower.

TABLE 10. SHOWING VALUES OF 1¼-INCH COAL SCREENINGS AS AFFECTED BY AVERAGE DIAMETER OF THE PIECES AND VARIATION IN ASH CONTENT

Per Cent. of Ash in Dry Coal.

Average Diameter of Coal in Inches	4	6	8	10	12	14	16	18	20	22	24	26	28	30

0.50	0.67	0.66	0.64	0.63	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
0.55	0.71	0.69	0.68	0.67	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
0.60	0.76	0.74	0.73	0.72	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
0.65	0.81	0.80	0.78	0.77	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
0.70	0.89	0.87	0.86	0.85	[illegible]	[illegible]	[illegible]	0.75	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]
0.75	0.96	0.94	0.92	0.91	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]	[illegible]

It was in fact this superiority that caused the trouble. The coal was too large to form a sufficiently compact fuel bed on the stoker, with the result that an excessive quantity of air flowed through it, producing unsatisfactory combustion. The customer did not understand this feature, however, and attributed the trouble to some inherent quality of the coal itself, and believed that it was a fuel of an entirely different nature, something on the order of an anthracite rather than bituminous coal.

At this stage of the matter the customer was satisfied by screenings shipped from another mine, which operated in an entirely different coal seam, although producing fuel through a 1¼-inch shaker screen with round perforations. Thus, it appears an actual change in the quality of the coal itself, although slight, when accompanied by suitability in size, gave satisfaction.

Exceptional Example of Benefit from High Ash Content

A large coal user, in an experimental way, invaded a new field for its fuel supply and a number of tests under boilers were made. The screenings from a certain mine gave an unusually high efficiency compared with those obtained from other points in the same general locality. This fuel, however, was extremely high in ash, but it was felt, at the time, that the coal was especially suited to requirements, although the high ash content was considered an objection and an investigation was made to ascertain if "similar" coal containing a reasonable ash content could be found. The investigation showed that, while the fuel in question contained a very large amount of ash, it was not of a seriously fusible character, therefore did not make trouble by clinkering, and that the amount of ash was sufficient to close the opening at the back end of the furnace between the bridgewall and end of the stoker grates, thereby excluding a very large excess of air which had found entrance when other coal of much lower ash content had been burned. An investigation at the mine showed that the roof was of such nature that a large amount of dirt became, at times, mixed with the screenings, but that as far as the coal itself was concerned, it was not different from adjacent mines, but which, however, had a much stronger roof and for this reason produced screenings which had much less dirt mixed with them. This is an illustration of an exceptional instance where high ash produced a desirable result.

Bad Stoker Action

A steam-boiler plant served by a particularly faulty mechanical stoker, was the cause of much trouble and indifferent service. On one particular occasion, however, performance was unusually satisfactory and the manager decided that it was due to his having some special coal which was superior to that usually burned. He thereupon called up the coal company and asked where the coal was produced. He was given the town and the mine from which it was shipped. He therefore decided that it would be desirable to obtain coal in the future from this mine. The dealer, however, was unable to regularly supply it, but shipped from an adjoining mine only a few miles distant, operating in the same seam and whose source of coal was exactly the same as the other mine. The performance of the plant when it was burned, however, was not satisfactory. This led the manager to call up the coal dealer and complain of the fuel. He was told that it was from the same locality and that it should in every way give the same result as that from the mine which he considered satisfactory. But in an effort to please the customer, special pains were taken to obtain additional coal from the desired mine and a report as to its performance asked for. The statement of the operator of the plant was that it was no better than the previous shipments. He was then told that it was fuel from the mine which he wanted and which he had stated had given satisfaction before. Notwithstanding the explanation, the manager could not realize that the fuel was from the same place as that which he had considered to be suited to his requirements and felt that if the coal dealer would deliver him "the right kind of coal" he would have no trouble.

Example of Confusing Report from Employees

Coal dealer No. 1 supplied a certain size of washed coal by wagon to a customer. When the time of expiration of the contract approached, coal dealer No. 2, who was an important patron of the customer, solicited the business for the coming year for his company, with the result that the contract was awarded to him. Dealer No. 2 purchased coal, which was of the same size, from the same producer who had furnished it to dealer No. 1. He sent his teams to the same team track, loaded it out of cars of the same railway, or, in other words, furnished exactly the same product that dealer No. 1 had supplied and it would be reasonable to expect that the results and service would be identical, but the report received from the boiler room was that the fuel supplied by the new dealer was decidedly inferior in quality to that which had been received from the previous dealer, that a much larger quantity was required to do the same work and that the cost of furnace repairs had been increased owing to its use. The purchaser, of course, who could understand none of these things himself but who must depend upon the statement of others, laid the case before dealer No. 2 and explained to him that while he was very anxious to reciprocate in a business way, he expected to receive equally good fuel as that which had been delivered under the previous contract. Of course, fuel furnished by the two dealers was of precisely the same grade, quality and prepared by the same washer, but how could the customer be expected to believe it in the face of statements of his own employees?

It is not the intention in the foregoing to intimate that the coal dealer or producer always furnishes satisfactory fuel, or that he delivers what he should, but it is the purpose to show to what extent and in what way it may be possible for him to fail to meet the consumer's demands.

B.t.u. in Coal

By J. M. Leunam

Manufacturers have for many years known that the value of coal depends upon the heat units in a pound, or, as we say, British thermal units per pound, which is usually abbreviated to B.t.u. They have been much handicapped in not having a ready method of determining such units, being unwilling to employ chemists for this purpose, or to go to the expense of a coal calorimeter and its operation.

A coal agent suggested to me a happy rule for determining this. It is such a valuable rule that all readers of Power should be informed of it. It involves no intricate analytics, trigonometry or calculus, but simply the multiplication and division of numbers. The rule is as follows:

Divide the pounds of coal in a car by the railroad number of the car, and multiply the quotient by the price per ton. The final result is the heat units or B.t.u. per pound.

In this connection, it may be interesting to know that a green salesman for coal approached an engineer of a large company recently, with a view of securing his year's business. The engineer asked him how much sulphur the coal contained. The salesman was ready with his answer and said, "As low as 1 per cent." The engineer next asked him how much ash was in the coal. Again he was ready with his reply and stated that it had 5 or 6 per cent. The engineer next asked him how much fixed carbon was in the coal. That was a new term to the salesman, but he was going to carry his bluff and said, "From 15 to 20 per cent." The engineer next asked him how many B.t.u. were in the coal. The salesman was again ready with his reply and said, "Do you know we have tried time after time to find those pesky B.t.u. but we have never succeeded in locating one in our coal."

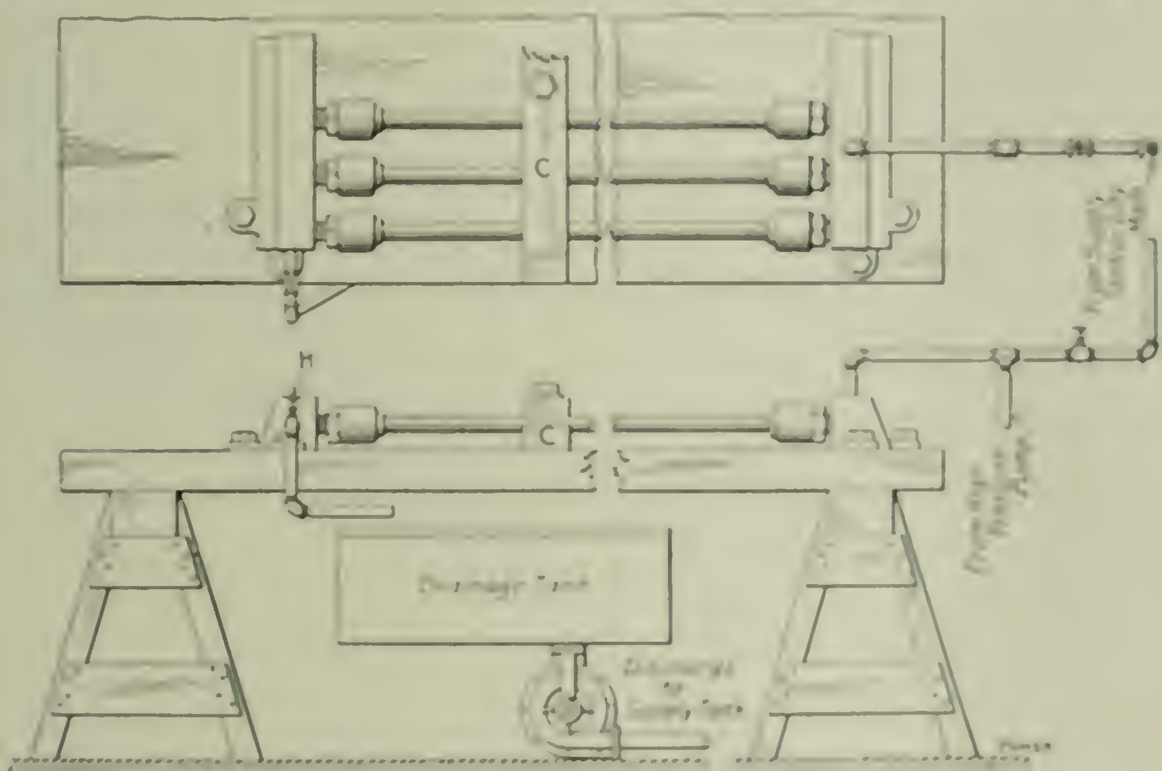
Reëxpanding Condenser Tubes

By Frank S. Bunker

Description of an apparatus designed to reëxpand old surface-condenser tubes and fit them for further use. Rigs for sawing the tubes and for hydrostatic testing.

In condenser tubes the most common defect is to have the ends crushed in by the packing. This not only causes a reduction in area of the tube, but also necessitates a large size of packing, which, as a rule, tends still further to crush the tube.

A rig which is used on the Pacific coast to roll the interior of the tube back to its original size is shown in Fig. 4. The rig was made by placing two small speed lathes tail to tail, with the headstocks in line. One lathe was bolted securely to the floor, and the other secured in slides which allowed the lathe to be moved to admit of longer or shorter tubes being handled.



Figs. 1 and 2. Top and Side Views of Apparatus for Testing Condenser Tubes

Block *A*, Fig. 4, is mounted on the shears of the lathe and securely held there on a proper fitting, in a central position. This block is of tool steel, hardened, and is hinged so that it will open and admit the tubes. The block is provided with a half-round groove in both top and bottom halves and, when the block is closed and locked, these grooves form a perfectly round hole the exact outside diameter of the tube when new.

A boilermaker's tube roller is used, only it is in miniature and made to roll the tubes to the proper inside diameter. With two boys, one at each lathe, the operation is simple.

Cutting Off

If the tubes are to be used in any but the original condenser from which they were removed, the length of tube required may be less, and the tubes must be shortened.

The rig shown in Fig. 5 is an excellent one for cutting them to the proper length. It is made with a column *A*, which is bolted to the table of a milling machine. The top of this column is cut out to receive the ends of the steel leaf spring on the end of which is a hinged clamp which is held open by a small steel-wire spring.

Fig. 3. Connection to Manifold

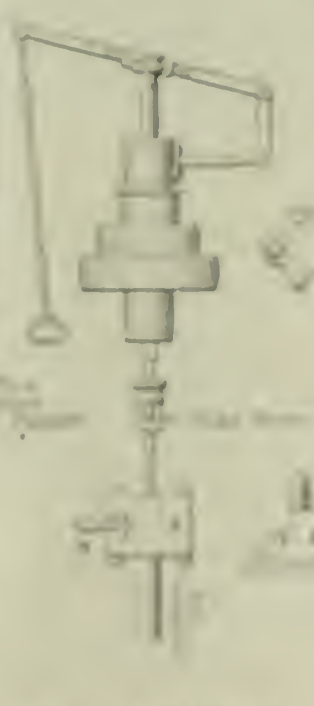


Fig. 4. Expanding Tube in Lathe

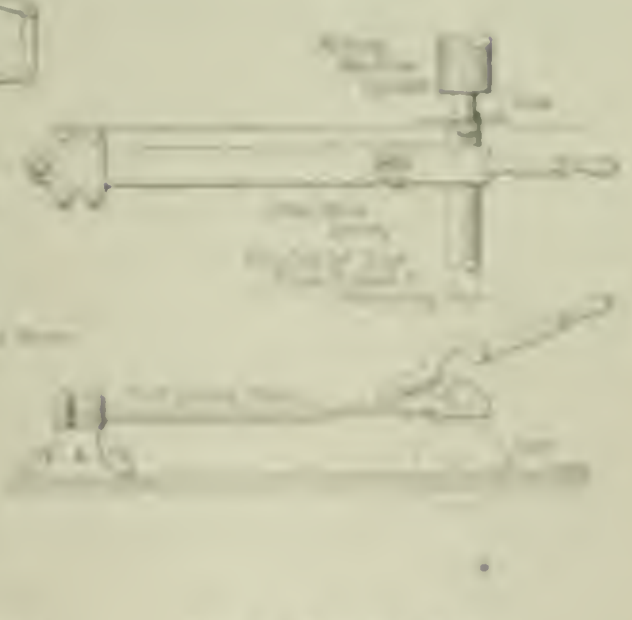

Fig. 5. Rig for Sawing Off Tubes

The tubes are backed against some conveniently arranged stop, and the end to be cut is rolled into the bottom half of the clamp. With a downward motion of the handle, the top of the clamp comes into contact with the tube, securely holding it and bringing it into contact with the saw. The burrs are removed with a cutter bar and small cutter mounted in an air drill which is held in a vise, the tubes being pushed against the cutter.

Testing

To make sure that the tubes are perfect the testing rig shown in Figs. 1, 2 and 3 is used. In the economical testing of small parts, such as tubes, etc., speed is the main object and it was with this in view that the rig was designed. It consists of two hollow manifolds of bronze, suitably designed to stand 1000 pounds per square inch hydrostatic pressure. One of the manifolds is mounted at the end of any suitable base, such as a long piece of boiler plate. The other manifold is mounted so as to be adjustable along the length of the base and thus permit the testing of various lengths. It must, however, be bolted securely to the base.

Fig. 3 shows the fitting which holds the tubes and forms a water-tight joint. This is made possible by the hydraulic cup leathers. The front end, or mouth of the fitting, is made bell shape to facilitate the adjusting of the tubes. One fitting is made like the sketch and the one which is to take the opposite end of the same tube is bored through on the dotted lines x y, x y.

To place a tube in the rig, simply shove it in through the bell mouth as far as it will go (see dotted lines showing extension of tube, Fig. 3). The other end of the tube should now be just clear of the bell-mouthed fitting in the manifold. Pull back and shove the tube into this fitting until it strikes the shoulder $x\,x$, and when tubes are in all of the fittings proceed with the test.

Owing to the tendency of the tubes to buckle, it is necessary to put on a restraining clamp, as shown at *C*, Figs. 1 and 2. This consists of a piece of timber grooved to let the tubes rest in it, and with another timber swiveling on a central bolt to swing over and clamp them down. For long tubes, two or more clamps of this nature may be necessary.

There is no restriction as to the number of bell-mouthed fittings to put in the manifold, as the more fittings the greater economy. By making the parts *A B*, Fig. 3, in one size for ¾-inch tubes, and another set for ⅝-inch tubes, the same manifolds will serve for the two sizes. When the apparatus is in use, be sure to leave valve *H*, Fig. 2, open until the tubes and manifolds are filled with water to the exclusion of all air; then close it.

An outfit of this kind is in use on the Pacific coast and is doing excellent work, saving a great deal of money. I hope someone else may find use for it, as it "delivers the goods."

The Patitz Steam Turbine

If the velocity of a body is doubled it will have four times the energy stored in it. If the velocity of a body is halved three quarters of its energy will be taken out. The inventor of this turbine, instead of getting up a low velocity and abstracting practically all of it in each stage gets up a high initial velocity, abstracts about one half of it, restores the initial high velocity by further expansion for the next stage, and gets out three times as much energy per stage as a turbine working on the lower half of the velocity range.

The energy required to get a weight W into motion at a velocity of V feet per second is $\frac{W V^2}{2g}$.

Taking g at 32.16 the energy in a pound weight would be approximately

$$E = 0.015\ V^2$$

The energy is thus seen to vary directly as the square of the velocity. A body one pound in weight having a velocity of 1000 feet per second has stored in it

$$0.015 \times 1000 \times 1000 = 15{,}000 \text{ foot-pounds}$$

of energy; but if it has a velocity of 2000 feet per second it has

$$0.015 \times 2000 \times 2000 = 60{,}000 \text{ foot-pounds}$$

To increase the velocity of a body 1000 feet per second starting from rest, then, takes some 15,000 foot-pounds; but to increase its velocity another 1000 feet starting from 1000 feet per second takes some 45,000 foot-pounds.

A turbine blade running at a certain speed will reduce the velocity of the jet passing through it a certain amount. Suppose this reduction to be 1000 feet per second. Then, if the jet enters the wheel at 2000 feet per second and leaves at 1000, the wheel will take out 45,000 foot-pounds of energy for each pound of steam passing, but if the reduction be from 1000 feet per second to rest, the same wheel at the same speed would take out only 15,000 foot-pounds.

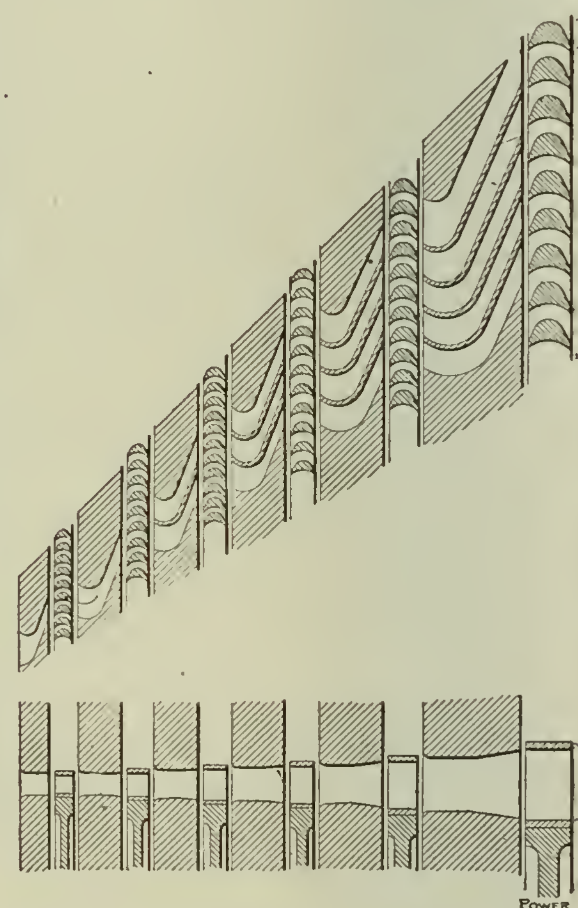

Fig. 2. Diagrammatic Sketch of Patitz Turbine

Based upon this fact, J. F. M. Patitz, of the Allis-Chalmers Company, has taken out a patent for a steam turbine in which the steam enters the first wheel at a comparatively high velocity. This velocity is only about one-half abstracted, however, by the runner, and the residual velocity is increased again to the maximum by further expansion before the steam acts upon the second wheel.

Fig. 1 represents diagrammatically an abstract case, the ordinates being velocities and the abscissas energy converted. Suppose the total energy derivable from a pound of steam flowing from the initial to the condenser pressure to be 240,000 foot-pounds, represented by the length of the line *O A*. Suppose that in a turbine of the multiple pressure-stage, single velocity-stage type, like the Rateau,

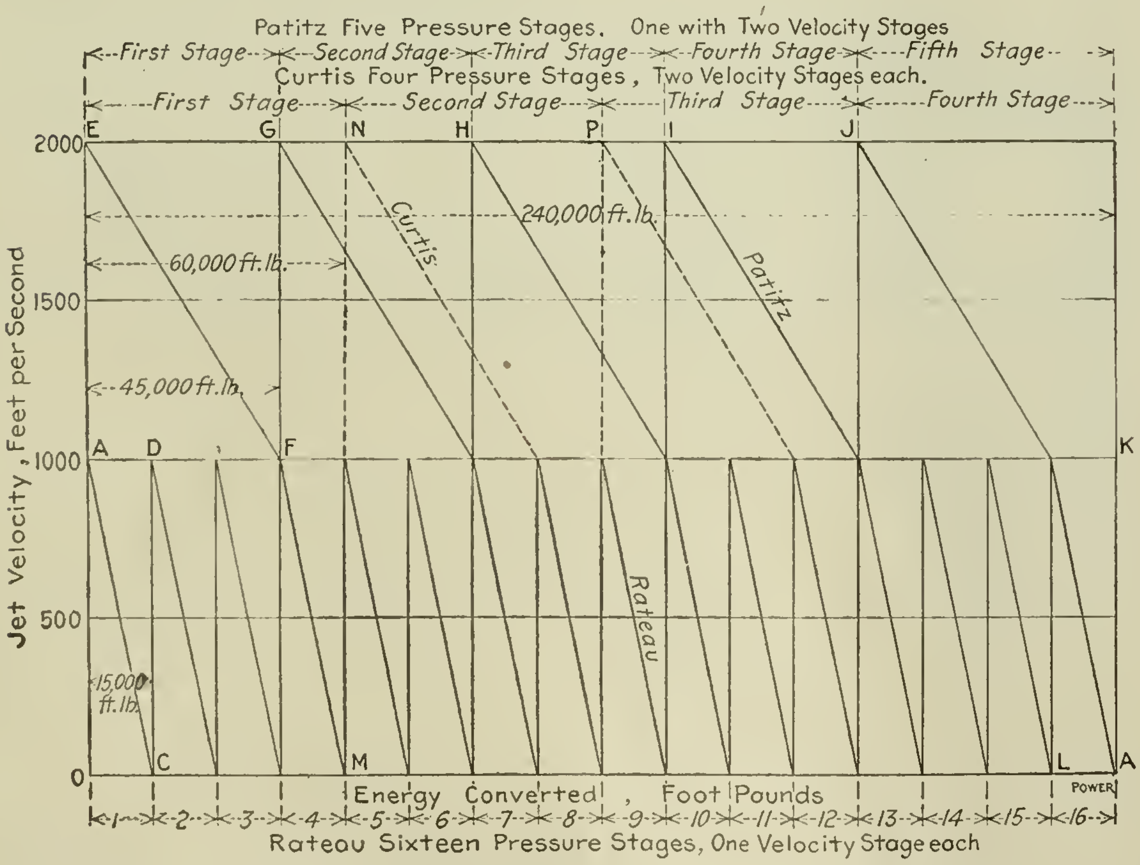

Fig. 1. Energy-Velocity Diagrams for Three Types of Turbines

the steam is expanded in the first stage sufficiently to give it a velocity of 1000 feet per second, represented by the line *O A*. Then a turbine wheel running at 500 feet per second (this takes no account of angle of entry, friction, etc.), would bring it to rest again, and convert into work the 15,000 foot-pounds of energy required to get up its velocity of 1000 feet per second. Its velocity would then be raised to 1000 feet per second again by expansion in the second set of nozzles, as represented by the line *C D*, and the process repeated until the 240,000 foot-pounds available had been all absorbed. This would, as the diagram shows, require 16 stages, absorbing 15,000 foot-pounds each, as

$$16 \times 15{,}000 = 240{,}000$$

If, however, the steam be sufficiently expanded in the first set of nozzles to give it a velocity of 2000 feet per second, represented by the line *O E*, a turbine running at 500 feet per second would reduce its velocity to 1000 feet per second and convert 45,000 (represented by the distance *A F*) of the 60,000 foot-pounds required to get up its initial velocity. If now its velocity is restored to 2000 feet by further expansion, as represented by *F G*, and the process is repeated it will be seen by the triangles whose apexes are at *E*, *G*, *H*, *I* and *J* that the process could be completed in five stages. Not completed exactly, for the steam would leave the last wheel with a velocity of 1000 feet, as shown at *K*, and it would be necessary to put in an additional low-velocity stage to reduce the velocity from *K* to *A* and rescue the last increment of energy *L A*; or to double blade the last wheel, as in the Curtis system, in which case the second blade upon the same wheel would take the steam at 1000 feet velocity, reversed in direction by a stationary blade between the two moving ones, and bring it to rest.

If the whole turbine were made in this way it would require but four stages, but with three times the amount of blading in each. In addition to the single blade of the Parsons wheel there would be the stationary reversing blade and the secondary running blade in each stage. A comparison of the three systems in this respect is shown in Fig. 3.

The course upon the diagram, Fig. 1, would be: generation of velocity to 2000 feet per second, *O E*; reduction of velocity to 1000 feet per second, *E F*; with the first running blade, reversal of direction by the stationary blade and reduction from 1000 feet per second to rest, *F M*, the absorption for the whole stage being 60,000 foot-pounds, *O M*. Expansion between the first and second stages would restore the velocity to 2000 feet per second, *M N*, and the process would be repeated, giving the four diagrams similar to *O E F M*, the apexes of which are at *E*, *N*, *P* and *T*.

This is, of course, simply an abstract discussion, the principal modification of which to make it apply in a comparison of the actual machines would result from the fact that some residual velocity is inevitable at all the wheels, which rather emphasizes the advantage of the new type. A disadvantage is that all the steam is used at high velocity, involving greater friction upon each blade, but there is a smaller number of blades subject to such friction.

The arrangement of the blades whereby the direction of flow is reversed and the residual velocity preserved and increased by further expansion is shown in Fig. 2, and a section of the turbine in Fig. 4, both reproduced from the patent drawings.

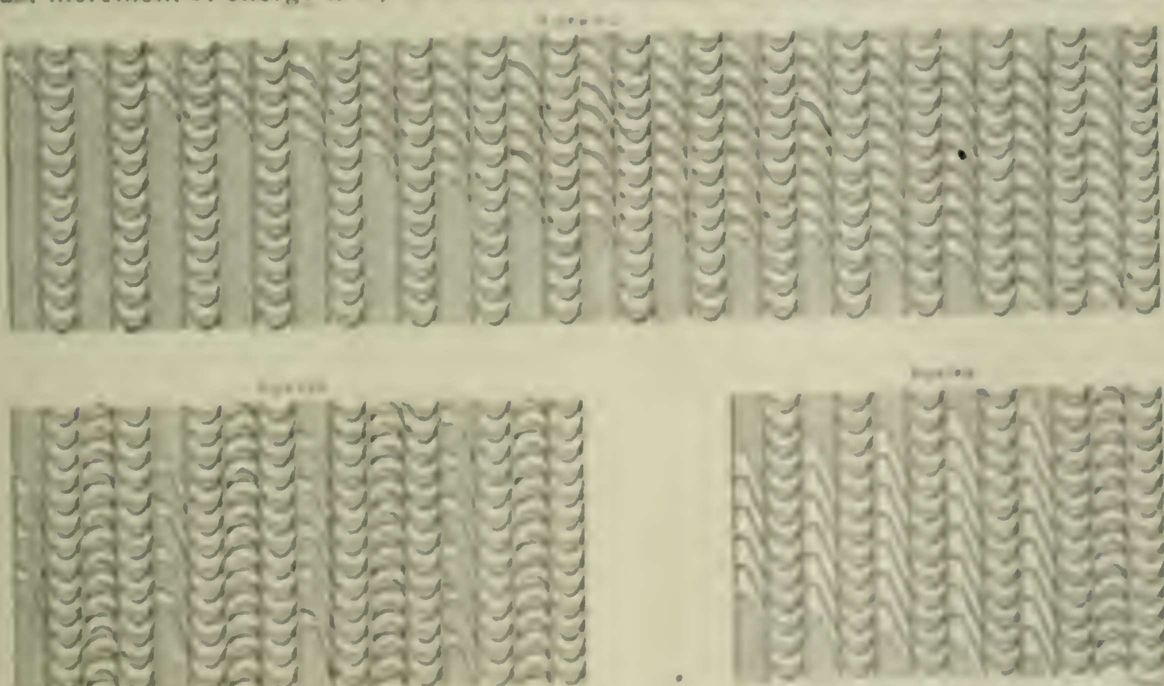

Fig. 3. A Comparison of the Three Types of Turbine

Why Smithy Didn't Get a Job

An erecting engineer was recently called upon to go to a steam plant in a city not many miles from Brooklyn, N. Y. Arriving at the plant he found that the running engineer had substituted a new throttle valve in place of the old one, but could not start the engine—why, he did not know.

The erecting engineer cast his eagle eye over the engine, and at once located the trouble, or rather troubles. The steam chest was cracked. The engine frame was broken and the crank rod was badly bent. Later he learned that the engine had received a dose of water the day before, and that the engineer, in his ignorance, blamed the throttle valve when the engine would not start, not knowing that the engine had sustained serious injury.

Some time later, as the erecting engineer was putting the finishing touches on a new installation, a voice addressed him saying, "What is the chance of a job governor?" When the erecting engineer turned to answer he beheld the engineer who had the throttle-valve trouble. Well, he did not get a job.

Uncle Pegleg on Force of Gravity

In which the old man tells, in his simple way, all about gravity and incidentally why Jim and the salt bag did not balance.

Fogchurn Hollow, Tenn., March 15, 1911.
Dear Uncle Pegleg:

I've bin readin' some of your talks with the kid in POWER (which hits the trail into this here lumber-chuck about as regular as the mail man) about ropes and pulleys and things. I want to ask you some questions about things in that line I can't understand.

'Bout three weeks ago I made a trip with anuther feller down the crick to town, to see the sights. Most of what we saw I don't remember very well, but early in the day we went around to the artifishul-ice plant to see how they made ice by machin'ry. and there we saw a sight I shan't forget so long's I live—though's I kum so pretty near dyin' o' laffin' right there I wuzn't so far from forgittin' that too.

They got a sizable engineer down to that plant, named Jim Taintor. My chum's father knowed him, and thet's how we kum to dare go round there and ask questions. Jim's got more fat to him th'n he has git-up-n-git. He don't ketch himself doin' 'n hour's labor thout he spends about half a day figgerin' out which is the easiest way to do it. Thet's how he come to do the vodeville act that near bust us up.

Ye see, they use a lot o' salt to thet plant, to make the ice—though Jim showed us as how they didn't use the salt to make the ice cold, 's they do in makin' ice cream, but only to make brine what wouldn't freeze. (Funny, I thought, to spend all thet money to make somp'n what wouldn't freeze, when the whole fact'ry was set up to make things freeze.) Howsmdever, they do use a lot o' salt, and it comes in big wagonloads o' sacks, and its Jim's job to get the sacks up into the storehouse loft above the "can room," as they call it.

Well, so Jim told us after he got cooled off some, them bags o' salt weigh about 180 pounds apiece. The only helper Jim's got, besides his fireman, who can't leave his fires, is a boy not big enough to do much pullin' on the rope. Besides, Jim needed him up in the loft, to untie the bags when they got up there. So he had to pull 'm up there himself, 'n they air heavy enough to most pull Jim off'n the ground—he weighs only about 200—at ev'ry heave.

So Jim got his thinker to work and figgered out 's how his legs were lots stronger 'n his arms—just 's sailors, he said, knows enough not to pull ropes down with their arms, but to jump up on it with their leg strength 'n then let their weight swing the rope down. So he'd first tie the rope to a sack o' salt on the ground, 'n then climb upstairs to the loft, ketch holt o' the rope out o' the door, 'n swing himself out on the rope. All he had to do was to hold on tight, 'n down he'd kum, just as easy, while the sack went up past him 'n stopped opp'sit the door when Jim stopped on the ground. Then the boy d' pull the sack in the door, untie the rop 'n Jim 'd be ready for another trip upstairs.

This went bully. But one day the salt man got a carload o' salt from a new place, 'n without sayin' anythin' to Jim about it he sent round a wagonload o' salt in sacks 'at weighed only about 120 pounds to the sack. Jim didn't notice no difference, 'n tied the first one on and clumb upstairs an' swung hisself out on the rope, expectin' ev'rything to work just 's it allus had. But it didn't work that way. Stead o' slidin' down easy to the ground he went away like a shot. The sack got such a yank thet it bumped Jim pretty hard on its way up, 'n bout time he wuz gettin' straight in his mind what had happened to him when the sack hit him, he found the ground had kum up 'n hit him hard from below—a good deal harder 'n ennybody 'd ever hit Jim that way sence he was a small boy; for it had all happened so quick Jim hadn't had time to get his feet down into shape fur landin', 'n he came down sittin' down.

But he didn't have much time for bein' dazed, cause when he landed he hit so hard, what with the whack the sack had given him on the way down, thet he let go his holt on the rope. Well, o' course, then the sack o' salt, which was up opposite the loft door, started back home agin; 'n as the boy had already caught holt of it, he a'most kum too. But he let go in time.

The sack didn't come down very fast, for it couldn't move along thout whippin' the rope, coil after coil, out from under Jim, 's he sat there wonderin' whether he'd been a big enuff fool to deserve treatment like that. The sack pulled powerful hard 'n jerky, 'n Jim couldn't help wonderin', he told me afterward, what sort of a horizontal buzz-saw it wuz he'd set down on, ennyhow.

Pretty soon he quit wonderin' 'n commenced to talk. I spose he'd made up his mind as to the buzz-saw, 'n was speakin' it freelike. Ennyhow, the langwidge was most enuff to make that sack o' salt ashamed o' intrudin' on his sassiety 'n turn round 'n go back to the loft agin. But it didn't do no sech thing. It kum right along down. 'N just about the time Jim had made up his mind that not even strong langwidge could appeal to thet buzz-saw, 'n he'd better stand up, the sack o' salt kum along 'n countermanded the order. It knocked Jim so flat there wuzn't no room left for langwidge at all.

He lay there so long I really thought he wuz hurt, though chum 'n me wuz so bad off for laffin' we couldn't do ennythin' to help. But he kum to bout 's soon ez we did—'n then we *had* to quit laffin' 'n ask him if he wuz hurt, 'n where.

It wuzn't until I got back up the crick on the job agin thet I've hed time to think about this thing. I haven't been able to figger out just how this thing happened, 'n why it wuz he went so much faster 'n usual. No, I don't mean thet. I can see *why* he went faster, but I can't figger out how ennyone wuz to know *how much* faster he wuz to go, under sech tryin' circumstances 's a 120-pound sack o' salt. Please help me, Uncle Pegleg.

Your lovin' nevvy,
DAVE.

The problem which is puzzling Dave is an important one, for it concerns all cases where force sets matter into motion.

Our most familiar instance of such a phenomenon is that of simple falling bodies, where there is no rope and counterweight attached to complicate the problem. We are accumstomed to say: "Oh, a body falls 16 feet the first second, 32 feet the next, and so on." But the schools do not commonly teach the broad significance of this fact.

We who live on the surface of the earth, where all bodies, except for air resistance, have this same rate of fall, naturally take this particular rate for granted, as an inherent property of matter. But, those who live elsewhere at times—and every mind which studies natural science must often wander above and below the surface of this earth—know that this is not so.

Every solid body presents to our senses at least two qualities. One is its *mass*. The other is its *weight*.

The mass of a body is the quantity of matter within it. This naturally is the same, wherever you may carry it. If Dave, for instance, should heave a chunk of coal at his chum, it would strike just as hard a blow wherever the act was performed, at sea level, on mountain top, on the surface of the moon or of Mars etc.

The *weight* of a body, on the other hand, is not an attribute of that body, but of its relationship with other, usually larger, bodies, such as the earth, moon, Mars, etc. Consequently it varies whenever you change either the other body or the relationship with it. This same chunk of coal, for instance, would weigh quite differently at the earth's surface accordingly as it were at the sea level, up in a balloon, down in a mine, at the North Pole, at the equator, etc. It would also weigh quite differently at the surface of the moon, Mars, etc., from what it does anywhere on earth.

Now *motion* is merely the result of the effect of this varying force *weight*, acting upon this constant *mass*. It is only a coincidence that at all the places inhabited by man the force of weight is so nearly constant that we say that the rate of fall is constant. Horizontally we may have any force acting on a given mass and any resultant rate of motion; and, in mechanical engineering, these laws of horizontal motion are all-important.

It was Sir Isaac Newton who first gave us the law of motion, or of acceleration, to speak exactly. He said that (a) the acceleration, or the gain in velocity each second, is proportional to the force and (b) told us what that proportion is.

We know, for instance, that when we drop a piece of iron which weighs one pound, the velocity at the end of the first second is about 32.16 feet per second. Therefore, this is called an acceleration of 32.16 feet per second.

According to Newton, this fact represents the broad law that

$$Force\ (=weight) = 32.16 \times mass$$

From this we get

$$Mass = \frac{weight}{32.16} = \frac{W}{g}$$

wherein g is the acceleration of gravity. Or, for other rates of acceleration,

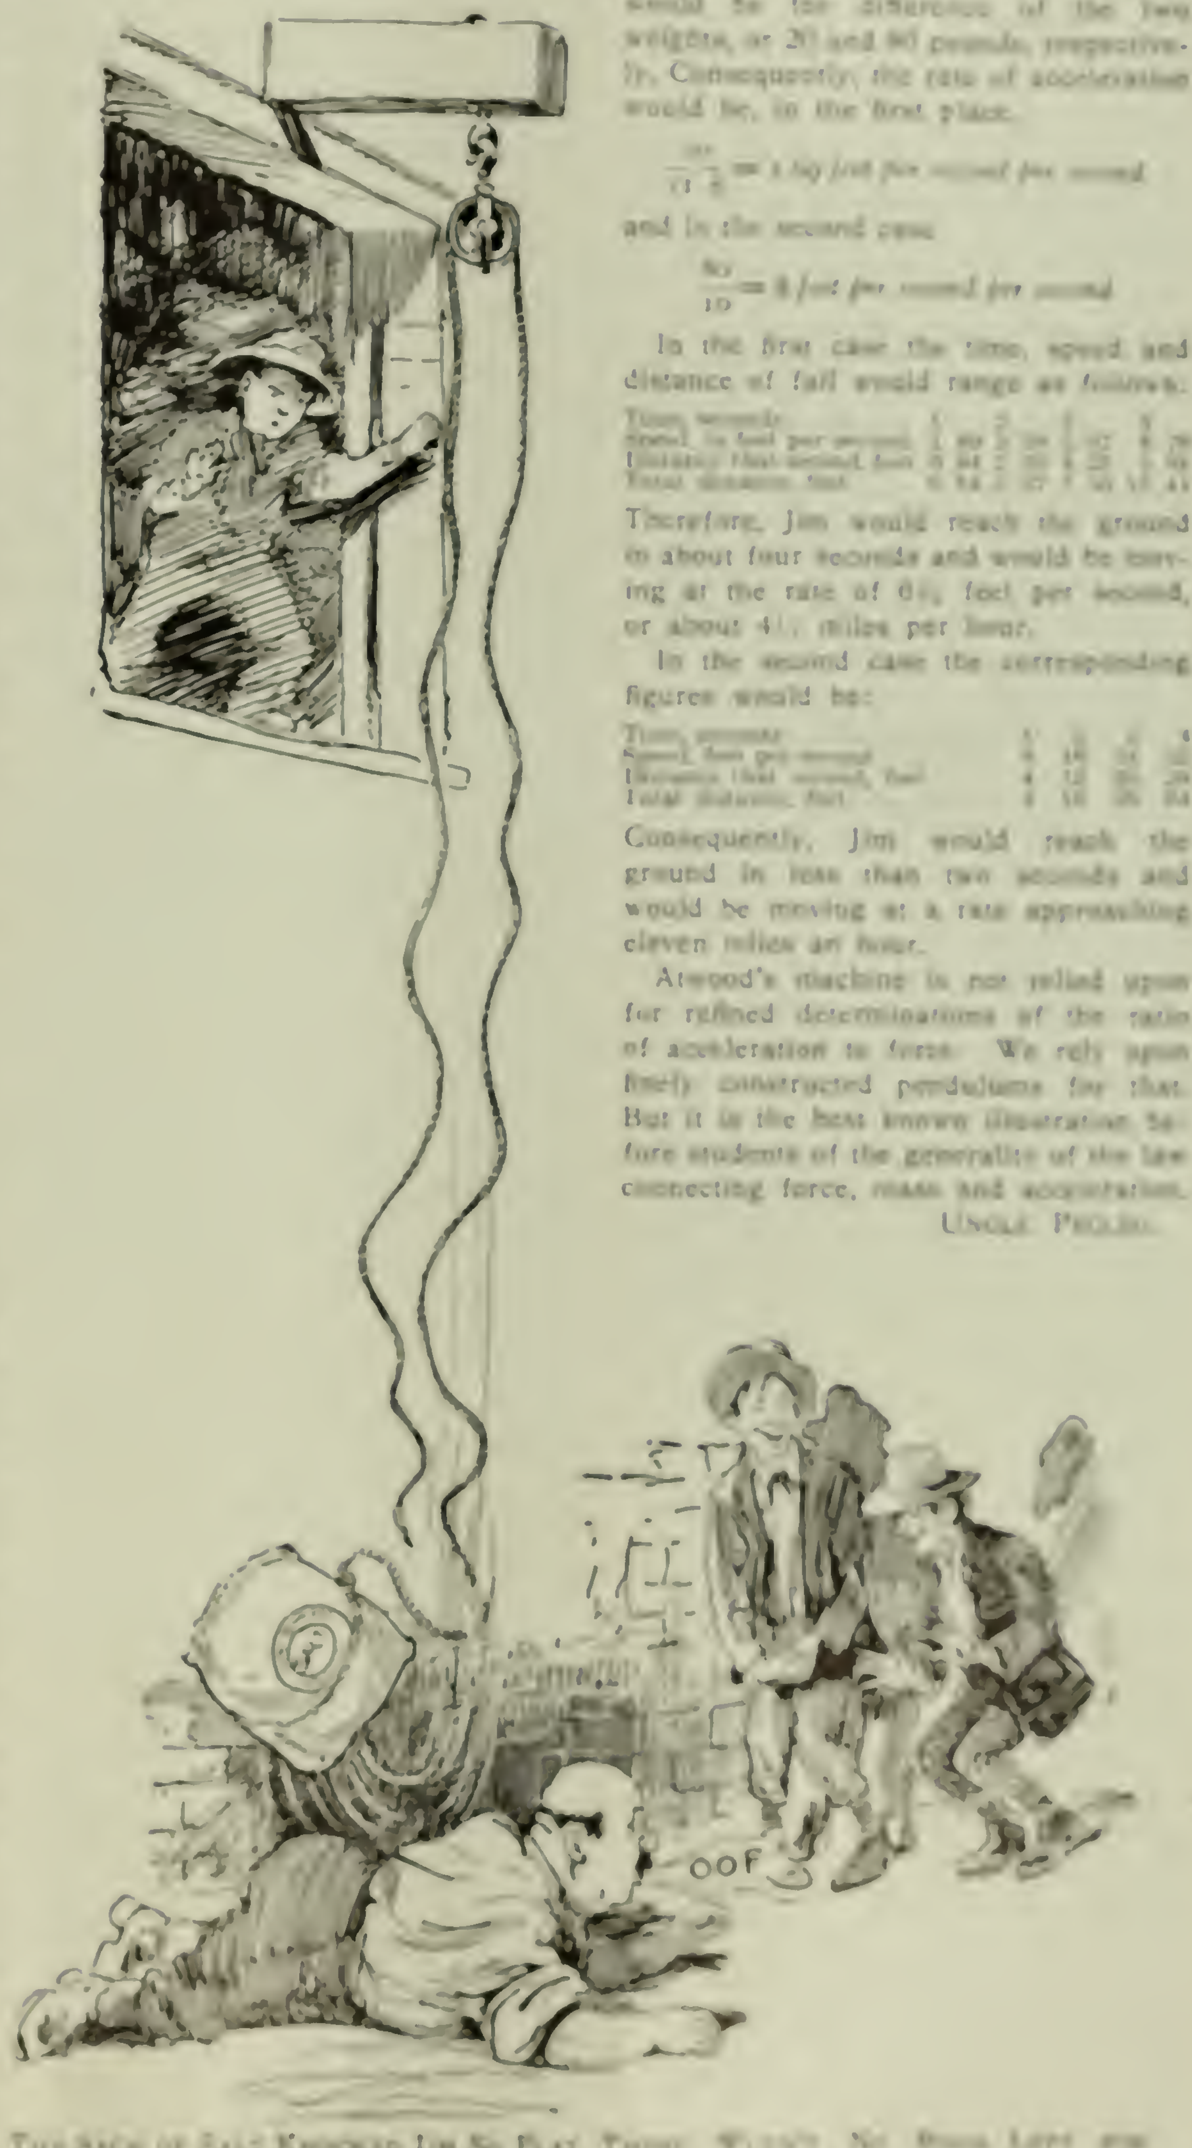
$$Acceleration = \frac{force}{mass} = \frac{force}{\frac{W}{g}} = g\,\frac{force}{weight}$$

In other words, the acceleration is proportional to 32.16, as the force is to the weight of the body subjected to it.

These facts are very hard to study on the earth's surface, because all vertical motions are tied down to the particular vertical force (gravity) which we cannot get rid of here, and all horizontal motions are afflicted with heavy friction due to the same. Newton studied the problem in the heavens, astronomically, because there we get rid of these earthly obstacles. But we ordinary mortals cannot do this.

To help this situation out a famous scientist, Atwood, built a machine modeled quite after Jim's salt-loft pulley and whip. By using *two* weights instead of one, attached to the two ends of a cord passing over a pulley above, and by making the pulley very carefully to be as frictionless as possible, vertical motions could be used and yet the effective weight of the mass being studied could be varied.

That is to say, in this machine the mass being set into motion is the sum of the two bodies. The force or weight which is promoting their motion is their *difference*. So, by making the two bodies fairly nearly the same weight, their sum becomes very large in comparison with their difference. Consequently, the motion will be very much slower than that of freely falling bodies and can be studied much more conveniently.



The Sack of Salt Knocked Jim So Flat There Wasn't No Room Left for Landscape at All

If we take Jim and his salt bag as an instance of such a machine, and disregard the friction of the pulley and rope, it appears that the sum of Jim's weight and that of the salt is, in the first case, 380 pounds and in the second 320 pounds. Consequently, the mass to be moved is about 11.8 and 10 units respectively.

The motive force, on the other hand, would be the difference of the two weights, or 20 and 80 pounds, respectively. Consequently, the rate of acceleration would be, in the first place,

$$\frac{20}{11.8} = 1.69\ feet\ per\ second\ per\ second$$

and in the second case

$$\frac{80}{10} = 8\ feet\ per\ second\ per\ second$$

In the first case the time, speed and distance of fall would range as follows:

Time, seconds	1	2	3	4
Speed, in feet per second	1.69	3.38	5.07	6.76
Distance that second, feet	0.84	2.53	4.22	5.91
Total distance, feet	0.84	3.37	7.59	13.48

Therefore, Jim would reach the ground in about four seconds and would be moving at the rate of 6¾ feet per second, or about 4½ miles per hour.

In the second case the corresponding figures would be:

Time, seconds	1	2	3	4
Speed, feet per second	8	16	24	32
Distance that second, feet	4	12	20	28
Total distance, feet	4	16	36	64

Consequently, Jim would reach the ground in less than two seconds and would be moving at a rate approaching eleven miles an hour.

Atwood's machine is not relied upon for refined determinations of the ratio of acceleration to force. We rely upon finely constructed pendulums for that. But it is the best known illustration before students of the generality of the law connecting force, mass and acceleration.

UNCLE PELEG.

Engines in British Rolling Mills

By Thomas B. Mackenzie

Abstract from a paper recently delivered at a meeting of the Institution of Engineers and Shipbuilders in Scotland. The relative merits of simple and compound engines for rolling-mill work are considered and also the application of low-pressure turbines.

Steam engines in use in the early days of the malleable-iron trade were mostly of the simple noncondensing type working with a late cutoff. As the puddling and reheating furnaces were able to supply enough steam for them, and as there was then no other known method of using the surplus heat, there was no inducement to install more economical types. With the advent of steel, however, this was changed; more power was required for rolling and less waste heat from the furnace was available for the generation of steam. Then when it became necessary to install new engines some attempts were made to improve their steam economy. The simplest of these was the introduction of feed-water heaters and by this means a saving of from 10 to 12 per cent. was obtained.

In the case of mills the rolls of which run continuously in one direction, compound-condensing engines of the most modern type with automatic expansion gear have been, and still are being, used with excellent results. In the case of reversing rolls the case is different. Early attempts at compounding such engines in England ended in failure and prejudiced those in charge against them; and it is only since they have been introduced successfully on the Continent that they are again beginning to be taken up by English steel makers.

The conditions which a reversing rolling-mill engine must fulfil are briefly these: It must be simple and free from all unnecessary complications, in order that it may be able to work day and night with the minimum risk of breakdown; it must be able to start with the cranks in any position, and with the load on; and it must be easily handled; the handles requiring to be continuously used should never be more than two, one for the steam and one for the reversing gear. The first of these conditions is met by making all the motions as direct-acting as possible and giving all parts ample strength. The second condition means that with two-crank engines the cutoff cannot be earlier than 75 per cent., and with the three-crank engines 55 per cent. of the stroke. The third condition almost prohibits the use of expansion gears, and leaves the control of the engine to be effected by throttling the steam supply, which operation is as follows: The engine is turning slowly round in the proper direction when a hot ingot is brought forward and caused to enter between the rolls; the driver at this instant opens the throttle and the ingot is pulled through, the throttle being closed just as the steel is about to leave the rolls. There is still steam in the connecting pipes and valve chests, which, together with the kinetic energy stored in the rotating parts, causes the engine to race until the reversing gear has been brought into use, when the engine begins to rotate in the opposite direction. The steel again enters the rolls and the operation is repeated until it has been rolled down to the required dimensions.

The early compound engines made in England were constructed in the way usual in land and marine practice, with a throttle on the high-pressure cylinders only; consequently, the racing was very much accentuated. In addition to the steam in the high-pressure pipes and valve chests, there was the steam in the connecting pipes, intermediate receiver and low-pressure valve chests. Furthermore, when the engine had been reversed the receiver pressure had fallen to that in the exhaust pipes of the low-pressure cylinders, and only the high-pressure cylinders were available for starting the mill. The drivers had, therefore, to use their own expression, "to take a race at it," that is, the engine was allowed to get up to speed before the piece was entered, causing severe shocks and often leading to breakdowns; hence the compound engine was condemned as unsuitable for rolling-mill purposes.

As is commonly the case, the cure is almost ludicrous in its simplicity, consisting as it does in merely placing a valve between the intermediate receiver and the low-pressure valve chests, connected to, and acting along with, the high-pressure throttle valve. Therefore, when the driver closes the throttle valves, he bottles up the steam in the receiver, and the steam in high-pressure pipes and valve chests, together with the kinetic energy stored in the rotating parts, compresses this steam and raises the receiver pressure, at the same time bringing the engine quickly to rest. On reversal the receiver supplies the low-pressure cylinders, so that all are available for starting under load, and the engine starts easily.

The question: "How much steam does a reversing rolling-mill engine use per horsepower-hour?" is perplexing, and one to which it is difficult to obtain a direct answer. Last year a paper was read at the London meeting of the Iron and Steel Institute by Messrs. Sehmer and Drawe on "Economy and Design of Modern Reversing Rolling Mill Engines," in which it was stated that on a forty-five hours' test of a compound rolling-mill engine the average steam consumption was 350.77 pounds per ton of material rolled to 9.222 times its original length. This is equivalent to about 22 pounds per horsepower-hour. The steam pressure was 103 pounds gage, and the absolute back pressure in the low-pressure cylinders 3.25 pounds per square inch. It was also stated that formerly, with a noncondensing engine, under the same conditions, the steam consumption was 880 to 1100 pounds. In the case of the compound engines the steam consumption named is said to have included that required for the condenser pumps and auxiliaries. There can be no question as to this being an exceptionally good performance, and one which could not be maintained under ordinary working conditions. For everyday practice 24.2 pounds per horsepower-hour will be nearer the figure.

Until within the last few years the only use to which the heat in the exhaust steam from noncondensing engines could be applied was for heating feed water, etc. Since the advent of the steam turbine, however, it has become possible to collect this steam in a closed system of pipes and use it in exhaust-steam turbines. Such an installation, when used with intermittent running engines, consists of three essential parts: first, a thermal storage tank, called by Professor Rateau the heat accumulator; second, the turbine proper, and, third, the condenser and its pumps. The pressure in the thermal storage tank supplying these turbines is usually 17 to 17½ pounds per square inch absolute. It is dangerous to let the pressure fall to that of the atmosphere, and fatal to let it get below that point. To prevent such an occurrence it is customary either to fit a reducing valve which will allow live steam to pass at the lowest permissible pressure in the storage tank, or, as in more recent practice, to use a mixed-pressure turbine. There can be no question as to the latter being by far the better method, as the live steam can then be used with maximum efficiency.

In considering the adoption of an exhaust turbine, it must be kept in mind that the result of its introduction will, by raising the back pressure, increase the steam consumption of the engines exhausting into the thermal storage tanks.

In the case of the noncondensing engine cited, it would increase the steam consumption about 20 per cent. The increase of back pressure will not be less than three pounds per square inch. The loss by condensation, leakage, etc., between the reciprocating engines and the turbines will generally be about 15 per cent. For every 100 pounds of steam which a noncondensing engine uses when exhausting freely into the air, it will, when connected to thermal storage tanks, use 120 pounds. Of this 102 pounds will be available in the turbine. The author recently had occasion to witness a careful test of a mixed-pressure turbine, and the result showed that with dry saturated steam at a pressure of 17 pounds per square inch absolute and a vacuum of 27 inches of mercury the steam consumption was 26.6 pounds per horsepower-hour, the thermal efficiency of the turbine being 0.626. From this performance 102 pounds of steam would be capable of developing 3.83 horsepower. As a live-steam turbine, working with the same initial pressure and degree of superheat as the reciprocating engine, would use 54.7 pounds of steam to develop the same power, the noncondensing engine should be credited with this amount, making its equivalent net consumption

$$120 - 54.7 = 65.3 \text{ pounds}$$

in the same time that it formerly used 100 pounds when exhausting freely to the atmosphere.

A compound engine uses 58.7 pounds of steam for every 100 pounds used by a noncondensing engine doing the same work. Also, it has just been shown that a live-steam turbine will use 54.7 pounds of steam to develop the same amount of power which could be gotten from an exhaust turbine placed beyond and in series with the reciprocating engine, which the compound replaced, per 120 pounds of steam used. The sum of these is

$$58.7 + 54.7 = 113.4 \text{ pounds}$$

instead of 120 pounds required by the noncondensing engine with the increased back pressure due to its exhausting into the thermal storage tanks. The same amount of work can therefore be done with 6.6 pounds less steam, an apparent saving of 5½ per cent. The real saving, however, is greater because it is impossible to so arrange matters that the load on the turbine will always be proportional to that on the engines exhausting into it. There are therefore times when the supply of exhaust steam is in excess of the turbine's requirements when it blows off at the safety valves on the storage tanks and is wasted. Conversely, there are times when there is a deficiency of exhaust steam, and the turbine's demands have to be made up with live steam. With compound engines and live-steam turbines, on the other hand, each takes from the boilers just what it requires and no steam is wasted.

Gas Explosions in Boiler Flues

Before the Oldham Engineers' Association, of England, William Ingham recently delivered an interesting lecture on the above subject. *The Engineer*, of London, abstracted the lecture and we are thus enabled to present briefly the gist of his remarks. In the course of his lecture, Mr. Ingham referred to the Distington boiler explosion which occurred on December 18, 1889, when eight Lancashire boilers were simultaneously destroyed, four exploding violently and completely destroying the other four. The boilers were fired by blast-furnace gas and beneath each gas burner at the front of the boiler a small coal fire was kept constantly burning to ignite the gas flame should this become extinguished.

At the time, there was a certain amount of mystery surrounding the explosion, and it was suggested that, as there was considerable fluctuation in the gas pressure and variation of the quality and constituents of the gas, if, after the flame were extinguished and the gas and air were discharged in considerable quantities in the flues before ignition, an explosive mixture might accumulate, and the ignition of a large volume of such mixture by the flame from the coal fire or by the flame from an adjacent boiler might cause the explosion, which would lift the boiler and cause it to explode from internal pressure in dropping down again.

Careful investigation and calculation showed, however, that the maximum pressure which could be produced by such an explosive mixture would not exceed 10 pounds per square inch if confined in a closed vessel. Immediately a boiler was lifted, however, or the brick envelop forming the flues gave way, the force of the explosion would have spent itself and the gas pressure would fall, and probably the boiler would drop on its seat again or roll over. Certainly the boilers would not be blown into fragments, many of which were hurled to great distances by this explosion.

The conclusion arrived at by the underinsurance company's engineers and the engineer surveyors of the Board of Trade was that this multiple explosion was caused by an excessive accumulation of pressure in one boiler due to the blocking up of the orifice leading to the safety valve in some manner not clearly ascertained.

It was Mr. Ingham's opinion that no really disastrous boiler explosion or economizer explosion had ever been due to sudden and violent combustion of an explosive mixture of gas and air. In a dozen or so of cases investigated by the lecturer, the effects all bore a marked similarity to each other. They occurred in most cases after the fires had been banked for some time. In one case the flue covers were blown away and about two-thirds of the brickwork from the top of the boiler. Another occurred in the overtop flue of a Galloway boiler. In one case the chamber of a Green economizer was blown down and the upper portion of the back end of the economizer was blown away. In all these cases it will be noticed that the results of gas explosions in boiler flues were almost invariably of a mild character, seldom doing more than finding vents for the gases by blowing down the brickwork forming the flues, or lifting up the iron plates or other coverings.

The Central Station Could Not Meet His Figures

At the March meeting of the National Isolated Plant Association, held at the Engineering Societies building, several members related their experiences with the central-station solicitor. Among the most interesting of these was the story told by the chief engineer of a large association building. The plant is of approximately 300 boiler horsepower and has a fairly high load factor, owing to the elevator service. Complete records are kept of all fuel, supplies, meter readings, etc., and all labor is charged to the proper items. As a result power is produced here for less than two cents per kilowatt-hour, including all fixed charges. Some time ago the management was approached by the central-station solicitor who wanted a chance to submit figures for central-station service. He was accordingly given access to all the plant records and allowed to take such instrument readings as he wished, with these data he departed and promised to return within a few days with an attractive offer. A month elapsed, however, and he did not return, whereupon the engineer called up the central-station office in regard to the matter. He was informed that they were figuring upon the proposition and would be prepared to submit figures in a few days. After another prolonged wait, followed by another telephone message, the solicitor finally put in appearance and rather sheepishly informed the engineer that the central station was not prepared to offer a proposition which would better the figures of the present plant and ended by congratulating him upon the good showing.

Among the various committees appointed at the meeting was one upon "standardization," one of the duties of this committee being to draw up a standard form of records which will enable the engineer to tell at any time just what it is costing him to produce power.

Sulphur is one of the best things for hot bearings and is often used on the engine guides and crank pins. It is best used in a powdered form mixed thoroughly with oil.

Electrical Department

Especially conducted to be of interest and service to the men in charge of the electrical equipment

A New Engine Type Alternator

The accompanying engravings illustrate the construction of a line of low-speed alternators built by the Westing-

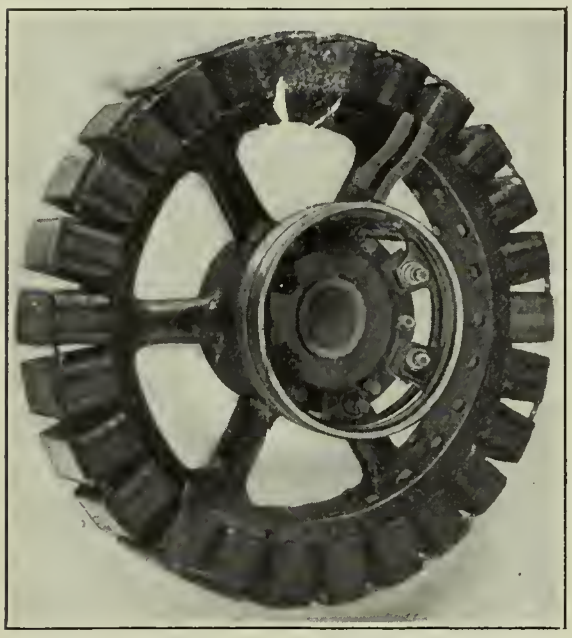


Fig. 1. Complete Field Magnet

house Electric and Manufacturing Company for mounting the revolving field magnet directly on the shaft of its driving engine or waterwheel. The field magnet (Fig. 1) consists of a steel wheel, exactly like a flywheel, the rim of which forms the yoke of the magnet, with laminated poles bolted to the face of the rim and exciting coils surrounding the cores. The magnet poles are of the usual type, having extended poletips at the faces, as indicated in Fig. 2. The poles are held on the rim by simple hrough bolts, no dovetails or other means than the bolts being employed. The magnet coils are composed of copper ribbon or strap wound edgewise with fireproof insulation between the convolutions.

The collector rings are of cast iron with radial lugs projecting inwardly. These lugs are bolted to a supporting cast-iron ring which, in turn, is bolted to the hub of the field-magnet spider, as shown in Fig. 2; the lugs are insulated, of course, from the bolts and the supporting ring. This construction obviously leaves the collector rings entirely open on the interior, permitting heat to be dis-

Fig. 2. A Field-magnet Pole

sipated from the inner as well as the outer surfaces.

The armature core is built up of segmental stampings of the form shown in the upper part of Fig. 5. The dovetail projections stamped on the backs of the

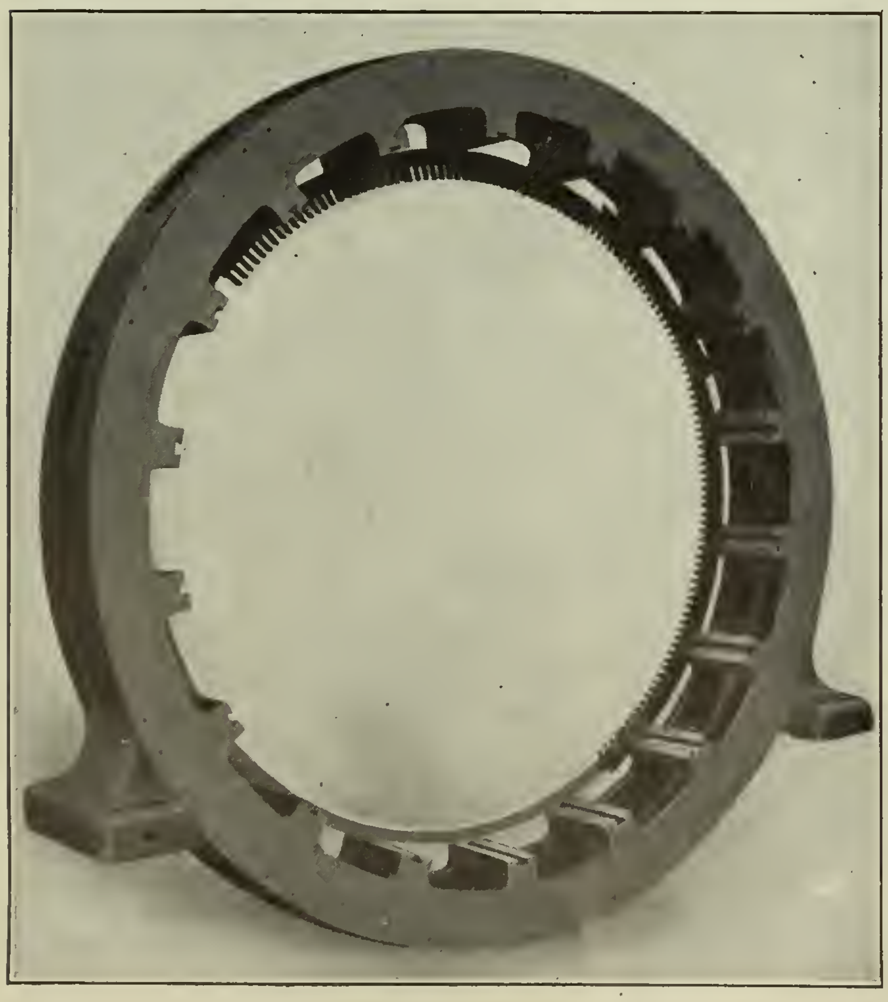

Fig. 3. Armature-housing Ring

Fig. 4. The Complete Armature

segments fit snugly in slots milled in ribs which extend axially across the face of the housing ring, as shown in Fig. 3. The joints between the ends of the segments are staggered in successive layers so that each joint is flanked by solid sheet on each side of its own plane. The housing or main frame is of cast iron of skeleton cross-section and ventilated by large slots cored in the center of the housing face or "rim." Fig. 3 gives a very clear view of the construction of this piece, which combines lightness, strength and ability to get rid of heat to a remarkable degree. The segmental laminations are assembled in the housing ring under pressure and held in place by malleable-iron finger plates of the shape shown at the center of Fig. 5, backed up by cast-iron end rings which are keyed to the housing. The segment shown at the bottom of Fig. 5 is a ventilating spacer. A ring of these is inserted between the core laminations at intervals, during the building up of the core, to form ventilating ducts in the completed core.

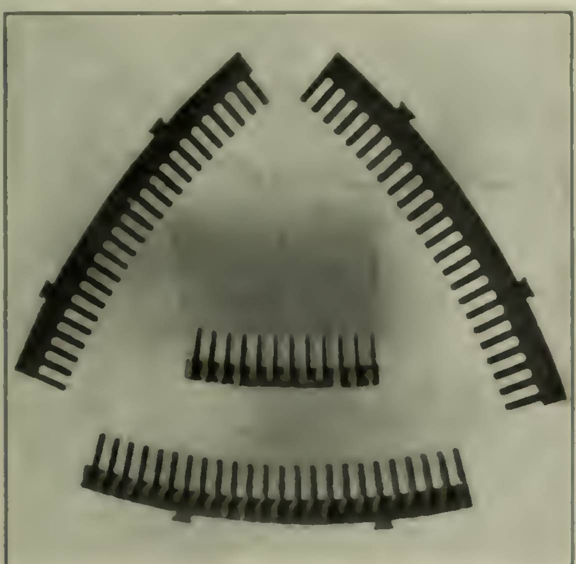

Fig. 5. Core Laminations, a Finger Plate and a Ventilating Spacer

Very close inspection of Fig. 5 will show that the core teeth are notched on each side near the free ends; these notches are to receive hard fiber strips which close the slots after the winding is in place. The armature coils are form-wound and individually insulated before being put in the slots, as is now the standard practice in the construction of machines for moderate and high voltages. After each coil is wound and shaped, it is dried in a vacuum and impregnated with a moisture-proof compound under pressure; then the wrapping is applied and finally the insulated coil is coated with an insulating varnish.

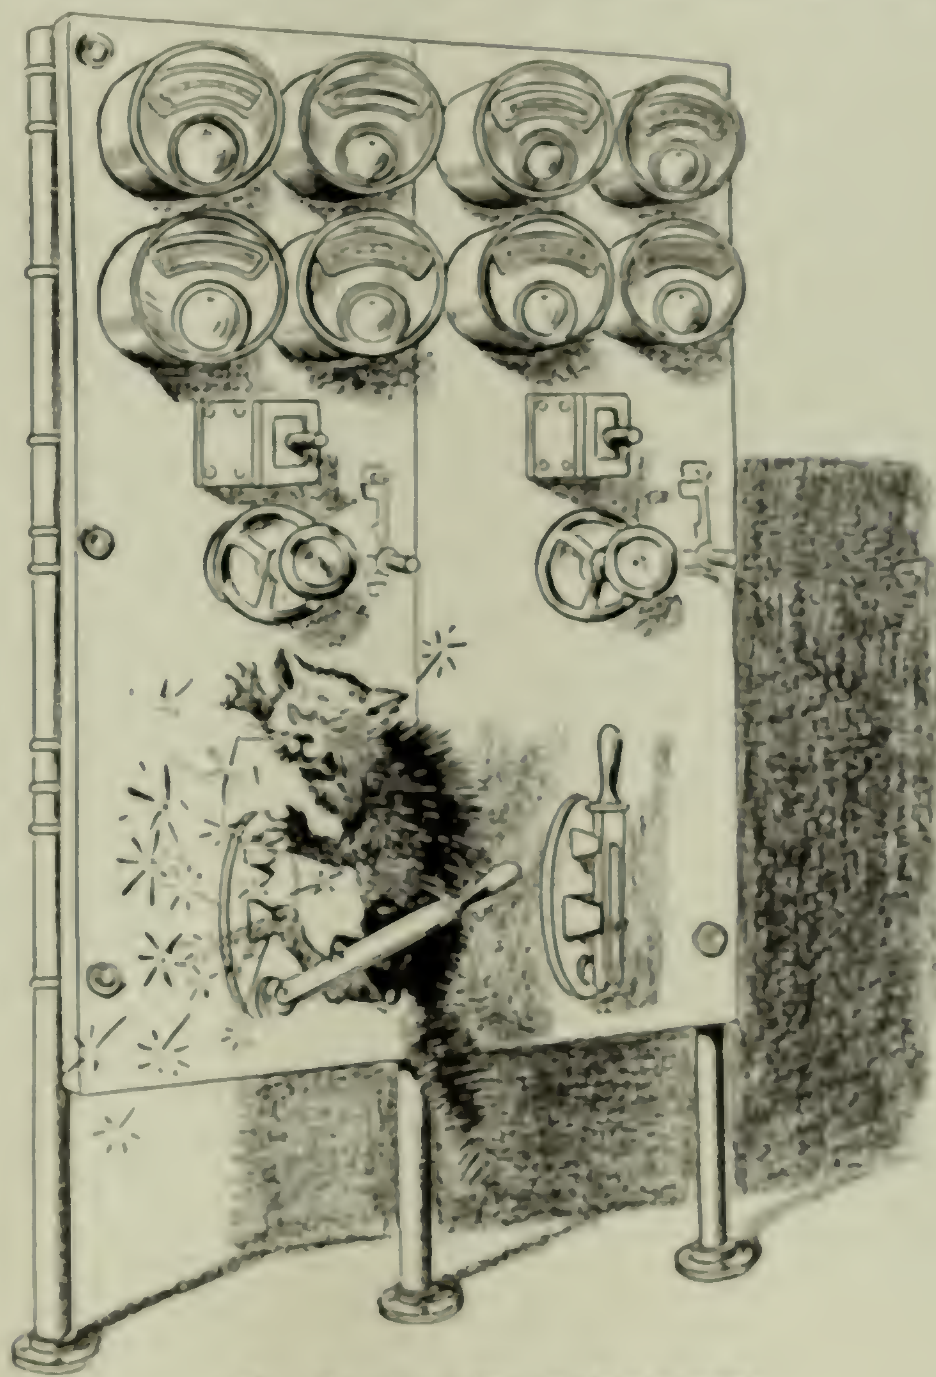
The armature or stator winding is protected from mechanical injury by steel cages or "bells" bolted to the housing ring, as shown in Fig. 4. These cages are built up of bent strips and circular segments of sheet steel riveted together.

These machines are built in sizes ranging from 50 to 1100 kilovolt-amperes and potentials of 240 to 2400 volts. They are wound for either two-phase or three-phase delivery at the standard frequency of 60 cycles.

Reddy Causes a Catastrophe in the Power House

By S. Kirlin

Reddy's official position in the power house was that of fourth assistant to the second engineer's oiler and he was supposed to make himself generally useful in any department in which he was needed. He was about ten years old, had a freckled face and a shock of brilliant red hair which had given him his nickname of "Reddy." His wearing apparel consisted of a shirt, overalls, one suspender and an impish smile which had never been known to come off before the occurrence of the event herein related.



The Result of Reddy's Experiment

His duties were supposed to begin at 7 a.m., but he usually got around earlier and put in the spare time tying knots in the legs of the overalls belonging to the day shift. Then he sat in a convenient place out of their reach and offered sundry bits of advice as they struggled to untie the knots. His activities in this line finally led to agitation among the men to be supplied with lockers, and after this was done Reddy had to find other means of entertainment. The men claimed that these lockers were the only good that had ever resulted from Reddy's connection with the company; yet, if he had been discharged for any of his tricks every man in the station would have joined in a petition to have him reinstated, for life around the plant would have been very dull without him.

One of his first capers after coming into the plant was to set fire to a small piece of oily waste, tie it on the [illegible] rim of one of the engines, and then enjoy the frantic efforts of the second engineer and the oilers as they ran around trying to find a hot box. After this had happened a few times they caught him at it and the chief convinced him of the inadvisability of doing it again. He occasionally varied his tactics by abstracting fruit from the cook's lunch basket, inserting a liberal amount of red pepper in it and returning it to the basket; the facial and lingual expressions of the victims at lunch time were his reward.

This trick usually exhausted everybody's patience and the men would catch him, carry him out to the boiler room, hold his feet up and pour coal dust down the legs of his overalls. After he had accumulated all the dust that would stick they would take him out in the yard to the overflow tank in which the condensers discharged and throw him in. Reddy enjoyed the latter part of the treatment as much as any of them, but did not like the amount of work that was necessary to get the coal dust out of his pants.

He met his match one day when he tried to play a joke on Hans, the station repair man. Business had been poor in Reddy's line all the morning and he was looking for trouble. He had not been able to find an opportunity to start anything worth while until he happened to spy Hans down on his knees scraping the end of a belt which was to be spliced, the glue pot being near at hand. When he discovered Hans in this position the possibilities for breaking the monotony appealed to him at once and he began to plan the most effective way to break it. The belt driving one of the exciters was close to where Hans was working and was charged heavily with static electricity, and an overpowering curiosity induced Reddy to find out if Hans' overalls were thick enough to insulate the electricity. Going into the stock room he found a piece of heavily insulated wire, one end of which he laid on the floor, bending it up so as to come near the belt; the other end he wrapped around a stick and touched it to the seat of Hans' overalls.

Ordinarily Hans was very slow in both speech and action and had never before been known to make a sudden move, but the effect of the shock was surprising. "Gott in Himmel," he yelled, and making a violent effort to straighten up, pitched forward on the floor and upset the glue pot. Scrambling to his feet he looked around and, seeing Reddy, knew instantly the cause of his trouble. Reddy had been so surprised by Hans' sudden move that he delayed making his exit, and as he turned to run he tripped over the belt. Before he could get on his feet, Hans had him and was calling to the other men to come and see what was going to happen to Reddy. The entire station force turned out to see the show, many willing hands helping to drag Reddy back to where the glue had been spilled, and while they held him, Hans wiped up the glue, using Reddy's hair for a mop. After getting it thoroughly saturated they carried him out to the boiler room and rubbed his head in the coal pile. Reddy spent the next two hours in the overflow tank trying to wash the coal and glue out of his hair, but with poor success. Coming into the engine room he tried to complete the job with a bunch of waste soaked in gasolene while the men stood around and gave him all kinds of advice about the danger of premature ignition from getting the gasolene so near his hair.

After this strenuous experience, Reddy remained fairly quiet for a few days, but such a condition could not last long and everybody around the station was wondering where he would break out next. His success in applying electrical treatment to Hans prompted him to try it, a few days later, on old Tom, the station cat. He had often tried the experiment of rubbing Tom's fur in the dark, and knew that as a generator Tom was a success; but he was curious to know if the process were reversible and how Tom would perform as a motor in case the current should be applied to him from an outside source. As a motor old Tom proved to be a "howling" success.

Reddy found him curled up asleep on the operator's desk, which stood just in front of the switchboard panel containing the circuit-breaker and instruments controlling one of the main units that was in operation at the time. He made the connection with Tom in somewhat the same manner that he had with Hans, but the result was rather different. Old Tom let loose a blood-curling yowl and went up in the air several feet. As he came down "all spraddled out," his feet landed on the handle of the main switch; his struggles pushed the switch open and there were fireworks all along the line.

Here was where Reddy's smile faded. After the men had got things straightened out and the service had been restored, the superintendent came in and investigated. Upon learning of Reddy's experiment on the cat he took that youthful genius "on the carpet" so effectively that he didn't smile for the next hour and a half. Then the superintendent went out into the boiler room where he could laugh without Reddy seeing him.

A Big Hydroelectric Development in India

A hydroelectric undertaking has been promoted by a Mr. Tata, of Bombay, which will require a capital of about twenty million rupees (more than six million dollars). The site for the generating plant is at Lanowli, about 40 miles from Bombay, the chief commercial city of India. The waterfall has a head of about 1734 feet, which is one of the highest in the world, being ten times as great as that of Niagara and four times as great as that of Kauveri. The average rainfall in this locality is 175 inches.

The power is to be carried over a transmission line only 43 miles long at a pressure of 80,000 volts. The plant, as at present laid out, will suffice to supply Bombay in the season of least rainfall with 30,000 electrical horsepower, on a basis of 3600 working hours a year, but provision is made for enlarging the plant by developing another valley, which will bring the total power to 50,000 electrical horsepower. The company expects to be able to bring the cost of the power down to 0.55 anna (about 1 cent) per kilowatt-hour. The development is being financed entirely by local (Indian) capital.

CORRESPONDENCE

Effect of Field Adjustment on a Rotary Converter

I once installed some compound-wound rotary converters for supplying current to 550-volt direct-current power circuits. One Sunday I received a hasty message from the power house that the transformers furnishing current to the rotaries were burning up. I found the transformers smoking hot but no permanent injury had been done.

As the power load was very light on Sunday, the operator had decided that high voltage was unnecessary and therefore proceeded to weaken the field of the converter in service, causing the current to lag and increase in value until the transformers were seriously overloaded. When the shunt field rheostat was set back to the point marked for maximum power factor the transformers soon cooled down.

To those who have had no experience with rotary converters a few words explaining their characteristics which bear on this trouble may be of interest. The direct-current voltage delivered by a rotary converter bears a certain fixed ratio to the alternating-current voltage supplied to it. Hence, in order to change the direct-current voltage the alternating-current voltage must be varied; altering the field strength merely alters the power factor of the alternating current. There is one field strength of a rotary converter that is called "minimum-input" field. At this point the alternating current delivered to it is minimum because the power factor is 100 per cent. To decrease the field current below this point will cause the current taken by the rotary to lag; to increase it will cause the current to lead. In either case the current is increased because the power factor is decreased. Therefore, when the operator weakened the field strength of the converter he caused the alternating current to increase sufficiently to overheat the transformer windings.

Anniston, Ala. G. J. Reynolds.

A feller frum over t' Jayville kum inter my ingin room tother day an' after he'd gawped at th' ingin fer awhile he ast me what th' thing wuz thet wuz whirlin' 'round so fast. I told him it wuz th' flywheel; he sed he didn't see how th' gol darnd flies cud stick to it with it goin' so fast.

Gas Power Department

Everything worth while in the gas engine and producer industry will be treated here in a way that can be of use to practical men

The Gas Power Boat "Holzapfel I"

There was launched recently from an English shipbuilding yard a producer-gas power boat for the Holzapfel Marine Gas Power Syndicate, Ltd. She is the first gas-power sea-going vessel to be built, and measures 120 feet in length between perpendiculars, 22 feet in breadth and 11 feet 6 inches in molded depth. She will carry a little over 300 tons on a draft of 10 feet. The vessel will be fitted with a set of high-speed six-cylinder vertical engines, developing 180 brake horsepower at 450 revolutions per minute. The plant will be in duplicate, each division being of 100 horsepower. The generators are square in section and will stand side by side on the port side of the vessel, with their "faces" to the engine room. The scrubbers, which will stand forward of the generators, are about 13 feet high, the lower portion being the wet cooler and the upper portion the dry scrubber. Both generators and scrubbers will be inclosed in a gas-tight compartment separated from the engine room, and provided with adequate ventilating arrangements.

The power of the engine will be transmitted to the propeller shaft by means of the Fottinger transformer, which reduces the revolutions of the latter to any desired number, within certain limits, while the engine is running at full speed. It can also stop or reverse the propeller while the engine is running at full speed ahead. The loss of power entailed by its use varies from 3 per cent. to 20 per cent., according to size, and to the gear or ratios of the number of revolutions of the prime mover to the number of those of the propeller shaft. A favorable ratio is from 300 revolutions of the prime mover to about 100 revolutions of the propeller shaft. In the vessel just launched the transformer is geared from 450 revolutions of the gas engine to 120 revolutions per minute of the propeller. The transformer, together with the thrust block, is coupled directly to the engine, and the total length of the two is about 20 feet.

It is expected that the consumption of anthracite coal will be from 2800 to 3400 pounds daily, as against 3½ tons of steam coal for compound steam engines of equal power. An air compressor and air cylinders will be provided for starting the gas engines. The blowing up of the gas producers while they are being fired up will be effected by air injectors supplied from the compressed-air cylinders. The vessel's average speed will be 7½ knots.—*The Mechanical Engineer.*

A Bituminous Producer Gas Power Plant

There has recently been installed at the works of S. F. Bowser & Co., Fort Wayne, Ind., a mechanically poked producer using Pennsylvania run-of-mine bituminous coal, the gas being used for operating a number of Riverside gas engines for lighting and power purposes. This producer installation, which was put in by the Holbeck Gas Power Company, of Cleveland, O., is one of the first of its type to be used for power, although this type has been in successful operation in furnace work several years.

Fig. 1 is a cross-section of the type of generator, cooler, rotary washer and dry scrubber used at this plant. It will be noted that the generator is of the up-draft type and the gas passes directly from it to the cooler by a short connection lined with firebrick and provided with a manhole cover at M. Bituminous crushed, nut or slack coal is fed automatically through the revolving drum D, which regulates the fuel according to the load.

The gas generator, which is 10 feet in diameter and rated at 750 horsepower, revolves on steel trunnions, making about one complete revolution every twenty minutes; it is driven through a gear train by an electric motor. The cast-steel poker P is oscillated by the gear mechanism, stirring the fire as the generator revolves. As the top remains stationary a water seal is provided at the top to prevent the escape of gas. Peep holes are provided through which to inspect the condition of the fuel bed at different points.

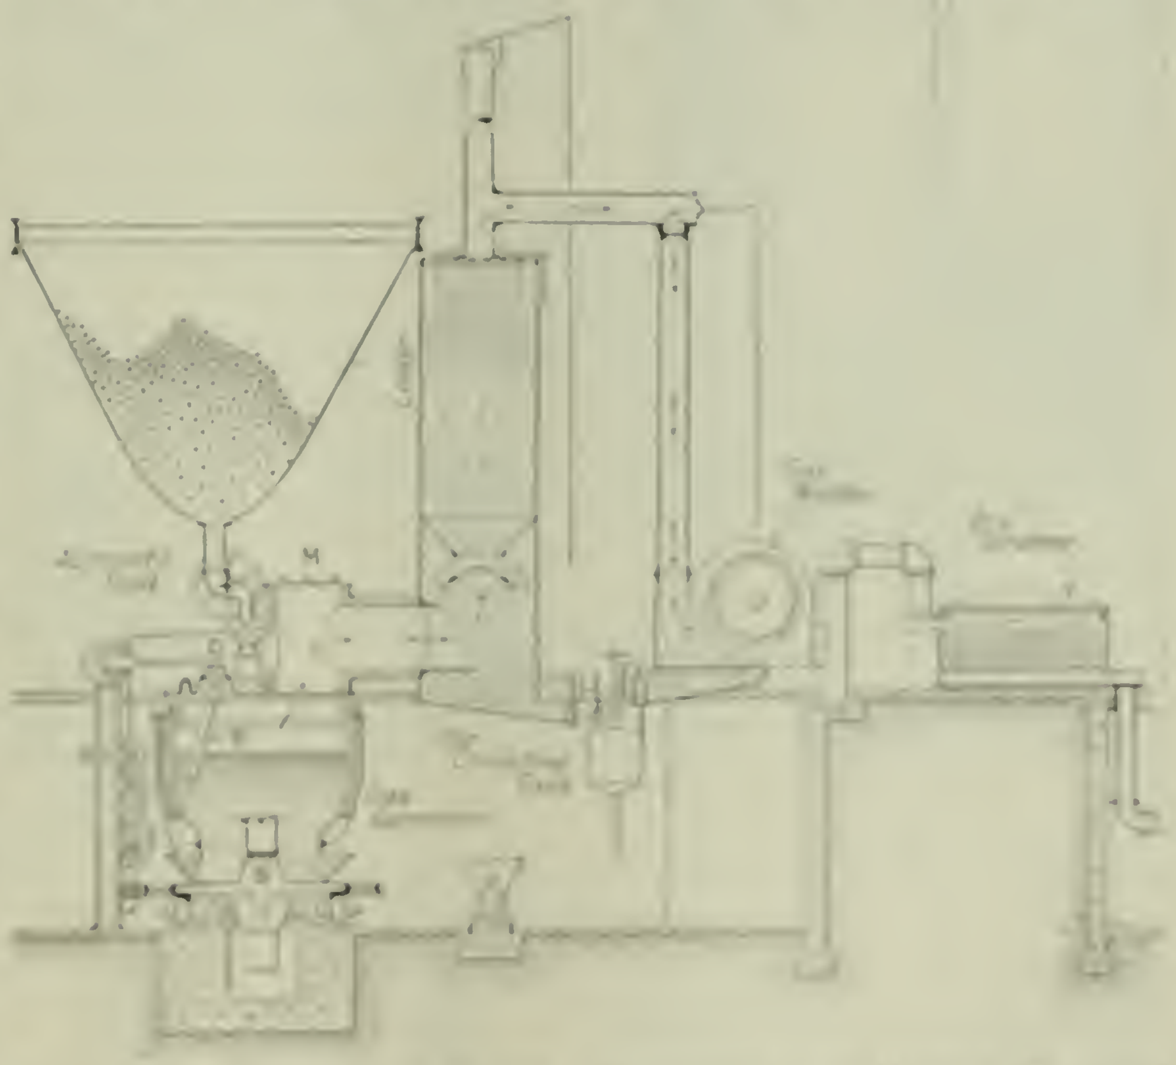


FIG. 1. SECTIONAL ELEVATION OF THE ELEMENTS OF THE HOLBECK EQUIPMENT

Ash is taken out through the lower water seal, this operation being necessary only once in 24 hours. Air and low-pressure steam are delivered to the fuel bed by the induction blower *B*, through the central tuyere immediately above it. The relation of grate area to the horsepower developed is such that at no time is a combustion rate greater than 16 pounds of coal per square foot of grate surface per hour required. No attempt is made to work at the high temperatures sometimes attained in producers. It was thought better by the designers to run at a lower temperature and make no attempt to fix the tar.

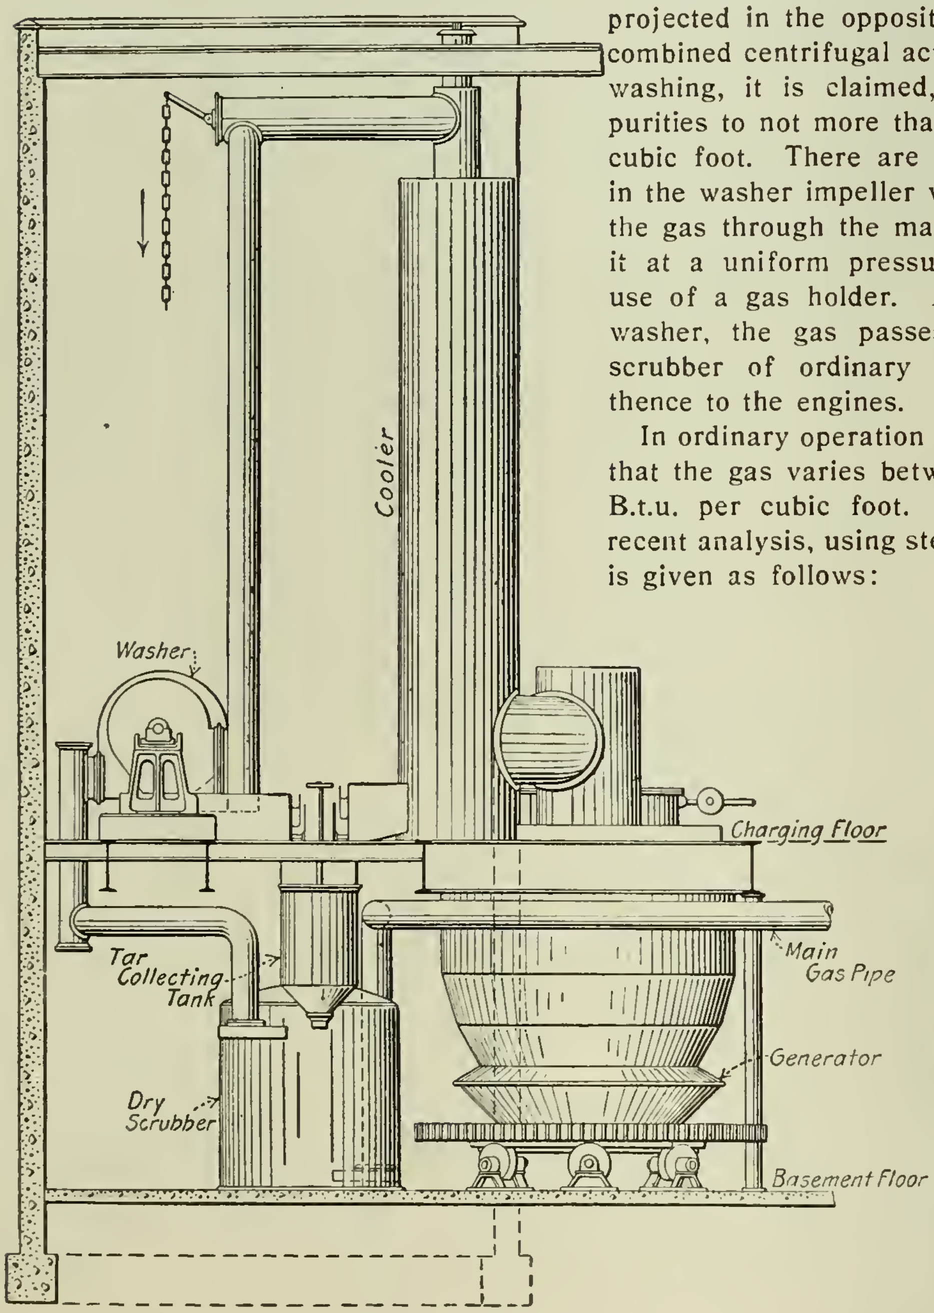
The cooler shell is a tall steel tank of simple riveted construction. In this tank the gas meets a fine spray of water discharged downward and filling the entire shell. The hot raw gas enters at the bottom and passes upward, being intimately mixed with the spray, cooled and partially purified. The tar which accompanies the gas in vaporous form is condensed and forms into tar bubbles, most of which pass off with the gas to the washer. A part of the tar, however, falls to the water seal at the bottom of the tower and sinks to the bottom, whence it is periodically drained into a tar-collecting tank.

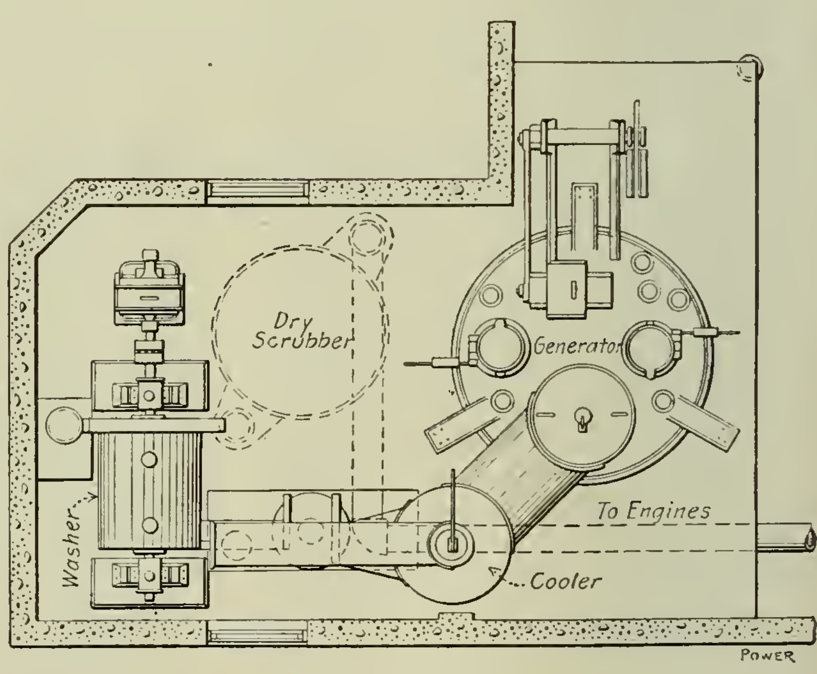
One of the vital parts of the system is the rotary washer, which mechanically separates the tar from the gas. This is of the Saaler type; its operation depends upon centrifugal force and the fact that the gas is lighter than the tar. The gas is caught by the rapidly revolving drum and whirled at high speed; the tar bubbles, being of greater density than the gas, are thrown outward by centrifugal action into a film of water covering the inner wall of the casing. Furthermore, the vanes on the revolving drum of the washer are so placed that the gas passing through the machine comes intimately into contact with a water spray projected in the opposite direction. The combined centrifugal action and thorough washing, it is claimed, reduce the impurities to not more than 0.015 grain per cubic foot. There are also incorporated in the washer impeller vanes which draw the gas through the machine and deliver it at a uniform pressure, obviating the use of a gas holder. After leaving the washer, the gas passes through a dry scrubber of ordinary construction and thence to the engines.

In ordinary operation it has been found that the gas varies between 175 and 180 B.t.u. per cubic foot. The result of a recent analysis, using steam at 20 pounds, is given as follows:

CO	20
H	18.9
CH_4	5.6
O	0.2
CO_2	8.4

The heat value was 184.4 B.t.u. per cubic foot. This high value, it is claimed, is largely due to the low temperature at which the producer is run, which evaporates the tar and enriches the gas with some of the higher volatiles of the coal which are ordinarily burned to carbon dioxide when higher temperatures are maintained.





Figs. 2 and 3. Elevation and Plan of the Producer as Actually Installed

Engineers for Gas Engines

By Charles O. Hamilton

For years salesmen—and builders, too, I am afraid—have preached the "no engineer" gospel in regard to the operation of gas and gasolene engines and there is no doubt that they and the misguided user have, in consequence, been reaping a big crop of trouble. What is the real truth about the gas-engine engineer question anyway? Why not thresh it out and settle it, now and for all time?

The "no-engineer" fallacy originated, I believe, in the early days when the gasolene engine was being introduced. The engines then offered to the public were of small power and low compression and had hot-tube igniters. They were sold largely to replace small steam plants, and once started—a mysterious operation understood about as well by a greenhorn as by a professional—they would keep on running as long as the fuel supply held out. If anything happened, the engine simply stopped. There was very little danger in its operation as compared with the known necessary care of a steam boiler and engine.

Nobody seemed to know much about the engines, not even the men who sold them. Therefore, why not make the claim that no engineer was needed? "No ashes"; "no dirty fuel"; "no cost except when running"; "no engineer." These looked like reasonable claims for the new power and were generally accepted by intending buyers as facts.

Gradually great progress has been made in gas power. Larger engines have been developed; new fuels found and used; higher compression, electric ignition, more exacting service conditions, all have followed. Now, the man familiar with steam engineering knows that the better-grade engine, with the accessories necessary for high efficiency, calls for more ability in the operator. This is equally true with gas engines. The better they are, the more efficient and reliable, the more attachments and appliances are required and the more skill needed to operate them.

The advancement in gas-engine practice was seemingly slow but it has, in reality, been very rapid. Ten years have produced a revolution in the way of sizes, types and fuels used. Yet many of the old-school salesmen are still active and cannot seem to get over using the arguments "No engineer" and the others which are so foolish in the light of present-day conditions.

This "no-engineer" talk has made an enemy of thousands of steam engineers. Even if they knew the truth about the silly claim, their antagonism was aroused and they naturally fought back in self-defense. Many have been so blinded by prejudice that they have not even recognized the advantages that the new prime movers possessed.

Many of us gas-engine men stopped talking this "no-engineer" nonsense long ago but we are still reaping the crop of trouble sown in former days and other crops are still being sown to some extent. We are, right now, at a most trying period in the industry. It is still hard to do business and do it right. For example, if a conscientious builder tells a prospective buyer that an engineer is necessary and another builder assures him to the contrary, what show has the man who tells the truth? The prospective buyer will naturally conclude that the conscientious man's engine is too complex and difficult to run and it will be extremely difficult, if not impossible, to get him to consider it at all.

Anybody with experience with both steam and gas power knows that a good gas-power plant requires less time from the operator than a corresponding steam plant. He also knows that it requires as good or even a better quality of man to get equally satisfactory results from the gas plant. Do not overlook this distinction. Less time, but as good or better men, are needed in gas-power plants.

It may interest the reader to know that a careful canvass of over two hundred plants put in by one company, ranging from 25 to 200 horsepower, shows that the average time required daily in plants running on natural or city gas or gasolene, where other work is at hand for engineer to do, is not over two hours. About 30 to 40 minutes of the time is spent stopping and starting at morning, noon and night, and the balance in occasional trips to engine room to look over the engine, and in overhauling, taking up bearings, repairing igniters and other incidental work at convenient times. Where a suction-gas producer is used it requires about another hour for handling the producer in the morning.

The experiences in these plants show conclusively that the better the operator, the less time he takes to take care of his engine. Where the operator is a good man, the engine is a good engine always.

The necessity for an engineer in a gas-power plant certainly does exist and always will. The sooner buyers realize it, the better for all concerned. Does the present steam engineer realize what an important voice he can have in saying who the gas engineer shall be?

LETTERS

Mr. Benefiel's Generator Lining

On page 494 of the March 28 issue there is a misprint in my letter on gas-generator linings. Instead of reading: "We set the firebrick in 8 inches from the shell," it should read "3 inches from the shell."

J. O. Benefiel.

Anderson, Ind.

Cracked Piston Faces

In the issue of March 28, John G. Kohnsberg asks for advice about cracked piston faces. I have handled a good many pistons from small gas engines, but I have never seen one cracked in the way shown by his sketch.

If all his cracked pistons are from the same make of engine, it would look as though it was due to the design of the pistons. An examination of the crack might help one to form an opinion.

I have seen a good many pistons from engines with the valves in the top of the cylinder which have had a piece knocked right out because of the valve stem breaking; lately, some of them have been completely and permanently welded with the oxyacetylene welding torch. I am very dubious about results with brazing, Smooth-on, or soft patches.

John Bailey.

Milwaukee, Wis.

I have been having a little of the trouble that Mr. Kohnsberg asks about and I believe the best way to repair a cracked piston face is to drill holes along the crack, plugging each one as soon as drilled and drilling the next so as to cut partly into the plug just inserted.

I cannot recommend this from experience, but will soon be able to report on the merits of the plan as I have charge of three 12-inch two-cylinder engines in which every piston developed a crack after about three years of service. Only one of them has ever leaked. This one I first calked with copper, which soon came out; I then used soft steel instead of copper, making small wedges which would drive tight in the crack. This has been holding tight for several months but the first time I have occasion to take the piston out I shall drill and plug it, unless someone suggests a better way.

Floyd L. Fearing.

Kane, Penn.

Mr. Hall's Inconsistent Engine

In the issue for March 28, Mr. Hall wants to know why opening the pet cock on the third cylinder of his engine makes the engine run faster. It seems to me that the mixture is too rich in that cylinder, perhaps due to the piping to the intake valves not being such as to feed the same mixture to all four cylinders, and when the pet cock is opened the third cylinder gets about the proper amount of extra air to make the proper mixture. The intake piping should be arranged as shown by the accompanying sketch.

Symmetrical Intake Manifold

B. M. Howe.

Rural Retreat, Va.

I think if Mr. Hall will examine his engine he will find that there is a pocket in the intake pipe leading from the carbureter to cylinder No. 3, which collects some liquid gasolene. Surface evaporation from this makes the mixture too rich until it is diluted by the fresh air drawn in through the pet cock.

Another possible cause is a leak in the induction pipe which may admit air in such a way as to dilute the mixture going to the other three cylinders. Mr. Hall may have enriched the mixture to suit these cylinders and made it too rich for No. 3, which does not happen to be affected by the leakage of air. Opening the pet cock would tend to correct this.

I would suggest also that he examine the action of the exhaust valve on the third cylinder. It is quite possible that this valve opens too late or does not have sufficient lift to allow the exhaust to entirely escape and thus maintains some compression at all times unless it is relieved by opening the pet cock. I have repaired and adjusted several engines that had this trouble. If this is the trouble, it can be quickly proved by placing a thin piece of wood or iron under the end of the valve stem so as to increase the lift of the valve. If the trouble is due to insufficient lift, the engine will immediately speed up.

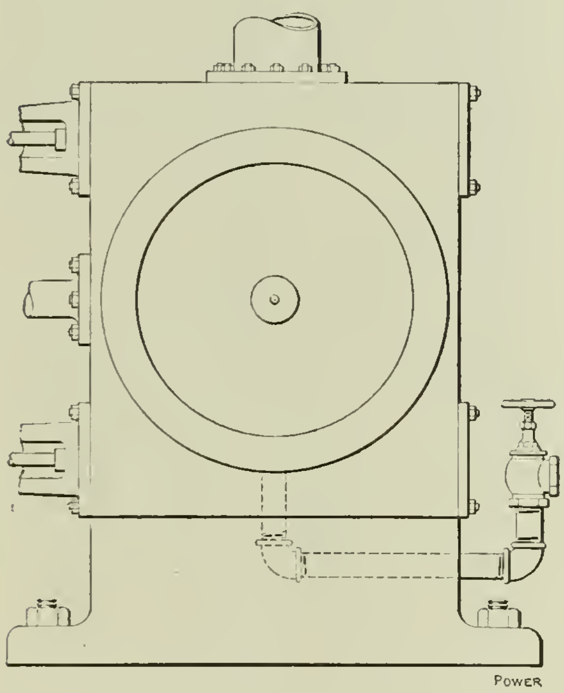
Readers with Something to Say

Practical information from the man on the job. A letter good enough to print here will be paid for. Ideas, not mere words wanted

Unnecessary Clearance Loss

Builders of reciprocating engines recognize that clearance is a source of considerable steam loss, and design their engines so as to reduce this loss to the lowest possible amount. The erecting engineer, however, frequently makes mistakes in erecting the engine which offset much of the builder's effort toward economy.

I recently saw an illustration of this in a municipal electric-light plant, in which one of the main generating units consisted of a 350-horsepower four-valve engine. Each end of the cylinder was equipped with a 1½-inch relief valve, the openings for which were on the bottom of the cylinder. There was plenty of room to have placed these valves in an inverted position directly underneath each end of the cylinder, by simply using nipples long enough to reach through the lagging. Instead of doing this, however, the erecting engineer had connected them as shown in the illustration, putting in a trifle over three feet of 1½-inch pipe between the valves and the cylinder.



A Case of Unnecessary Piping

The total volume of this six feet of pipe amounts to something over 125 cubic inches and as this volume was added to the total clearance of the cylinder it is easily seen that it did not add anything to the engine's economy; in fact, the engine gave such poor results in this respect that it was only used when the peak load made it necessary.

Leaving Things Right for the Man Coming On

The duties of the men in the power plant are made imperative by the demand for satisfactory service and the assignments by the chief. Nevertheless, a man can make the duties of the man coming on the next shift difficult, although apparently leaving everything in a satisfactory condition. When leaving his shift the operating engineer should make a tour of the plant to determine the pressure on the boilers, the water level in the boilers, and to see if all engines and pumps are in proper working condition.

If an engine is running condensing, the degree of vacuum maintained should be noted, making sure that all apparatus is working satisfactorily and, if not, it should be reported to the man coming on duty so that an investigation can be made and the trouble remedied without delay.

The oiler should, as a final duty, take a trip around the engines, feeling of all bearings and running parts to see that they are not running unusually warm. If anything should be found not running right, the oiler should report it to his successor, so that he can keep a special watch of it. In feeling for hot bearing or pins, always use the back of the hand, because it is more sensitive than the front of the hand. The oiler should leave all oil and grease cups, reservoirs and lubricators full or nearly so and make sure that they are feeding. He should also leave all oil cans full and see that all drip pans are empty and wiped out. He should also pick up any waste that may have accumulated during his shift and leave everything as clean and orderly as circumstances will permit.

One of the most important duties of the fireman in this connection is to leave good fires for the next man. Sometimes in a plant where the fuel on each man's shift is weighed and kept on record, there is a temptation to leave light fires for the next man to build up. Of course, this low coal consumption looks good to the "powers that be," so the mean fireman gets the credit of being a more economical fireman than the other.

If the man coming on duty is to clean fires at the beginning of his shift, the man relieved should leave them in the right condition. He should have a heavy bed of incandescent coke in one-half of the furnace, and the other half burned almost down to the ashes. He should also have the water level as high as practicable. These conditions enable the man coming on duty to clean the fires with comparative ease and without the necessity of feeding water to the boilers during the period of cleaning.

The night fireman in a manufacturing plant should leave the fires thoroughly clean and as well coked as possible, because there is no demand for steam while the fires are coming up in the morning; the pressure quickly rises to that required for the day's run before the fires and furnaces have become thoroughly hot, consequently the day man has to get a morning's start under adverse circumstances. The morning's start is the hardest part of the day, assuming the boilers are worked at or above their rated capacity.

The night man can also help matters by having the water well up in the boilers, so that the day man will not have to feed water to the boilers until everything is in running condition. He should also leave the ashpits clean and partly filled with water, the floor swept and the lubricator or the feed pump full of oil.

Greenfield, Mass.

Reduced Compression and Lead Saves Coal

At one time I worked in a plant in which there was a 24 and 48 by 48-inch cross-compound Corliss engine, rated at 1500 horsepower.

The economy of the plant was not bad, but the engine did not carry the peak loads at all satisfactorily. I applied the indicator and reduced the lead and compression until the engine began to run noisily. After adjusting for quiet running, the engine was let alone.

Another engine that was rated at 800 horsepower was indicated and the valves set about the same as in the first instance. The load varied considerably each day and at different times in the day. The load the next two days after the engine had been adjusted happened to be heavy, but when I went into the fire room the firemen were taking it easy and remarked that the load was lighter than it had been. The recording instruments, however, showed that the load was being carried much more easily and the voltage held up better than formerly. Last, but not least by any means, not as much coal was being burned per kilowatt-hour as formerly by an average of 3000 pounds less of coal per day out of a total of from 70,000 to 80,000 pounds.

The engine had double eccentrics and the governor controlled the cutoff of both cylinders. The high-pressure cylinder was steam jacketed on the heads only. Saturated steam was used which, by calorimeter tests at the throttle valve under similar conditions, showed from 98 to 99% dry.

Vacuum Increased by Reducing Pump Speed

In the power plant where I am employed there is a condenser that is supplied with water by a rotary pump. This pump was run at a speed of 72 revolutions per minute and a vacuum of 26½ inches maintained.

Recently, a shortage in the supply water was experienced. The speed of the rotary pump was reduced to 44 revolutions per minute, and paradoxical as it may seem the vacuum is now maintained at 28½ inches.

Fairport Harbor, O.

Adjustable Indicator Cord Hook

The object of this device is to provide a means whereby the indicator cord can be adjusted to run parallel with the center line of the engine. The accompanying drawing shows that it is adjustable both horizontally and vertically. The pointed screw *A* passes through the flange of the plug *B* and is intended to prevent the plug from unscrewing from the crosshead in case the hook should get caught in any way, as the block *C* would turn on the long arm instead.

Adjustable Indicator-cord Hook

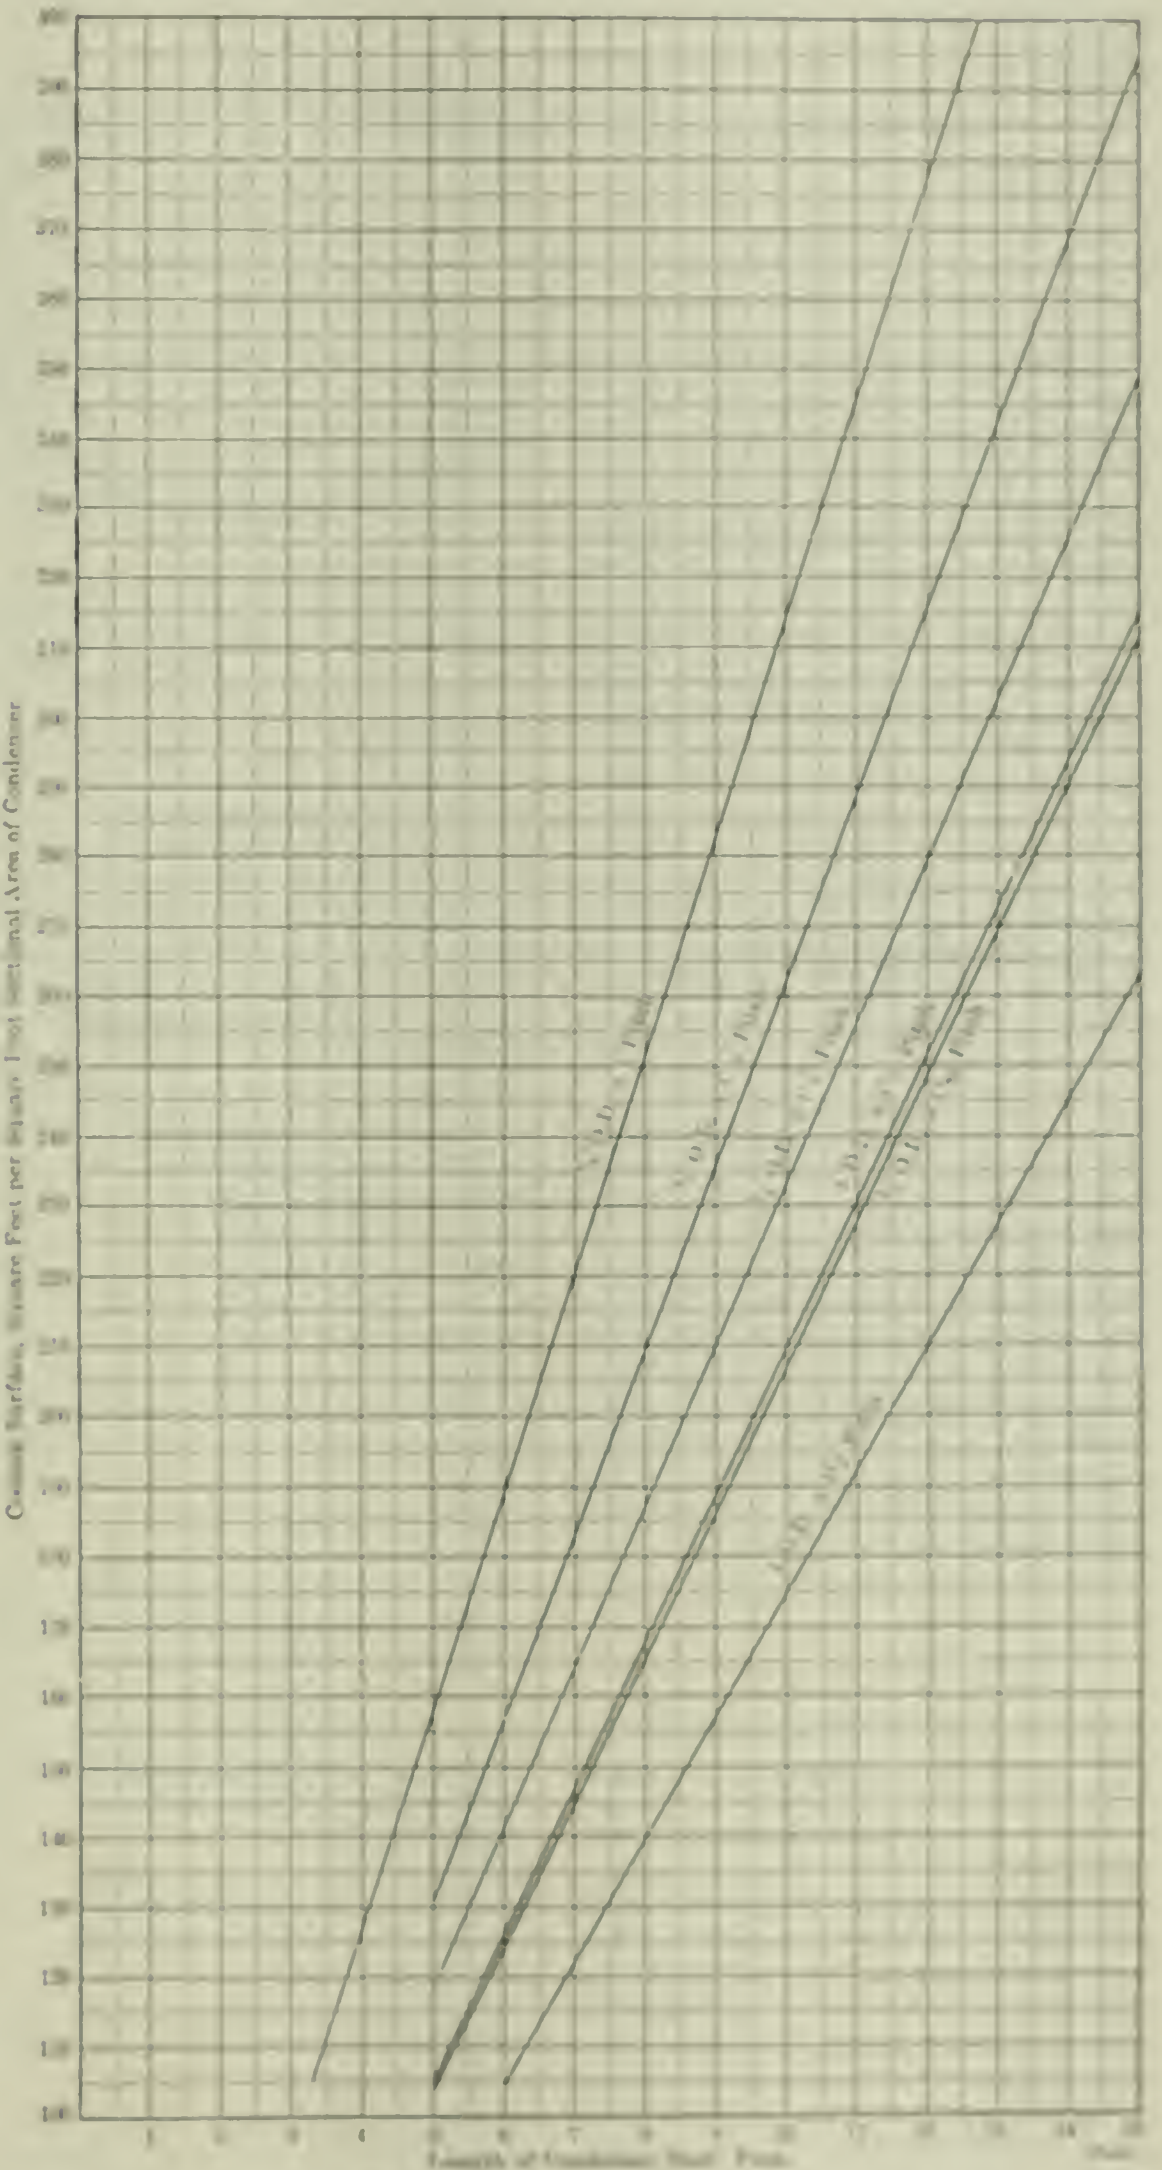
Passaic, N. J.

Condenser Diagram

The accompanying diagram gives curves which enable one to approximate the dimensions of surface condensers to be estimated, having been given the surface in square feet and the length of condenser shell in feet.



Condenser Diagram Chart

The tubes have a 5/8-, 3/4- and 1-inch external diameter, 18 Stubs wire gage thickness and a 60-degree pitch. The tubes are arranged for two passes of circulating water, but with a four-pass condenser deduct approximately 30 per cent. of the surface shown. If the ...

dome is dispensed with, necessitating provision of steam paths between the tubes, suitable connections should be made.

This has proved of considerable value to me and doubtless will be to many engaged in the design of condensing plants.

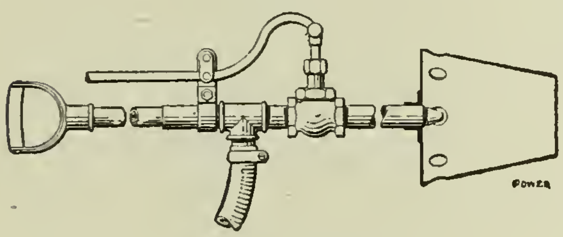
W. VINCENT TREEBY.

Goodmayes, Eng.

Homemade Tube Blower

Following is a description of a tube blower that I made from a few old fittings. The accompanying diagram shows the completed blower.

I took an old tee and screwed a short piece of pipe into it and plugged the inner end. Then a wooden handle was fitted into the other end of the pipe, an old shovel handle being used to furnish a grip. The controlling valve was made out of an old ¾-inch globe valve, with the threads removed from the stem, so it would work freely in the gland nut.



TUBE BLOWER

The valve is set so the pressure will come on top of the disk.

The blower head was made of No. 18 gage iron; the nozzle projecting about one inch into the head, which is 6 inches long. The end that enters the tube is 3½ inches, and the other end is 6 inches in diameter. It is used on 4-inch tubes.

I can blow out seventy 4-inch tubes in four minutes. A hand scraper is used once a week, the blower being used the rest of the time.

W. H. MATTHEWS.

Tecumseh, Neb.

Head End Cinders for Fuel

This is a description of the apparatus used and the results obtained in a steam-power plant using head-end cinders under the boilers. Head-end cinders are the half-burned particles of coal which are drawn out of the firebox, through the flues, and lodge behind a screen in the smoke chamber of a locomotive engine. An analysis of these cinders shows them to be a form of coke with most of the volatile matter and moisture liberated, but still very rich in fixed carbon.

The boiler under which a test was made was an ordinary return-tubular boiler of 100 horsepower capacity, set exactly as it would be set for coal burning. The grates were of the very fine sawdust type and were placed 30 inches below the boiler to provide space for the very thick fire required. The grates had 10 per cent. greater area than would have been required for coal burning.

All ashpit doors were entirely removed and the openings bricked up, leaving four 4-inch tiles protruding through and extended to about the center of the firebox. In the center of each of these tiles was placed a ½-inch pipe for a steam jet, the four small pipes being fed by a 1½-inch pipe from the boiler. These steam jets serve the double purpose of assisting combustion in the furnace by the mixing of steam with the gases, and also creating a forced draft by drawing air through the tiles in the firebox. About 10 per cent. of the steam capacity of the boiler was required for the jets.

An extra door was placed in the side of the ashpit for the removal of ashes and it was found necessary to clean the pit about once in two weeks.

To appreciate fully the results obtained in this plant it is necessary to first consider the cost and supply of cinders. This plant is located at a railroad division point where engines are cleaned out and where cinders accumulate, more than enough to supply this plant. Cinders are sold at $5 per car, regardless of the weight of the car, but the average car probably contains about five tons.

This plant has a 50-horsepower engine and a 35-kilowatt generator running from dusk to midnight and from 5 a.m. until daylight, making a total run of about 12 hours per day at the time this test was made. During the remaining 12 hours per day there was just sufficient fire under the boiler to heat the building in which it was located. The daily consumption of cinders was 3000 pounds, of which 2500 pounds were used on the lighting load and the remaining 500 pounds to keep the building warm.

The low fuel cost of this plant is apparent. The total average load was 240 kilowatt-hours per 12-hour run, which means 10.4 pounds of fuel per kilowatt-hour, not a very low fuel consumption when compared with some coal-burning plants, but an extremely economical plant when taking into consideration the low cost of the fuel. The cost of fuel averaged $0.0052 per kilowatt-hour, which compares very favorably with the fuel cost of internal-combustion engines in plants of this size.

Aside from the economy of this fuel, another great advantage was found in that it was practically smokeless, due to the fact that the volatile matter was entirely removed while in the locomotive firebox. Another advantage was the almost total absence of ash and the attendant bother and expense of the removal of same.

There are, however, some objections to this fuel, some of which are rather serious. Chief among them is the care of the fire, as the cinders are very light and quick burning and the fire requires frequent replenishing to maintain the necessary thickness; the fire must be thoroughly cleaned at least once every hour or the clinkers will get so large that the fire will have to be practically killed to take the clinkers out. Another objection is the fact that 10 per cent. of the steam output of the boiler is used to blow up the fire and, consequently, the full capacity of the boiler could not be depended upon. The life of a boiler is materially shortened by the use of this fuel, just how much I am unable to say, but I know of one boiler that was so badly crystallized after ten years' use that it had to be condemned, but this was at least partly due to lack of care of the boiler.

Taking all things into consideration there is no good reason why these cinders should not be used more in plants which are located at points where they are obtainable, provided the plant is not sufficiently large to make the necessary investment to get the highest efficiency out of a coal-burning plant a drawback.

Fort Dodge, Ia.

Catalog Misstatements

Manufacturers, for a reason best known to themselves, put in at the back of their catalogs a section entitled, "Useful Information." While the body of the catalog is written by their best engineers and carefully revised and checked, this information section is a haphazard miscellaneous collection of supposed facts which I hope were not compiled by anyone higher up than the office boy.

I have often noticed rather serious errors in this section of catalogs and have now at hand three catalogs all containing the same mistake. Evidently the error was made in one of the catalogs and copied by the other manufacturers. This shows the necessity of avoiding any misstatement of facts, for, if the men getting up a catalog and who are on the lookout for errors are led into copying such a serious blunder from another catalog, how much more likely are engineers reading the catalog apt to use the incorrect figures and be led into serious mistakes.

Any one error in itself may not seem of much consequence, but the principle at stake is large, and the consequences arising from the use of such misstatements may be great. For most engineers take the statements in the catalog of a reputable concern as facts and unless they can be correctly presented, it would be much better not to present them at all.

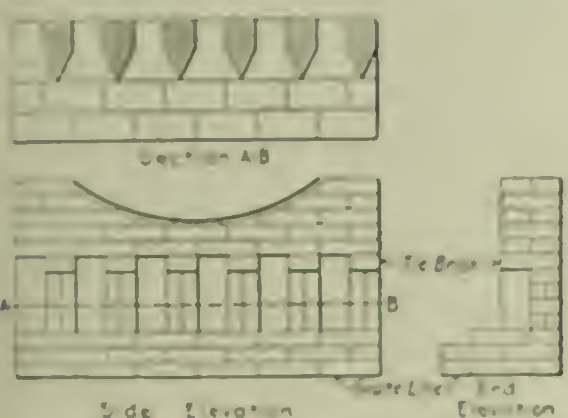
Questions Before the House

Comment, criticism, suggestions and debate upon various articles, letters and editorials which have appeared in previous issues

Furnace for Bituminous Coal

It was a pleasure to read F. B. DeMotte's letter in the March 21 issue. His thought for the welfare of the men under him is very creditable, and I feel sure that he will have their full support and coöperation.

In regard to changing from bituminous to anthracite coal, it appears to me that the price of the latter makes this impossible. Suppose anthracite containing 14,000 B.t.u. were procurable at the price mentioned in his letter. The increase in the cost of the coal would be 100 per cent. and the increase in the available heat would be only 16.7 per cent. Then, the cost of installing a fan to increase the draft and the cost of furnace alterations, together with the loss due to steam used to run the fan would



Design of Bridgewall for Aiding Combustion

probably eat up the gain due to the extra heat available from the anthracite coal.

I suggest the arrangement of a system of firebrick arches and baffles to secure smokeless combustion with the bituminous coal. The accompanying figure shows a bridgewall design of which I have a high opinion. The hot gases leaving the grate strike against the wedge-shaped bricks that are placed vertically on the bridgewall; the gases are spread out by the wedges. This results in a much better mixing of the combustible gases and more nearly complete combustion.

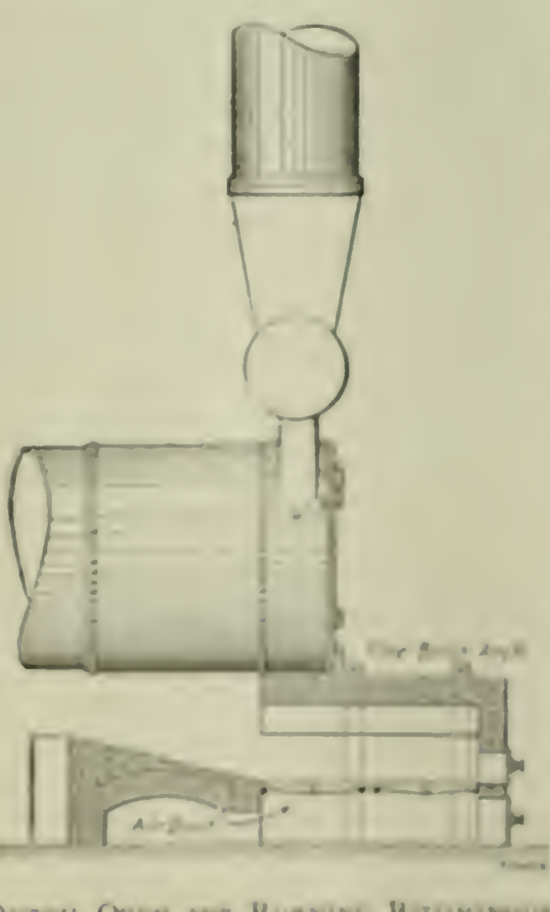
Care should be taken when installing the bridgewall to have the area of the openings at least equal to that of the tubes. The reversed arch rising around the boiler shell should be about [illegible] inch clear of the shell to allow for expansion. The soot found in the combustion chamber will be of a gray color and more like a fine ash, proving that combustion is quite complete.

The only way I know in which to keep the boiler house clean is to keep at it. A steam nozzle used in the chimney while the tube blower is working would certainly keep much of the dirt out of the room.

H. Prew.

Montreal, Que.

The question of F. B. DeMotte in the issue of March 21 in regard to the smoke and dust nuisance in his boiler plant is a creditable one. Wanting to improve the plant and the conditions of the fireman, he asks for the opinions of Power readers.



Dutch Oven for Burning Bituminous Coal

If he does not have to crowd the boilers while using run-of-mine bituminous coal having a heat value of 12,000 B.t.u., a steam jet is not necessary to secure smokeless combustion. A jet should never be used for continuous operation but only applied for temporary use in cases where there are extreme demands on the boilers during short periods.

As Mr. DeMotte has ample boiler capacity, I would suggest the installation of a dutch oven, as shown in the accompanying figure. This arrangement of furnace has proved very successful in just such cases and is not expensive. The room it occupies is generally not of urgent need as there is generally at least 20 feet of space in front of the boilers as clearance for the tubes. The dutch oven takes about 5 feet; this would leave 15 feet for the firemen to work in, which is ample.

The principle of operation of the furnace is easily explained. Under ordinary circumstances the air by passing through the air duct is preheated and comes hot under the grates. In the meantime it has cooled the firebrick arch forming the roof of the duct and in that manner it lengthens the life of the arch.

The fire fed by preheated air will be a good deal hotter than under present conditions and the flame will be about 5 feet longer, giving the smoke an opportunity to burn thoroughly before striking the cold boiler shell. Under the present conditions the flames strike the cold boiler shell before the smoke formed has an opportunity to burn.

Furnaces as proposed have been very successful in preventing the smoke nuisance when the boilers were not overcrowded. They also greatly abate the dust nuisance of which Mr. DeMotte complains.

As to the use of anthracite pea coal, this does not seem advisable. It is twice as expensive as the run-of-mine now used and requires a little over twice as much draft.

Rulof Klein.

New York City.

Effect of Discharge Pipe Size on Motor Load

Referring to Mr. Lee's letter in the March 14 issue, it is my opinion that Mr. Lee is mistaken about the size of the discharge pipe of the triplex pump under discussion. I was assistant engineer when the pump was purchased and I helped to install it. Unless my memory does not serve me well, the discharge outlet was 3 inches in diameter and not 4 inches as he stated.

During the years that I had charge of the plant the pump motor took 5.1 kilowatts per hour.

Francis J. Doyle.

Watertown, S. D.

Water Gages

Various writers have expressed their opinions as to the different kinds of valves and their location on water-column connections.

Where the water is nearly free from scale or sediment the globe valve should give satisfaction, but if there is a great amount of scale to contend with I prefer the gate valve and would use a cross in the water connection. Instead of connecting the drain to the bottom of the cross as Mr. McGahey showed in the December 13 issue, I would connect it directly opposite the boiler connection by using a short nipple and plugged tee as an elbow and carry the drain down according to circumstances. With this arrangement there would be much less danger of scale lodging in the cross and the tee would be handy as a means of cleaning out the pipe in case of an emergency.

I see no reason for using a cross in the steam connection as very little, if any, solid matter would rise to that hight. In exceptional cases where the boiler foams a great deal a cross might come in handy in the steam connection.

William E. Piper.

Farmington, Utah.

The Cost of Power

I was much interested in the editorial in the March 21 issue on the cost of power and with the writer thereof regret that at the recent meeting of the American Society of Mechanical Engineers there apparently was no determined effort made on the part of the isolated-plant engineers to refute the arguments of the central-station people.

It has been my experience that the central-station salesman or sales engineer has not been overburdened with conscience when competing with the isolated plant. He has invariably used high figures for cost of installation, high coal bills, discrediting the matter of the use of exhaust steam, and has done everything possible to make the figures for the cost of power with the isolated plant appear as high as possible, bringing in many items which are rather questionable in their actual application to the situation.

There is no real reason why the generating outfit of an isolated plant should not be quite as economical in its operation as a fair-sized unit in the central station, if bought for the express purpose of low cost in power production. Frequently, however, this point is not of prime importance. The value of the exhaust steam as a means of heating water or for serving some other purpose and for heating the buildings, is of greater importance than is good steam economy of the engine. The mechanical efficiency, however, is no lower for engines for this service than any other, nor should the efficiency of the generator be any different.

When a fair-sized central station can produce a kilowatt-hour at the switchboard with 4 to 5 pounds of coal and often even less, there is no reason for assuming that a fair-sized unit in an industrial plant should not do the same. This, however, does not seem to enter into the calculations of the central-station agent, as is seen in the article by Mr. Parker, where he takes 6½ pounds of coal per kilowatt-hour as the consumption for a plant of 150 kilowatts capacity. Further, I note that Mr. Parker makes a charge of $936 against the industrial plant for emergency service, whereas in the electrically driven plant with power purchased, there is no such allowance; is the practice of central-station companies such that they can guarantee continuous service? The records of the past few years would hardly warrant any such assumption. On the other hand, the records of many individual plants are better than those of the central station, so we could reasonably wipe out the emergency-service charge or put a corresponding charge against purchased power.

I also note that the manager's time and the clerical expense are charged against the isolated plant at $1150, whereas the manager's time and clerical expense under the head of purchased power are but $25. It may be Mr. Parker's experience that no attempt is made to check the bills or to follow up the meters or to pay any attention to the cost of power as purchased. My experience, however, is different, and I believe that the proportion of manager's time and clerical expense chargeable against power in a plant with purchased power is very nearly as much, if not quite, as in an isolated plant.

I further note that the fixed charges against the isolated plant are pretty heavy, so heavy as to cause some question as to their actual fairness; I am led to question whether the central-station company makes any such charges against its own plant when it is supplying power at the low rate quoted. The central-station business is, of course, that of producing and selling power and if it invests any money in apparatus for the production and sale of power, it does it with the expectation of getting a fair return on the money, just the same as does an industrial enterprise of any character. If there is to be a charge termed profit ratio against the money invested in an industrial enterprise for production of power, in order that it may produce its goods, it would seem equally true that there should be a similar charge against the money invested in the apparatus of the central station. I decidedly question whether this is done.

It seems to me that the amortization figures would be somewhat larger for the central station than for the average industrial plant, owing to the fact that the machines are harder worked and scrapped earlier in their life to make place for new and more efficient apparatus. The taxes and interest might be somewhat smaller. My figures, comparing the central plant with the industrial plant, are as follows:

Marginal interest	5 per cent.
Amortization, so called	5 per cent.
Taxes and insurance	2 per cent.
Fair profit ratio	11 per cent.
Making total fixed charges	23 per cent.

Taking this as a basis of the fixed charges, I examined into the report of one or two of the big electric companies as given in the State report, and have taken their own figures as regards cost of plant, electric lines, transformers, meters, arc lamps, etc., and have taken their operating expenses, including operation of station, distribution of power and management. I have also taken the income as given in this report, which, according to the report, includes income from sale of current and other sources. In addition, I have taken into account the total kilowatt-hours generated and the total kilowatt-hours sold, also in accordance with the report. Against the total cost, I have made a charge of 23 per cent., leaving out, however, in this particular case, one-half of the real-estate cost, as the company owns considerable land which is not built upon and I wish to give all a fair show. From these figures I find that the average remuneration for the total kilowatt-hours generated is 4.7 cents per kilowatt-hour, and for the total kilowatt-hours sold, 6.6 cents per kilowatt-hour. Its expenses have been:

Operating, including distribution and management, 2.5 cents; per kilowatt-hour sold, 3.5 cents.

On the fixed charges, the cost per kilowatt-hour generated is 4.7 cents; per kilowatt-hour sold, 6.5 cents, making a total cost per kilowatt-hour generated of 7.3 cents, and for a kilowatt-hour sold, 10 cents.

These reports are average, but they show conclusively that there is something lacking in the method of charging if the total cost of producing power is 3.3 cents greater than the price for which it is sold. This would show, then, that according to Mr. Parker's figures and method of figuring that this company is operating at a loss. The company, however, is paying exceedingly good dividends and the stock is selling at considerably over par.

Apparently, then, the central station does not figure its costs on the same basis as it would have the individual plant figured. The average purchaser of power has not the remotest idea what his power bill is going to be. He leans entirely upon the sales agent of the central station, and in many cases goes so far as to allow the engineer of the central station to lay out his plant, in some cases relying upon him to such an extent as to wipe out his original plant, in the firm belief that the figures given to him by the central-station sales agent will be realized. The only safe way for the purchaser of power to make a contract with the central station is on the guarantee basis of the cost of power; and if the central station will not give a contract on the guarantee basis, the sales agent is either a fool or a knave and the chances favor the latter, for the fact that he will not make a guarantee is pretty good evidence that he is certain that his figures are not correct.

The purchaser has one recourse, that is to put the matter into the hands of a disinterested party for thorough investigation, in order that he may have a careful and concise estimate of the cost of the power used throughout his plant, what it will cost him to make the changes necessary to install the electric drive, and an estimate of the cost of power as operated by electric drive with the increased fixed charges due to the added installation and the loss of the apparatus which may have to be discarded. Every item entering into the operation of the plant should be gone into, for in the northern latitudes especially the question of heat is of much importance. There often is also the item of steam for industrial purposes, for heating water for toilet and other purposes, all of which should enter the calculation. The value of the electric drive as regards its cleanliness, convenience, economy of space, uniformity of speed and the possible increase in production due to the constant speed must also be considered.

The owner should be very careful that the man he employs to examine into these details goes into them so completely as to preclude any possibility of error, and that he, the owner, thoroughly understands what the engineer has done and what his figures mean. The engineer should explain the weaknesses and possible dangers of power as supplied from the central station. It is usually claimed that central-station power is more reliable than the power generated by isolated plants. This is questionable. The engines in an isolated plant are no more liable to break down than are those of the central station, nor are the boilers. There are no long-distance transmission lines to take into account, little or no danger of electrolytic troubles, practically no danger from operating troubles in the operating station, lighting is not a factor, and on the whole there is more reason to believe that the isolated plant is less liable to interruption than the central station. The isolated plant has against it the charges in common with the central station, except the added clerical expense of solicitors for business, meters and the meter readings, the clerical expense of rendering the bills and keeping track of the accounts and the very heavy expense of distributing lines and the losses over these lines, so that in isolated plants of fair size it ought actually to cost less at the isolated plant for power than at the central station. It would have to be a plant of pretty small size that could not produce power as cheaply as the central station could deliver it to this plant, not taking into account the value of steam for heating purposes, but figuring on using the best possible type of prime mover. Then, however, taking into account the value of steam for various uses, the cost of power might be considerably reduced; first, by a reduction in the first cost of the engine owing to using a less expensive type of engine, and, second, taking into account the value of the exhaust steam which would have to be supplied anyway.

HENRY D. JACKSON.

Boston, Mass.

Valve Leakage

At various times articles have appeared in POWER on the subject of leakage through slide valves. Some of these have tended to show the advantage of the single-valve type of engine over the four-valve type using flat balanced valves.

Perhaps my experience with a pair of engines of the latter type might be of interest in that it does not agree with some of the statements made in the articles referred to above, in which it was claimed that these valves were hard to keep steam tight due to excessive wear and the large amount of clearance required between the valves and pressure plates.

In the engines of which I am writing the clearance amounts to 0.003 of an inch on the steam side and 0.0025 of an inch on the exhaust side. During ten years' time the wear on these valves was about 0.01 of an inch, which was taken up at intervals of about two years, about 0.002 at a time. The method used to determine the clearance is to shut the engine down after a run and while all of the parts are as near the working temperature as possible insert the blades of a thickness gage at different points of the valve travel.

At one time the steam valve of one engine became leaky while the exhaust remained tight and the result was the engine would run off when no load was on the generator. A few hours' work with the scraping tools stopped this trouble. This goes to prove that leakage from the steam chest to the cylinder is not entirely lost as it is when the single valve leaks steam into the exhaust passage. The amount of clearance is largely a matter of design and temperature and the wear a matter of good metal and lubrication.

The advantage of independent release and compression is well worth the extra complication, and the large ports and small clearances possible with this design more than make up for the friction of the extra parts.

P. L. [illegible].

McKeesport, Penn.

Writers among Engineers

The question has been asked why more engineers do not write of their experience.

Those that do write should at least be given credit for their intention of letting others profit by their experience, and when their letters are castigated as "hot air" and "rot," I say it is wrong and uncalled for.

In the March 21 issue, under the heading "Specialists," Mr. Scotch tells us the class of an engineer that he is and he evidently thinks that the same class of engineer writes the practical letters in POWER.

I would like to tell Mr. Scotch that the writers of practical letters do not get their inspiration from furnaces or gas houses and that the erector or experts sent out by the manufacturer today are human and as liable to make mistakes as any other men. But, their mistakes, as a rule, do not come under the observation of the dinky one-horse engineer. The practical progressive engineer that has work going on, either repair or new installation, is onto his job and when things are not going right, whether it is the fault of the mason, carpenter, erecting engineer or laborer, he does not stop to consider how many years' experience he has had; he corrects the trouble, for that is what he is there for.

M. [illegible].

Burlington, Vt.

In the issue of March 21, Mr. Beck[illegible]with makes a good point. He asks for information in regard to getting up an article and the best subjects to write upon or rather the most acceptable ones. Here is the rub with most people, the failure to realize that many of the little, everyday happenings, the commonplace incidents of their own experience are not commonplace to many others, even to the editors, who have opportunity to see the work of many. The trouble is to get started on an article. The first word, the first paragraph is the hardest to get, the rest will come of itself. As for the subject it is hard to assign one offhand, but here is a suggestion for a number of subjects. Just use your eyes and your ears. Look around your own "diggings" and observe how you or the other fellow does something, then find out the reason and get busy. Just listen to the questions others ask you, the experiences they tell you; it is easy to find a story, for something which will interest you while one hears it will interest others when they read it.

The shape in which you present your material to the editor is not so very important if your subject is a good, strong one, but there are a few conventions that should be observed. The following are the most important:

Write on one side of the paper only. Do not try to crowd too much on a sheet. Start a couple of inches from the top of the sheet. Leave a fair margin at the sides. Leave some room between the lines. This will permit you to make corrections without rewriting. It will also permit the editor to make corrections and will save time. Paper is the cheapest thing about an article, so it is not worth while to economize in it. Do not waste your time in rewriting; simply make all the corrections in the first draft in such a way that they can be read. If you have to make a long insertion where you have left out something, write it on another sheet of paper and mark it and the place where it is to be inserted.

Write your name and address at the top of the first sheet. Number all sheets in consecutive order. It is a good plan to give your article a title and to place that title with your name upon each sheet of the article. Then if you happen to dump the bunch of literature on the floor you can sort it out and rearrange it without much waste of time.

Remember the one-page article, one page of your manuscript, may be more useful to the editor than the forty-page manuscript. It is easy to find a place for the short article; for the long one, it is sometimes a difficulty.

Finally, do not be afraid of your spelling or the way in which you write a thing down. Remember that the compositor, aye, even the editor, is not infallible. If you have a message, get it out of your system in some way or other, and then forget it. The most important thing is to get it out.

A. D. Williams.

Overload Boiler Test

In looking through the issue of March 21 I noticed an article entitled, "A Remarkable Overload Boiler Test." There are several things in the report of these tests that strike me as peculiar and I question some of the results given. For instance, the heat units given, upon which all efficiencies are based, are not, apparently, the result of a calorimetric test. Also, it seems to me something more than a coincidence that the grate efficiency of 97.12 per cent. should be identical to the last decimal place for both tests. I think you will find on investigation that the ashes in these tests were not analyzed and that the grate efficiency given is the result of a theoretical correction applied to the weight of the refuse based upon the coal analysis. It would indeed be remarkable if we could run a stoker of this type, or in fact any other, at the ratings given, with a grate efficiency of 97 per cent. It very likely would be closer to 95 per cent.

There is nothing very remarkable in the capacities developed, as with this type of stoker it should be entirely possible to operate the present-day boilers at 200 per cent. of rating continuously and I should think it would be well not to call this overload capacity as it seems to me that we are just learning how to burn coal and get some results out of the heating surface of the boiler.

I have in mind several recent contracts made for stokers of this type, which call for as high as 240 per cent. of builders' rating to be developed for a period of several hours.

Improvement Turned Down

All business men do not seem willing to take advantage of a saving in dollars and cents when it is put plainly before them. According to R. O. Warren in a recent issue they do. But, how about this:

The coal bill of the plant in which I am employed averages $82 per week. After due investigation and consideration I made the proposal to reduce the weekly bill $17 by the outlay of $500. About 80 per cent. of our work is supplying steam for drying rooms and for cylinders over which goods pass to be dried. In order to obtain proper drying it is necessary to carry a pressure of 80 to 95 pounds. After a test I found that 60 pounds pressure was enough for the power requirements but not enough for the drying. On inquiry I found that a separately fired superheater large enough for our needs could be purchased for $450 and $50 would pay for the necessary piping and fittings. This arrangement would give us 75 degrees of superheat with 60 pounds boiler pressure or about 380 degrees in the coils of the drying rooms, which is about 50 degrees higher than the temperature due to saturated steam at 90 pounds pressure. The expert from the superheater manufacturers went over the whole thing with me and agreed that the saving could be made. The saving would have been made by burning a cheaper grade of coal with which 60 pounds pressure could be maintained. In order to keep an average pressure of 85 pounds, I must burn coal costing 85 cents per ton more.

Perhaps it is not good engineering to reduce the pressure and then superheat to obtain the same results, but the saving in dollars and cents would be made and that is the main point. My proposition was considered by the firm and turned down. The reason why it was not accepted was because first cost only was considered.

Harold James.

New York City.

Pressure and Pump Plunger

It seems to me that the reason for the breaking of the pump described by Mr. Potter in the March 28 number is very apparent if the cycle of operations be considered.

Consider the pump to be ready for operation with all of the cylinders empty and with the proper connections made to the well and to the discharge main. As soon as the pump is started the cylinders fill with water below the pistons on the up stroke. Then, on the down stroke this water is discharged and a partial vacuum is created in the cylinders above the pistons. These spaces are connected each to the other and to the well. As the supply pipe to the upper chambers was not of sufficient capacity to admit of filling them at a single stroke, the pumping had to continue a little before the upper space was filled. This finally occurred, however, and then there was a solid body of water filling the entire volume including the supply pipe back to the well. This water was in a state of constant vibration or oscillation due to the motion of the piston and the total quantity remained constant.

Suppose, now, that the supply pipe or, in fact, any portion of the system were suddenly restricted to a greater or less extent. Pressure would instantly develop which in Mr. Potter's case only found relief in rupturing the pump.

The pump which Mr. Potter described is apparently neither a single-acting plunger pump nor a double-acting piston machine but rather a hybrid affair.

T. D. Hayes.

Cambridge, Mass.

Engineers and Boiler Inspectors

I have been taking a great deal of interest in the editorials and articles on boilers and boiler inspection which have appeared in Power from time to time.

I think that engineers should have nothing but the most kindly feeling toward inspectors. Unfortunately, there are engineers who seem to hate inspectors, who hide defects and in every possible way make it difficult for the inspectors to do their full duty.

When I am notified that an inspector will call on me at a certain time, I try to have things ready and convenient for him and I am careful to have things so that the inspector may see the boilers in the same condition as that in which they are operated—I do not touch a thing inside.

POWER

Technical Education

The Technology Congress recently held in Boston to commemorate the fiftieth anniversary of the founding of the Massachusetts Institute of Technology also marks an epoch of engineering development unequaled during any like period in history, a development in which the technically trained engineer has played a very important part.

Fifty years ago steam engineering was in its infancy; the steam engine in small units had been applied to mill work, but the power house, as we now understand it, had not yet made its appearance. Electricity had not been applied to commercial utilities, such as lighting and the transmission of power, but instead was still a product of the laboratory. The telephone was still in an experimental stage, tunnels were yet to be successfully constructed under rivers, the railroads were undeveloped and sanitary engineering, which has been such a large factor in improving health in our large cities, was then unknown.

The engineer of that day received his training through an apprenticeship course, which, although usually thorough, was more or less narrow. However, as the engineering problems were limited in extent, this preparation answered the purpose very well. Moreover, due to the limited size and character of these projects, they could usually be planned and carried out by one man. With the enormous increase in the magnitude and the diversity in the character of engineering projects during recent years, the methods of handling them have changed, and their successful completion has been made possible only through organization. Likewise, the qualifications of the engineer have changed; his training along engineering lines must be broader and he must possess executive ability.

Previous to 1860, the colleges had offered only courses in history, literature, languages, pure science and a few of the older professions, such as medicine and law. About this time, however, a number of far-sighted men, individually, conceived the possibilities of some of the rather crude mechanical appliances then in vogue and recognized that there was much in the realms of pure science which could profitably be applied in extending the industrial development of the country. In other words they did not coincide with the prevailing belief that theory and practice were incompatible, but instead were convinced that the two should be made to serve the ends hand in hand. To accomplish this they recognized the necessity of systematic study and training in applied science. Consequently, through the efforts of these individuals, several of our large technical schools were founded almost simultaneously.

There is a mistaken impression in many circles that the technical schools attempt to turn out finished engineers. Such is not the case, and no reputable school will attempt to make such claims. The most they can do is to give the students a thorough grounding in the fundamentals of engineering and to train them in systematic methods of attacking engineering problems. This, combined with the experience gained in actual practice, goes to make up the successful engineer and has been instrumental in placing engineering upon an equal footing with the so-called learned professions.

Chicago Smoke

In a report of the work of the Department of Smoke Inspection from the time of its organization in October, 1907, to December 31, 1910, Paul P. Bird, chief smoke inspector, calls attention to the fact that Chicago is essentially a manufacturing and commercial rather than a residential city, and that in attempting to eliminate smoke it is not possible nor practicable to pursue any policy which will injure the interests of the railroads, shops, factories, mills, packing houses, etc., that are spread over the one hundred and ninety-three square miles of the city's area and have made Chicago what it is today.

The power and heating for this large city are practically all produced from soft coal, only about five per cent. of the total coal being anthracite and about ten per cent. semi-bituminous from the West Virginia district. The remaining eighty-five per cent. is from the local coalfields of Illinois and Indiana.

At the close of 1909 there were, according to the department, about seven thousand high pressure boilers in Chicago exclusive of locomotive and marine boilers. Low pressure boilers which are also a factor in the smoke question number about twelve thousand two hundred and fifty.

Further investigation has shown that among the high-pressure plants there are on an average of two boilers to each stack, so there doubtless are in the city limits about three thousand five hundred smokestacks connected to high-pressure boilers. Similarly there are about 1.16 low-pressure boilers to each stack, or about ten thousand five hundred smokestacks in Chicago connected to low-pressure boilers, making a total number of smokestacks for stationary purposes of fourteen thousand.

During the last few months of the year 1910, the department made a careful investigation of the subject and, as a result, estimates that there are burned annually in the city limits of Chicago, ten million tons of bituminous coal, divided as follows:

Class	Consumer	Annual Consumption	Per Cent.
1	Central district....	1,500,000	15.0
2	Miscellaneous power plants...........	4,500,000	45.0
3	Flats..............	750,000	7.5
4	Domestic...........	650,000	6.5
5	Special furnaces....	600,000	6.0
6	Railroads..........	1,850,000	18.5
7	Boats..............	150,000	1.5
		10,000,000	100.0

To burn this enormous amount of fuel fifteen to twenty thousand men are constantly employed, and as long as the smokelessness of the city depends upon the carefulness of this great number of individuals, the work of keeping them at the highest degree of efficiency will be stupendous.

As an ultimate solution of the smoke question the department recommends the centralization of plants. In every block in the central district there are from two to twenty steam plants and in the manufacturing districts each factory, no matter how large or small, has its own power-generating outfit. If, in place of this multitude of small plants, a relatively few large power houses could be installed, the result, according to the report, would be most beneficial from a smoke-prevention standpoint, as the large plants would be equipped with automatic stokers, would operate under fairly uniform load conditions and it would be an easy matter to prevent smoke.

This recommendation is made, of course, without regard to financial or commercial considerations, which might, when analyzed, prove the scheme impracticable. As a matter of fact it is generally conceded that smoke from stationary power plants will give less and less trouble as time goes on and proper supervision by the city authorities is exercised. In the stationary plant there is generally ample room to install furnaces of proper design, with large combustion areas and mixing chambers, so that it is reasonable to hope for practical elimination of the smoke nuisance from this class of plant. It is from the railroads that the greatest trouble is encountered. Railroads are credited by the department with making forty-three per cent. of the total smoke of Chicago and over fifty per cent. of the total dirt, due to cinders, ashes, etc. Electrification is advanced as the only means whereby this may be absolutely eliminated.

During the present smoke administration there has been a great improvement in the atmospheric condition of Chicago. In the "loop" district this is especially marked. When it is considered that the fourteen men whose duty it is to observe the stacks of the city, have approximately twelve hundred stacks in each of their territories, covering fourteen square miles apiece, it is truly remarkable what has been accomplished along this line.

If the amount of smoke that was being made in 1907 at the beginning of the present administration be represented by one hundred, it is stated that the smoke now made, at the end of the administration, may be represented by sixty-six.

If all of the railroads coming into Chicago should be electrified, with other conditions remaining as they are, the amount of smoke that would then be made is estimated at thirty-eight.

With all the railroads electrified, all boats in the river burning hard coal, all flats heated by gas or coke and central-station power and heating plants covering the city, the amount of smoke is placed at five; while under the best theoretical conditions, with all power electrical, and all heat electrical, or obtained from gas or coke, the smoke conditions are placed at zero.

It will be a great many years before these ideal conditions are even approximated. In the meantime the smoke administration just coming to a close, has organized and placed on a solid engineering basis, a city department, the value of which, to the citizens of Chicago, cannot be overestimated.

Electricity and the Engineer

Although electricity has now found application in most fields of industry it is still regarded by the layman with a sense of mystery. This is probably due to the fact that scientists have thus far failed to furnish a simple definition of electricity; they know how it is produced and that it follows certain well defined laws; but all attempts at telling exactly what it is have resulted in elaborate theories which only they themselves can comprehend.

Electricity, however, is not alone in this position; there are numerous other phenomena which are known only by their effects, but which are of such common occurrence as to excite no curiosity. Perhaps the most common of these is gravitation. Everyone knows that a body left entirely unsupported will fall toward the earth with a certain force, depending upon its mass. The measure of this force is called weight, a term with which everyone is so familiar that it carries with it a certain assurance of its identity; yet if one were called upon to explain exactly what gravitation is, he would probably find himself in a position similar to that of a man trying to give a definition of electricity.

Engineering, however, is not concerned with what electricity is but rather with what it will do, and this is now pretty definitely known. It is not a source of energy but is a medium for the transmission of energy, in many ways fulfilling the same uses as shafting, belts and gears; it possesses, however, much greater flexibility of application than any mechanical means. If the operating engineer would regard electricity in this sense and then become familiar with the established laws which it follows, he would find little trouble in understanding the operation of the electrical part of the plant equipment. Such knowledge is essential to the engineer of today if he is to keep pace with the increased responsibilities of his position.

Many engineers will go down without a struggle before a formula which has a logarithm, entropy, or a sine, cosine or tangent in it. It is just as simple to look up one of these quantities and to substitute the value given in the table for the letters of the formula as it is to hunt up the steam temperature corresponding to a given pressure or the area corresponding to a given diameter, and the same book which contains the tables of the properties of steam and of circumferences and areas will usually have the other things too.

The correspondents of *The Engineer*, of London, are having an animated discussion regarding the live-steam feed-water heater. Will a boiler actually deliver more steam per pound of fuel burned, if a part of the steam which it makes is used to heat the feed water to the boiling point? And, if so, why?

Investigation will show that water powers are not "gold mines" and that it costs something for their development. In fact, in many cases they cannot successfully compete with steam or gas.

Have you ever talked things over with the owner and found him a gentleman and willing to help carry out your suggestions?

There seems to be a great variety of opinion regarding the proper control of water powers. At present the Government has no definite policy except to maintain the existing status of confusion.

Have you noticed in small plants that some men leave the door between the engine and boiler rooms open when coal is being delivered and ashes removed?

"It is not so bad to be ignorant as it is to know so many things which are not true."

Inquiries of General Interest

Questions are not answered unless accompanied by the name and address of the inquirer. This page is for you when stuck—use it

Area of Pump Valves

How is the proper area for the discharge valves of a pump determined?

J. C. K.

The area should be such that at a piston speed of 100 feet per minute the velocity of the water through the valves shall not exceed 200 feet per minute, that is, the effective discharge area of all the valves should, at least, be equal to one-half the area of the piston. Some builders, however, make the valve area two-fifths that of the piston.

Ratio of Air Pump to Steam Cylinder

What should be the ratio between steam- and air-pump volume for a simple condensing engine?

J. A. L.

For an equal number of strokes in the case of a single-acting pump and jet condenser the ratio of cylinder volumes should be from 5 to 1 to 10 to 1. For a double-acting pump the ratio may be from 8 to 1 to 16 to 1, depending on temperature of injection water, hotwell temperature, terminal pressure in the cylinder, etc. For a surface condenser a double-acting air pump may have a piston displacement 1/25 of the steam piston.

Compound Engine Cylinder Ratios

What would be the comparative diameter of the low-pressure cylinder of a compound engine to develop the same horsepower as a simple engine at the same speed and steam pressure?

C. L. R.

If the work done is to be the same in both cases the number of expansions must be the same, consequently, with the same initial and terminal pressures the diameter of the low-pressure cylinder of the compound engine must be equal to the diameter of the single cylinder of the simple engine.

Energy in One Pound of Coal

If all of the energy in a pound of coal could be utilized, how much power would it develop?

E. P. C.

Coals vary in heat value, but if a pound could give up 14,000 heat units it would be the equivalent of

14,000 × 778 = 10,892,000 *foot-pounds*

or energy enough if it could all be used to project itself over 2000 miles upward.

Dynamo and Motor Speeds

Why does a machine run at a slower speed when operating as a motor than when being driven as a dynamo, the terminal voltage being the same in both cases?

C. F. J.

Because the resistance of the armature circuit cuts down the net voltage to be balanced by the motor's counter electromotive force and adds to the electromotive force that the dynamo must generate. Suppose the armature winding and field strength to be such that the armature will generate one-tenth of a volt for each revolution per minute and the drop in the armature circuit is 5 volts at full-load current. Running as a dynamo delivering 110 volts, the armature must generate 115 volts total, to overcome the internal drop; the speed then will be 1150 revolutions per minute. Running as a motor on a 110-volt circuit, the armature drop of 5 volts leaves 105 volts to be balanced by counter electromotive force; to generate 105 volts, the speed needs to be only 1050 revolutions per minute, or 100 revolutions per minute less than the dynamo speed.

Shunt Strip of a Compound-wound Dynamo

What is the purpose of the shunt strip across the series field winding of a compound-wound dynamo?

T. B.

To adjust the proportion of the armature current that passes through the series winding and, thereby, the compounding effect of the winding. Read the "Primer of Electricity" in the February 21 number.

Proportions of a Gasolene Motor

In a gasolene motor for a small load, what relation of bore to stroke would you advise and what compression pressure and piston speed?

J. T. W.

Make the stroke one-fourth to one-third greater than the diameter of the cylinder bore, according to how your power and speed work out. The compression pressure should not be over 70 pounds gage; the piston speed may be anywhere from 400 to 800 feet per minute, according to your power and rotary speed requirements. The reciprocating parts must be designed in view of the speed selected as well as the pressures involved.

Ignition Current from Lighting Circuit

Can a jump-spark ignition system, using the ordinary induction coil and vibrator, be supplied from a 110-volt incandescent-lighting circuit?

J. R. L.

Not satisfactorily, unless special provision be made for reducing the voltage at the primary terminals of the coil. Simply putting resistance in series with the primary winding is not satisfactory because the vibrator has to open a 110-volt circuit instead of a 6-volt circuit. The nearest approach to a satisfactory arrangement of this sort is a resistance coil connected directly across the 110-volt circuit, the primary circuit of the ignition system being connected to the resistance coil at such points as to get 6 volts potential for the system (see accompanying diagram). This is wasteful, because current flows through the resistance coil all the time and at the full circuit voltage.

Advantages of Condensing Engine

What two advantages has a condensing engine over one which is noncondensing?

C. F. K.

Two advantages of a condensing engine over a noncondensing engine are that more power can be obtained out of a given sized cylinder and it can be obtained more cheaply; that is, for less steam per indicated horsepower-hour.

Reversing a Compound-wound Motor

What is the best way to change the connections of a compound-wound motor for reversing its direction of rotation?

S. G. R.

Exchange the connections of the cables leading to the brushholders so that the current will go through the armature in the opposite direction. Do not make any change in the connections of the field windings.

Government Control of Water Powers

A continuation of the report presented in last week's number on the water-power conference held by the National Electric Light Association.

J. R. McKee: The public domain of the Government of the United States, including all the cessions from the thirteen States that made cessions and, including Alaska, amount in all to about 1,800,000,000 acres. Of this there is left as purely Government property, outside of Alaska, something like 700,000,000 acres. Of this the National Forest Reserves in the United States proper embrace 144,000,000 acres; the rest is largely arid or mountain country, offering some opportunity for agriculture by dry farming and by reclamation and containing metals as well as coal, phosphates, oils and natural gas. To the above 144,000,000 acres of forest belonging to the Government should be added 26,000,000 additional acres withdrawn in two forests in Alaska. Omitting Alaska, the 144,000,000 acres of forestry land withdrawn is equivalent to more than 27 States the size of Massachusetts.

In giving the extraordinary figure as to the amount of land in the forestry bureau, I do not understand that these figures include the 92,000,000 acres additional of land covered by document 10,860—lands withdrawn from settlement under provision of an act of June 25, 1910. Adding these 92,000,000 acres it means an additional area equivalent to an excess of 17 States the size of Massachusetts; for the two combined an area equivalent to an excess of 44 States the size of Massachusetts.

Appropriations for the support of the forestry bureau beginning with the year 1900, when they were $48,500, increased until in the year 1911 the appropriations for the support of that bureau are $5,051,000, making the total appropriations for the support of the bureau to date approximately $23,000,000. According to Congressman Edward T. Taylor from Colorado, who quoted the former head of the forest service, this forest system when it reaches its real development will require the services of 118,000 to 120,000 men.

I have taken the list of appropriations made by the last Congress and, including all of the salaries from the secretary of the forest service down to the office boy, the average salary is in excess of $1200 per year each. Assuming these same figures it means when the forest service comes to its own the salary list alone will be $144,000,000 per year. The question naturally arises in the minds of some people as to whether this is not pretty nearly a case of the Government owning its own forests and buying them over again from itself.

For the benefit of those who are not familiar with the subject, I would state that the forest reserves are established not only for the cutting of timber but are let out for pasturing. For instance, during the last year, there have been pastured on the forest reserves nearly 1½ million cattle, in excess of 85,000 horses and over 7½ million of sheep and for this the Government has received over $986,000 which, however, was less than they received the previous year from this source. From the timber sold they received just a little over $1,000,000. Taking last year's (1910) appropriations for the support of the forest bureau, which were $4,682,000, the total cost for that year's upkeep amounted to a total of $6,711,428. We all know what compound interest means and if one will take these appropriations as a start and compound the interest on them and charge them against the forest reserves and add to that the additional appropriations as they come along, it is hardly necessary to say how startling the figures will become.

I have dwelt upon these figures and this situation because I am wondering if this has not a great deal to do with the attitude of the Government officials. It is only human that those who undertake enterprises want to see them work out successfully, whether they be individuals in the Government employ or otherwise.

The 92,000,000 acres mentioned as withdrawn under the special act included those upon which it was thought there might be found coal, oil, gas or sites available for water power. Now, in regard to the latter these lands as they now stand are so tied up that it is impossible for anyone, no matter how sincere or desirous they may be of locating upon them, to get located. In other words, there is no law under which the Government can allow him to acquire possession. Suppose you found a site or parcel you would like to take up and develop and you notified the department. The President might give orders to restore this land to the public domain and let you locate upon it. What right has the President to give you preference? In other words, would he not find himself in a position similar to the one, for instance, where the Indian or other reservations are thrown open to entry and where a date is fixed and an order is given and the proposed settlers line up at the border and at the sound of a gun make a rush and the first one to arrive at the location gets it.

Mr. McKee then presented a situation not only possible but not at all improbable, showing the difficulties that might be expected in building on a navigable stream and in erecting a pole line. A brief abstract follows:

Suppose that you own by outright purchase the shore lines along a stream whereby the erection of a dam, a head suitable for the development of power can be secured. It happens that the stream in question at some point below the proposed dam, not necessarily near it, is navigable, but at the particular point where you wish to put your dam, it is impassable. In other words, there is not sufficient water for navigation and the stream is not of sufficient size to be navigated above there, although presenting the possibility that by the aid of the Rivers and Harbors Committee in the way of an appropriation, it might be made so, but whether commercially is a question. You, however, own this property and want to develop it. You must go before Congress for the privilege because it is called a navigable stream. You get an act passed granting this right and there is attached to it the stipulations that you must at the time or thereafter, if the Government so orders, construct at your own expense and on your own land, locks and operate them without expense to the Government, giving preference to whatever water there may be available without regard to what effect this may have on your power-generating plant, which, by the way, may be a serious situation during low-water periods. You have now dealt with Congress and your stipulation is that you must thereafter deal with the Secretary of War and also the Chief of Engineers.

For your transmission line it happens that adjacent to your site is a farming land where the homesteader has filed and is living in process of acquiring title. Of course, the homesteader has not yet secured his title and therefore cannot give you any right to cross his land. The Government also cannot give you any right because the land has been filed upon by the homesteader and to that extent it is beyond the privilege of the Government. So if you go across this land with your pole line it must be illegally. Adjoining the homesteader's land and also to be crossed by your transmission line is land still in the public domain. If you wish to cross this you must deal with the Secretary of the Interior, who will impose upon you such restrictions as he deems essential, such as police regulations, stipulations as to charges and limit as to time. The next land your pole line has to cross is a forest reserve. You much now take up your negotiations with the Secretary of Agriculture who will suggest to you a use agreement with time limits and stipulations as to charges, etc., and these charges have been suggested on a basis as though your entire plant was on the public domain. Finally you reach your destination for delivery of power and it is a city where you own the electric-lighting company and you will probably come under a public-service commission who will also stipulate charges and other regulations. You now have a property to get together with which you have dealt with Congress, the Secretary of War, Chief of Engineers, a homesteader, Secretary of the Interior, Secretary of Agriculture and a public-service commission.

What is to be the solution of such a complex situation as this and is it not absolutely imperative that there shall be some solution before it is possible to persuade financial interests to undertake any such enterprises?

Personally I think that water-power sites ought to be made readily available and it should be possible for them to be taken up and developed the same as a railroad can locate on public lands, and presuming they will be developed as a public utility, which most of them certainly are, I do not see why it should not be a sufficient safeguard if they be brought under the regulations of the local authorities, the same as other public utilities. The true regulation of water powers is that which will prevail and pertain to the respective localities where they may be located. Public-service commissions are handling these questions broadly and I think that their experience demonstrates that this is the most satisfactory and the ultimate outcome of the entire situation.

Ralph D. Mershon: A discussion of this important question resolves itself into the following questions:

1. Shall the control of these hydraulic development sites lie with the Federal government, or with the respective State governments?

2. If the present Federal control be ceded to the respective State governments, shall such action be absolute or with restriction?

3. Whether the control rests with the Federal Government or with the respective State governments, shall absolute title in these sites be ultimately passed to the individual or corporation; or, shall the ultimate title remain with the people?

4. If the ultimate title be passed from the people, how shall it pass? By mere location and exploitation, or by some form of competitive purchase?

5. If the ultimate title is not passed from the people, how shall such title, as is passed, be limited as to the length of tenure and the privileges it conveys? Furthermore, what method shall be employed for determining who shall be the recipient of such title as conveyed.

My views in regard to questions 1 and 2 are that the control should be vested in the respective State governments, but that the Federal control should be ceded with such restrictions as will result in uniformity in these matters among the States. Regarding questions 3 and 4, I believe that in no case should absolute title to the water-power sites, which are at present on the public domain, be passed to individuals or corporations; that the ultimate title to these sites and all rights in connection therewith should remain with the people.

Item 5 cannot be so simply disposed of as the preceding items as individual cases will differ. It must be borne in mind that these enterprises should be attractive to capital, and ample time should be allowed in which to accumulate the necessary physical data, and in which to make financial arrangements under such conditions as will be manifestly fair toward those acting in good faith, while endeavoring to insure against mere monopolistic or speculative control.

It is held by some that the idea of a limited tenure is economically unsound and financially impracticable. I do not agree with either of these statements. Certainly at the present time no one, for either financial or economic reasons, would refuse to invest in a public-utility enterprise simply because the contract had a limited time to run. If such a limitation of tenure is unobjectionable in the case of a public utility, I can see no reason why it should be objectionable in the case of hydraulic development sites.

I believe it possible to satisfactorily and equitably handle these matters from the point of view that the rights conferred upon the individual or corporation making the developments are in the nature of a franchise, and are neither absolute nor perpetual.

As I understand it, Mr. Doherty's claim is that a limited tenure of water-power rights must necessarily result in greater cost of power and otherwise to the detriment of the consumer; that this is uneconomical and that the only course broadly economical is that of perpetual tenure in one form or another. The elements of this argument are as follows:

1. That limited tenure will make it difficult to finance and enterprise a development, which will mean a higher rate of interest and this, in turn, must be borne by the consumer.

2. That under unlimited tenure, bonds can be refunded as they fall due, thus obviating the necessity of a sinking fund, but that limited tenure will require amortization of the bonds; hence the sinking fund or its equivalent.

3. That as the end of the tenure approaches, it will be increasingly difficult to provide money for any needed extensions or improvements, with the result that either the service will be less effective or that the price of power will be higher.

The foregoing propositions are predicted upon the assumption that the physical property will at the end of the term of years pass in fee simple to the State. On such assumptions they are undoubtedly true, though the degree to which they are true will depend upon the length of tenure. I believe, however, that this assumption is not necessarily true. So far as limited tenure is concerned, objections 2 and 3 will evidently be done away with if the bonds representing the money expended in creating and extending the property carry with them the assurance that at the end of their term the principal will be paid or the property will again be available for bond issue.

The only apparent reason why limited tenure should, in itself, be productive of objection 1 is that if the enterprise were unsuccessful and they were unable to amortize the bond, they would find themselves at the end of the bond series with neither principal nor property on which to foreclose. But such contingency also will be obviated by the clause suggested for meeting objections 2 and 3.

It seems to me the conditions indicated will be fulfilled and therefore the objections met by the following clause:

This was to build and extend the plant under the State's supervision and operate it for a term of years under the State's supervision as to maintenance. Let the time be extended at its expiry or, if not extended, let the State redeem or guarantee the bond issue for the creation and the extension of the property.

I believe the majority of the people in this country are unalterably opposed to passing absolute title to these water powers to individuals or groups of individuals. It seems to me, therefore, that these gentlemen who are now opposing the policy of limited tenure had much better bow to the inevitable and cheerfully assist in devising effective plans for the carrying out of this policy. By so doing, they will be encouraged in that rapid development of water powers which they advocate, whereas their present attitude will merely serve to retard development.

Calvert Townley: I am strongly opposed to Governmental meddling with hydroelectric properties by control, regulation, by special taxes, or any other way whatsoever, except by the exercise of the ordinary police power to maintain and uphold the law where necessary, and by the collection of the usual and ordinary taxes the same as would be collected on all other real property.

A tax on water powers can evidently be imposed only for one or both of two reasons: First, to restrict or control the development; second, to produce revenue.

for the Government. It would be wrong in both counts. If a tax is to be imposed to produce revenue for the Government, it will fail in its purpose. If the rate be made so small as to have an insignificant effect upon the power company's expenses, can it have other than an insignificant effect upon the Government's revenue? And if the rate be made high enough to afford a substantial revenue it must act to deter many developments, which under the most favorable conditions might be made, and thus both keep the Government from getting any revenue and the neighborhood from any advantages which cheap power might offer toward improving that section of the country.

Public-service corporations of all kinds are now in process of being regulated and controlled. No one can say where the process will stop. Occasionally a corporation official is found who says he thinks this control will benefit his company. The very great majority, however, feel that such control will either limit their earnings or increase their expenses, or both, and thereby make their securities less attractive to investors.

It is impossible to convince the promoter who wants to invest other people's money that a water power is not a splendid investment, and it is useless to argue with the man who knows all about the subject but has not yet tried it. However, a list of hydraulic developments—real ones, those that actually have been and are now doing business—showing the amount of money put in and the amount taken out, would make interesting reading. The small percentage of earnings and the number of plants that have gone to the bad financially might astonish some of our able-bodied legislators who are afraid that somebody may make money while they are not looking.

Percy Thomas: The thing that is to be avoided is monopolistic control which will permit an original owner from reaping a tremendous profit, say, after fifty or one hundred years, when the property may have become extremely valuable.

Suppose we are going to give a fifty-year franchise for the development of a water power. The public, in addition to having fair service, etc., expects to get some rental from that. Suppose the Government is arbitrary and says—if you develop 50,000 horsepower, that shall be so much per horsepower, from the beginning to the end, each year. That would be very difficult for the capitalist. Suppose, on the other hand, the public is ready to take low rates at first, before the public demand is quite up to the full installation, and a higher rate toward the end of the term, when the consumption is fuller, and the load factor is satisfactory? That makes very little difference to the public. We will assume that the public gets the same total amount out of it, but it makes an enormous difference to the investor—he knows that he will not have to pay the taxes until he has something to pay them with.

Take the point about amortization—we have the same fifty-year term of the franchise—the public can be assured, nineteen chances out of twenty, that at the end of the fifty-year term in some form or other they will get back the money invested in the plant. At the end of the fifty years they will either agree, as a matter of reason, to extend the franchise, or make someone else pay the value of it, or force the Government to pay for it, if the Government will take it over. There is every chance that the Government will get something for it, and they might as well agree that they will take it over, as they have in the case of the New York subway. It makes little difference to the public whether or not it is arranged for in the beginning, but it makes an enormous difference to the man who has to raise the money.

If that point of view is taken by those who have the final arrangements to make, namely, that the rights of the public should be secured in such way as to be most favorable to the capitalist, and the capitalist is willing to take his security and profit in the way that will be of greatest advantage to the public, I think we will get along more satisfactorily than if each side is arbitrary and thinks its arrangement is best, and insists on something which appears to be theoretically correct.

Regulation must be arranged in such a way that the rivers which are interstate shall be protected. Take the case where a river flows from one State to another, and the development may have been made in the State in which the river flows somewhere near the border, and a profitable business built up. Now, the State which grants the franchise and the water rights to this plant has no control in the next State, and we will say, later, in the next State another water power is developed near the point at which this river leaves the second State. Now, in view of the fact that there may be pondage in the upper plant, they may store water by night for use in the day time, but if the two plants happen to be the right distance apart, the period during which no water is passed at the upper plant becomes the day period, when the maximum flow of water is necessary at the lower plant, and also the free flow of water occurring during the day in the upper plant will occur perhaps at night when in the lower plant it is of little use. Thus, if we are to have State regulation and State control of water powers, they must be secured in such a manner that one State will respect the rights and privileges already granted by another State.

Francis E. Frothingham: The public-service corporation, while it serves the needs of a great many people, serves the needs of a minority of the people, and it is right and proper, it seems to me, that many of the taxes borne should be directly levied against the public service and stood by those benefited from it, but there are other kinds of taxes which should not be so borne, such as the building of a lock in the Mississippi river development, for instance, and the giving of it to the Government, and a lot of things of that same kind, and these taxes should be distributed among all the beneficiaries. If we create a reservoir on the head waters of a stream, the beneficiaries therefrom are every power user below, and they should stand some of its cost. Every other abutting property owner, and every farmer who has land that is irrigated at high water, also benefits, as well as the navigable interests in the river, by such improvements. Therefore, these taxes should be distributed among all the beneficiaries. If the problem is gone at fairly and reasonably, I think the Government will meet us at every point, sooner or later, and all that we need is to be the source of the latest technical information and advise the Government, which, after all, wants to work to the best interests of all the people.

James H. Cutler: What we all want is the decision of this thing based on intelligence rather than ignorance, based on a spirit of fairness rather than that of self-interest, and I believe that the day is not far distant when that will be done.

It has been assumed, and I think correctly, that 3,000,000 horsepower are in the mountains of western North Carolina, and in that section, which, if the bill which has now passed Congress and has the President's signature, had not been passed and become a law of the land, the day would not be far distant when this 3,000,000 horsepower of water would be gone—and when such a power is gone, it is almost impossible to get it back again, except, certainly, at very great expense. They have been through that in France and know what it is to reforest the mountains, to get the land in condition so that the trees may grow. Now, that 3,000,000 horsepower we have saved. The difference of cost between water and steam is at least $15 per horsepower per year—3,000,000 horsepower at $15 per year means $45,000,000 per year, which would have been added to the cost of manufacture of cotton goods and other industries in the South. That might mean the difference between holding and losing a foreign market of cotton goods. That is only one section of the country. Without doubt, it is more than 3,000,000 horsepower that was in jeopardy in the West.

P. V. Stephens: There are in the Southern States over 9,000,000 horsepower which may be developed at a reasonable cost. There is a possibility of something like 25,000,000 horsepower which may be developed, with suitable reservoirs. Only one-tenth of this has been developed at the present time. The water powers of the Southern States are their most valuable resource, and yet the least developed resource, and I think that this statement, so far as development is concerned, applies also to the West as well as to the Central States. It means that for the salvation of our resources, especially in the Southern States, we need immediate and thorough legislation which will put aside the barriers to the water-power development.

Economy in Burning Oil on Revenue Cutter Vessels

Capt. C. A. McAllister, engineer-in-chief of the United States revenue-cutter service recently presented some interesting data in the *New York Herald* on using fuel oil as a motive power. It was first tried out by Captain McAllister on the revenue cutter "Golden Gate" at San Francisco. So economical were the results obtained that it has now been decided to gradually spread the system to all the revenue-cutter vessels. The three boarding vessels in New York harbor—the "Hudson," the "Calumet" and the "Manhattan"—will soon be equipped with oil-burning apparatus.

The revenue cutter "Golden Gate" is a vessel of the ordinary harbor-tug type, and is engaged in boarding duty in San Francisco harbor. This is an intermittent duty involving daily a number of short trips around the harbor, a state of readiness to go at a moment's notice, and consequent lying at a wharf with steam up for the greater portion of the time. The tug is 110 feet long and up to six months ago was provided with a water-tube boiler of the Ward type and a triple-expansion engine capable of producing 515 maximum indicated horsepower. Last year a new Babcock & Wilcox water-tube boiler was installed and fitted for oil burning. Grates were put in place so that coal could be burned whenever necessary. A small cylindrical tank with a capacity of approximately 23 barrels of oil was installed in the fire room well up under the deck beams so as not to interfere with the removal of the boiler tubes when necessary. The burners are spaced about 2 feet apart, project 12 inches beyond the door-frame liners and slant slightly downward to within a distance of about 6 inches from the grate. The entire installation for burning oil, including the tank and its supports and all incidental expenses necessary to make the apparatus ready for use, cost $2500.

The oil supply is sufficient for four or five days' steaming under ordinary circumstances. It is obtained from a pipe line on the wharf where the "Golden Gate" is moored, and the tank can be filled in ten minutes.

The relative costs of coal and oil as fuel may be deduced from the performances of November, 1909, and November, 1910, which are given in Table 1:

TABLE 1. COMPARATIVE COSTS OF COAL AND OIL FUEL

	Nov. 1909 (with coal)	Nov. 1910 (with oil)
Hours under way a day, average	4	3
Knots an hour	8.5	8.5
Total miles steamed a day	34	[illegible]
Banked fires, hours	620.5	461.2
Fuel used a day, average, pounds	4,728	1,265
Fuel used a day while under way	3,600	675
Fuel used a day with banked fires	1,128	[illegible]
Cost of fuel a day for steaming	$5.40	$1.73
Cost a mile	0.21	0.069
Miles steamed a ton of coal at 8.5 knots		21.2
Miles steamed a ton of oil at 8.5 knots		48.5

From these tabulations, it would appear that the cost of oil fuel under conditions found on a revenue cutter is only slightly in excess of one-fourth the cost of coal. A further reduction in the cost of operation of the machinery due to the use of oil fuel comes from the fact that the personnel has been reduced from four to three men by dispensing with the services of one coal passer who cost the Government $674 for a year's service.

Judging by the saving indicated by the returns from the operation of the oil plant for the first quarter, there will be an annual saving in fuel alone of $2160. This, with the reduction of $674 for labor, will make a total annual saving of $2834 due almost entirely to the installation of apparatus, the first cost of which was $2500.

The following notes from the report of the engineer officer in charge of the steam machinery may prove of interest in connection with the operation of this plant.

With oil, the steam pressure can be kept stationary, as the machinery responds to unusual or varying demands. A great economy is effected through the careful use of the damper. The firebrick in the furnace act as accumulators of heat and about 20 gallons of oil will maintain steam at about 100 pounds pressure for 24 hours, so that steam may be easily held at night. From water at 50 degrees Fahrenheit, steam is raised in one hour, with the middle burner turned down as low as possible and using an inappreciable amount of oil.

The proper adjustment of the firebrick over the grate bars is important. They are laid flat and lengthwise across the grate. The first five rows back are laid close together and three extra rows are added for ordinary steaming. The remainder are laid in the same manner with a space of 3 or 4 inches between each row, depending on the amount of air required. If too much air is admitted, oil is wasted and if too little the burners give out a dark flame and sputter.

The temperature of the oil in the tank is kept at about 80 degrees Fahrenheit. It is delivered to the burners at about 180 degrees Fahrenheit under a pressure of 40 to 60 pounds, depending upon the work required. It is a California product known as Richmond Hill oil, and its physical properties and chemical analysis are given in Table 2.

TABLE 2. RICHMOND HILL OIL

Ultimate Analysis	Per Cent	Physical Properties	
Carbon	[illegible]	Specific gravity	[illegible]
Hydrogen	[illegible]	Flash point	[illegible]
Sulphur	0.75	Fire point	[illegible]
Nitrogen	[illegible]	Calorific val.,	
Oxygen	[illegible]	B.t.u.	[illegible]
Moisture	[illegible]		

The efficiency of the entire system is dependent on the regularity of the oil supplied. If through any cause the pump is not operated uniformly, no amount of attention will avail at the burners.

Spring Meeting of Mechanical Engineers

Preparations are actively under way for the spring meeting of the American Society of Mechanical Engineers, to be held in Pittsburg, Penn., May 30 to June 2. The headquarters during the meeting will be at Hotel Schenley and the professional sessions at the Carnegie Institute which is in close proximity to the hotel.

The first session for the presentation of papers will be on Wednesday morning on the subject of "The Mechanical Engineering of Cement Manufacture," following which there will be an opportunity to visit the plant of the Universal Portland Cement Company through invitation of its president, E. M. Hagar. The special train to this plant will stop at East Pittsburg, giving members an opportunity to visit the Westinghouse works. On Wednesday evening there will be a session on "Machine Shop Practice" at which the subjects of assembling small machine parts and the development of milling cutters will be discussed.

On Thursday morning the session will be very short with miscellaneous papers, after which an excursion on the river is planned. In the evening will be the reception and dance.

On Friday morning there will be papers relating to steel-works machinery with especial reference to blowing engines and forging presses. Friday afternoon will close the convention with excursions provided for that afternoon.

A session is also planned for the gas-power section.

Previous to this meeting the American Foundrymen's Association is to convene in Pittsburg and the exhibit of foundry appliances, under the auspices of the association, will be held over during two days of the meeting of the American Society of Mechanical Engineers.

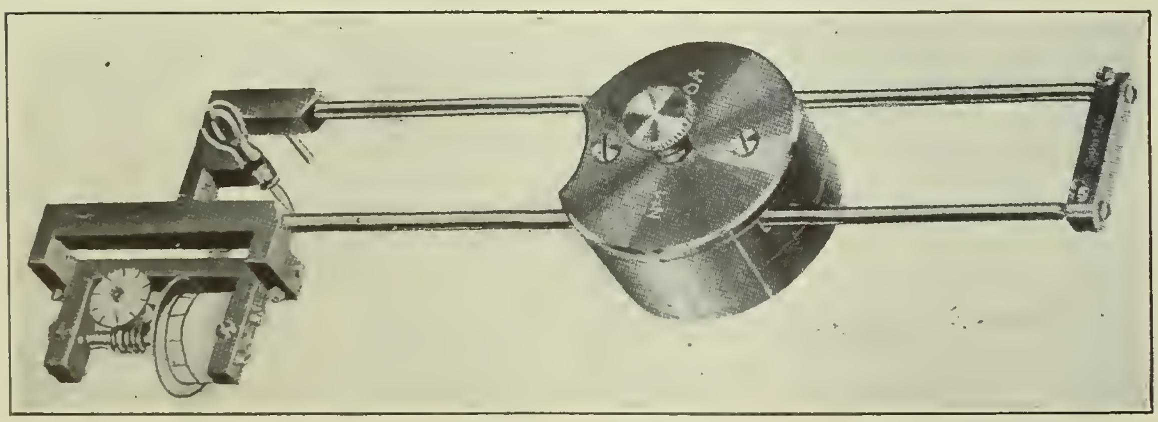
Durand Radial Planimeter

The illustration herewith shows a form of radial planimeter developed to meet a demand for a type of instrument which will give a mean value of the ordinates of a circular diagram or dial instrument in measuring and recording engineering quantities such as pressure, temperature, electric voltage, current, electric power, flow of water, etc., in the same manner as does the ordinary planimeter for a diagram in rectangular coördinates.

It contains the following geometrical elements: (1) A base which is to be centered with the diagram or chart to be averaged, and carrying a pair of parallel guide slots. (2) A pair of rods working in the slots of (1) and carrying at their end a frame to which is attached a tracing point and a pivoted carriage for the integrating wheel. (3) The integrating wheel for measuring the record.

The line joining the tracing point with the center of the base determines the radius vector at any one instant. The axis of the integrating wheel is parallel with this line. Under these conditions it is easy to show mathematically that the record counted on the integrating wheel will be proportional to the product of the average radius vector multiplied by the angle through which the radius vector is carried. Hence by dividing the reading by the angle the mean radius vector is obtained. The instrument is graduated to give mean ordinate in linear inches, so that by applying the appropriate scale factor it may be used for all diagrams no matter what may be the character of the engineering quantity recorded. The limits for the movement of the tracing point are from a circle of 1.5 inches diameter as a minimum to a circle of 10.5 inches diameter as a maximum. This form of instrument is made in Switzerland by Amsler, Laffon & Co., and its American introduction is in the hands of W. L. Durand, 929 K street N. W., Washington, D. C.



Durand Radial Planimeter

Randall Graphite Sheet Lubricant

This graphite sheet lubricant is a mechanical device the purpose of which is to eliminate friction in engine journals or other babbitted boxes. The lubricating element is composed of graphite that is held in bond in the form of tapered cones which are attached by hydraulic pressure to a fine copper-wire screen, as shown in Fig. 1.

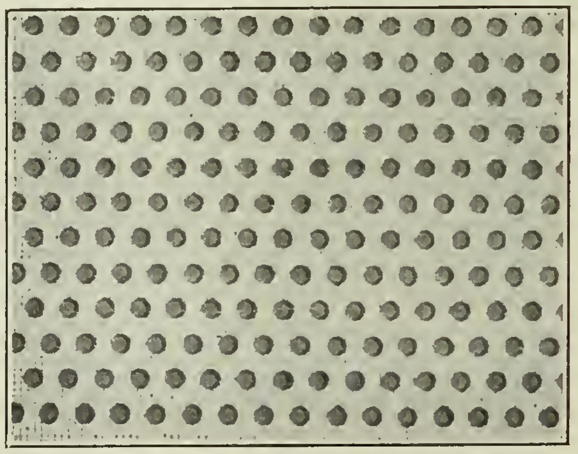


Fig. 1. Wire Screen Containing Graphite Cones

Anyone who is capable of pouring babbitt into a box can install this lubricant, as it is only necessary to use sufficient soft-copper wire to bind the sheet so that the surface of the graphite cones will be held tight against the shaft, as shown in Fig. 2. The babbitt metal is then poured as with the ordinary bearing.

When a bearing has been finished ready for use it has the appearance as shown in Fig. 3, the black places indicating the graphite cones.

The idea of this arrangement is to get the graphite in the right place and keep it there. This combination of graphite and babbitt metal is suitable for long or short bearings, and especially for high-speed machinery where the bearings have a tendency to heat.

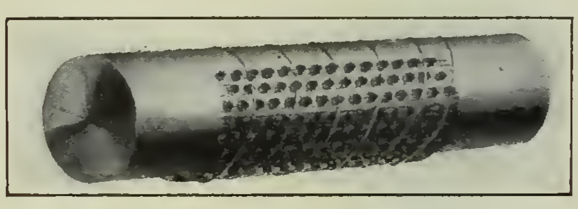

Fig. 2. Wire and Graphite Cones Against Shaft Ready for Babbitt

In order to show how simple it is to babbitt a box with the graphite sheet lubricant the following directions are given: A strip of the lubricant is cut wide enough to reach not quite half around the journal so that it will not reach quite to the top of the box, as shown in Fig. 2. It is then shaped by hand to a half circle a little smaller than the journal to be babbitted and placed on the journal so that the straight rows of graphite cones will run lengthwise of the box, and secured as already explained. The small ends of the cones should always be placed next to the journal so that the wire cloth will be embedded in the babbitt near the bottom of the box. This also produces a greater lubricating surface to the journal as the babbitt wears away.

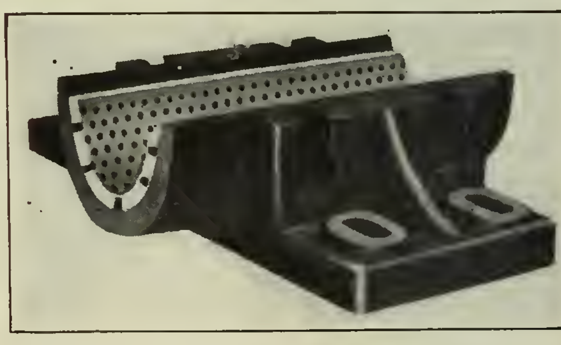

Fig. 3. Babbitted Bearing. Black Places Indicate Graphite Cones

The Randall Graphite sheet lubricant is manufactured by the Strong, Carlisle & Hammond Company, 326 to 339 Frankfort avenue, Cleveland, O.

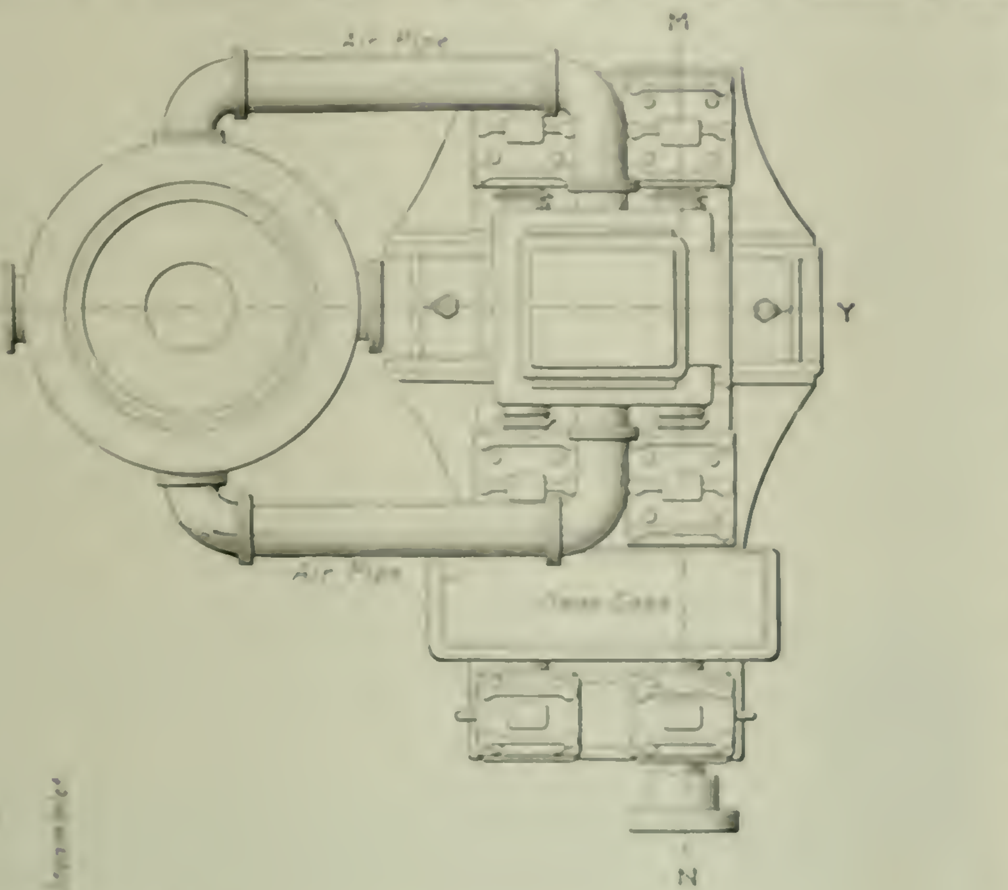
The Connersville Condenser

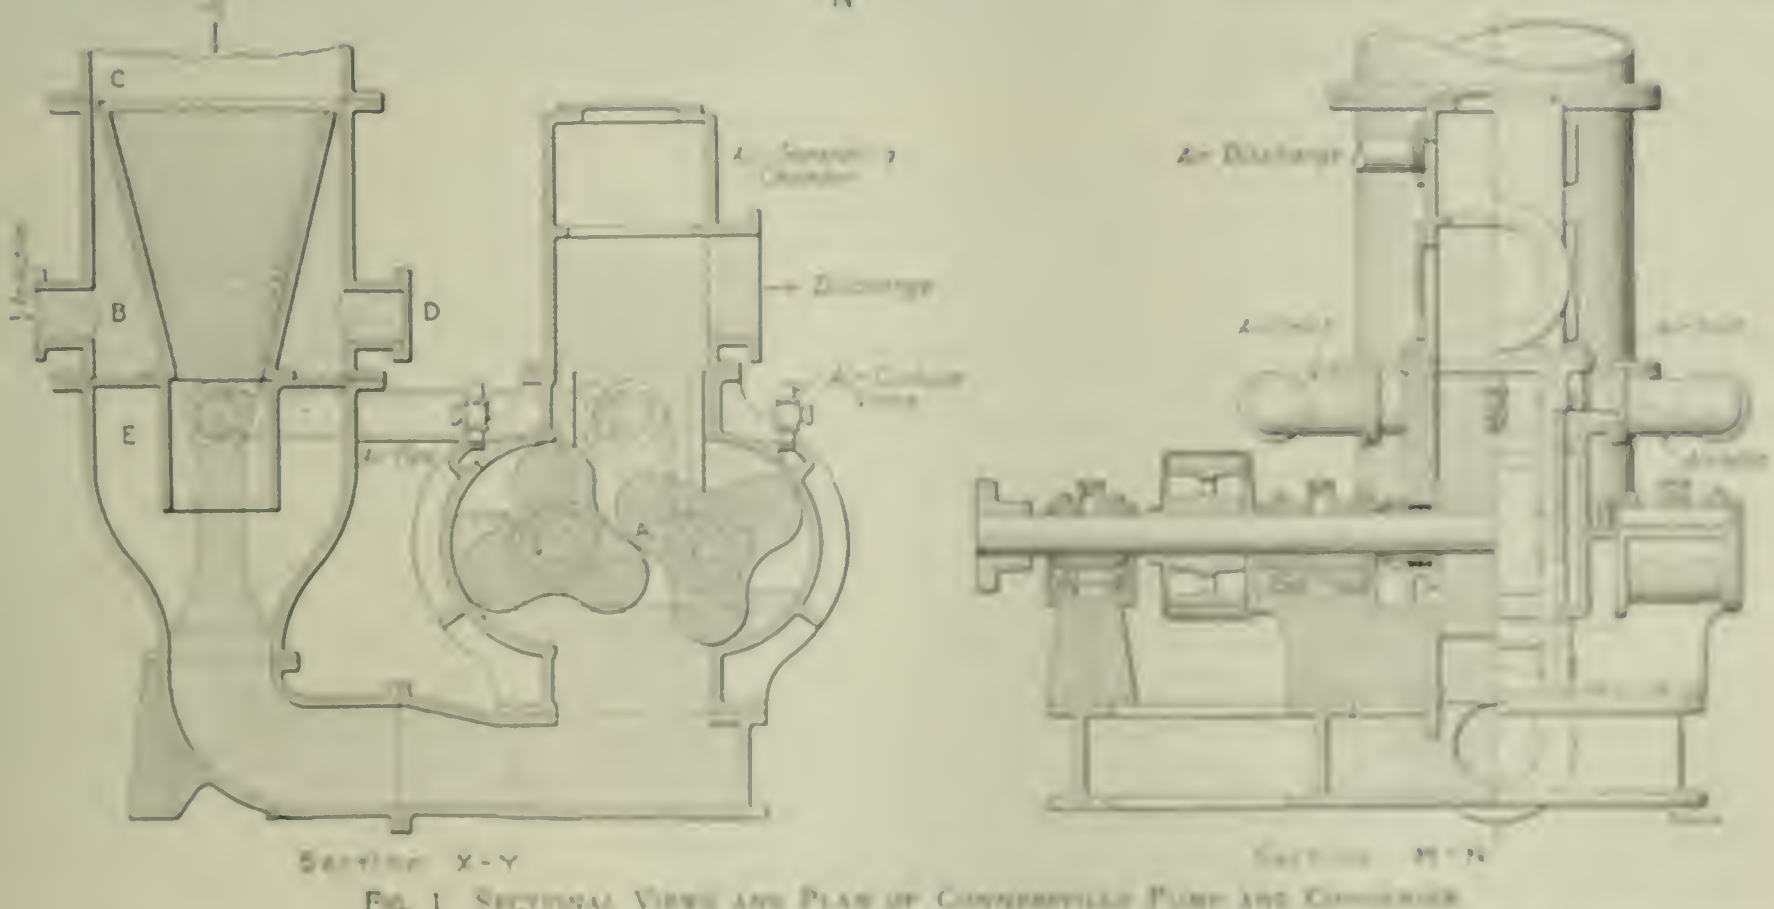
Although a rotary pump has hitherto received little consideration as a vacuum pump, it offers particular advantages for high-vacuum work.

The Connersville condenser, in which a modification of the well-known Connersville cycloidal blower is used as a pump, is shown in the accompanying engraving. Looking at the end elevation it will be seen that there is an uninterrupted communication between the condensing chamber and the vacuum portion of the air pump. That for the water is well shown in the end elevation. The air is taken off above the discharge of the condensing cone by two air pipes shown in the plan and delivered below the center of the pump by cored passages, one of which is shown in section in the front elevation. As the lobes of the pump revolve they entrap portions of the water and air in the way made evident in the end elevation, and carry them around to the delivery side; and as the lobes revolve at a speed of from 100 to 300 revolutions per minute, depending on the size, with six deliveries to a revolution, the gaseous and liquid contents of the condenser are removed as fast as they accumulate and in a practically continuous stream. The communication between the air space of the condenser and the volume that is cut off by each lobe is so direct that any degree of exhaustion which the pump is able to produce will exist throughout. Although the rotating lobes do not come into contact with each other nor with the sides of the cylinder, there can be no air leakage backward, as all of the points of possible leakage are water sealed and the water is being hurried along to the delivery side. Even the shaft stuffing boxes are water sealed and do not have to be packed against a vacuum. What water leakage may occur at the point A is unimportant as long as no air can get back.

The Connersville Blower Company, of Connersville, Ind., has furnished these pumps for jet condensers alone for an aggregate capacity of over 60,000 horsepower, but has recently developed the condenser illustrated herewith on its own account. As shown in the end elevation, the condensing water is received in a chamber B, of sufficient volume to retain without interruption to the service such stones and other bodies as are sometimes brought in, preventing them from passing to the pump. A handhole D furnishes access to this chamber without breaking any of the connections. The water filling this chamber overflows into the condensing cone through the annular space C, so large that it will not be clogged by grass, eels, etc.

Rolling down the inside it forms a hollow cone of water, into the interior of which the steam is received and condensed, striking nothing but water-covered and water-jacketed surfaces. The air and uncondensed vapors are carried forward by the velocity acquired by the rush of the steam into the vacuum, drawn together and delivered through the throat into the lower part of the condenser, where they collect above the water in the chamber E. The body of constantly renewed cold water in the chamber B immediately above serves not only to water jacket the upper part of the condenser and to keep it cool, but to cool the air and condense the vapor in the chamber E which is exposed to the effect





Section X-Y Section M-N

Fig. 1 Sectional Views and Plan of Connersville Pump and Condenser of the division wall cooled by the direct contact of the entering water and the contiguous exterior wall surfaces, cooled by conduction. This cooling of the air is very desirable as it reduces its volume and the work of compressing it to and discharging it against the pressure of the atmosphere is measured by its volume, and not by its weight.

The water and the air are thus handled independently, allowing of this natural separation and cooling, and yet by a single pump having no valves, springs or small working parts. The pump can handle very hot water and maintain a vacuum very close to that corresponding to the temperature. Piston pumps are handicapped in this respect, because the pressure in the pump cylinder is necessarily less than that outside the valves, due to the resistance of the valves and ports, and to the differential pressure necessary to overcome the inertia of the water and make it follow the increasing movement of the piston. When, therefore, in a piston pump the vacuum is carried near to that corresponding to the temperature of the water, the higher vacrum inside the pump cylinder causes reevaporation of the water in the cylinder, filling the pump with steam and causing it to race.

*Vacuum gage attached to low pressure end of turbine.

The accompanying table shows the results obtained with two of these pumps, 24x20 inches, having a displacement of 56 gallons per revolution, running in the power station of the Memphis Consolidated Gas and Electric Company, at Memphis, Tenn. These readings were taken on June 10 last and represent regular running conditions. When used as a dry-vacuum pump, the cycloidal rotary type can handle any amount of water up to its full capacity without injury. When used as water pumps, the larger sizes have shown an efficiency of 84 per cent. of the indicated horsepower of the engine driving the pump. These condensing units are now available in all sizes from 100 horsepower up.

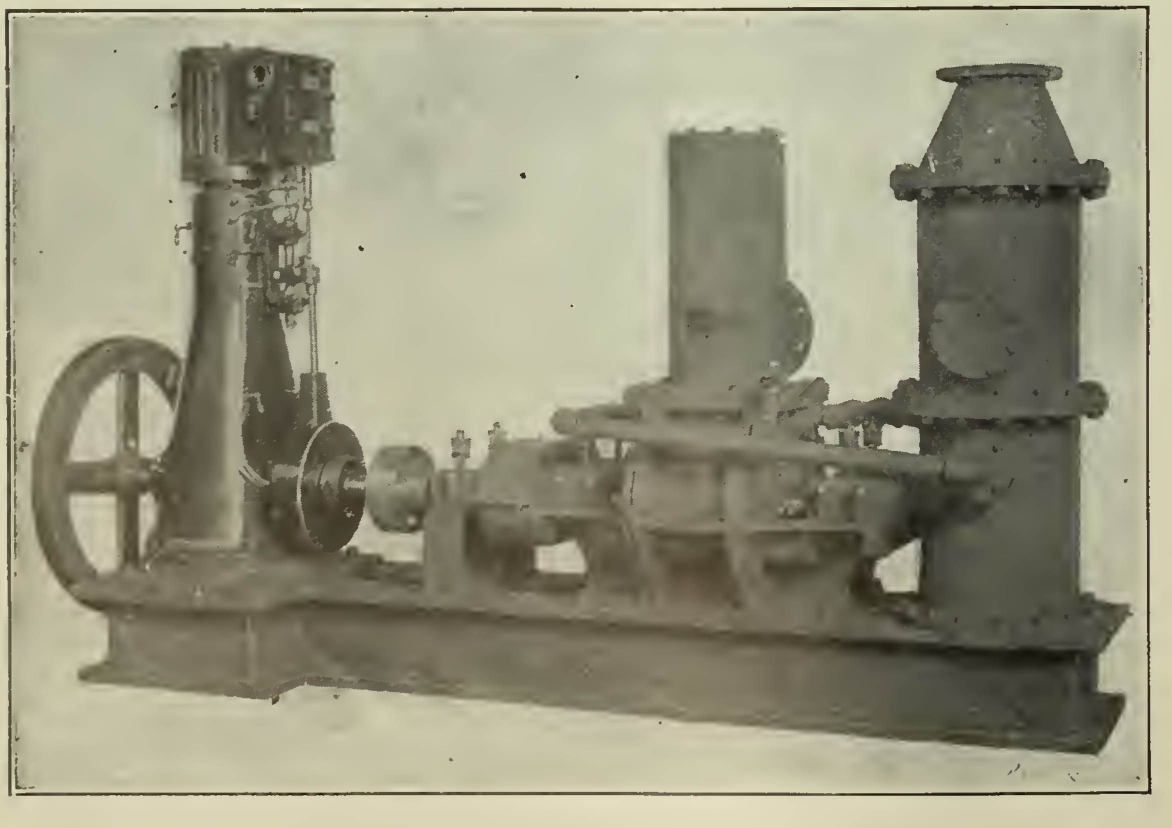

FIG. 2. PUMP DIRECT CONNECTED TO VERTICAL ENGINE

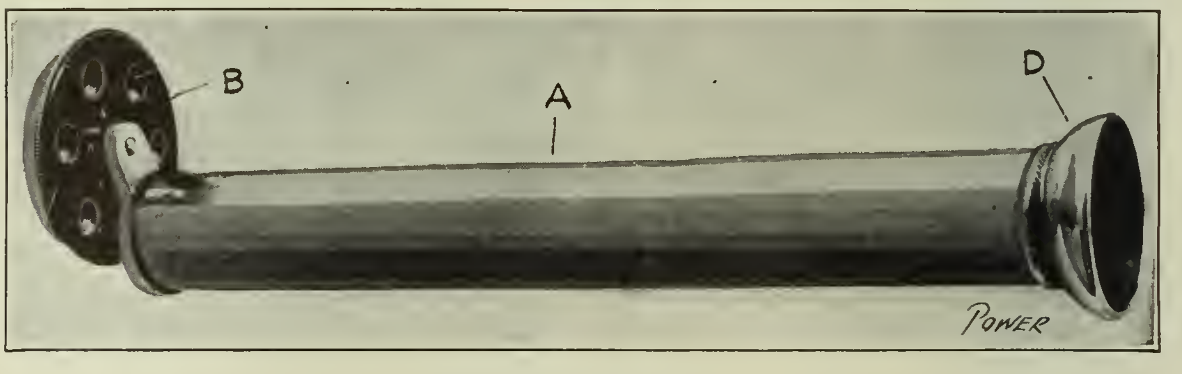
An air-separating chamber is provided on the discharge side of the pump, so the air and water can be discharged separately if desired.

The air-cushion valves on each cylinder are used to admit atmospheric air, so as to produce gradual rise to atmospheric pressure in the closed chambers, and prevent the water volumes meeting in a vacuum and producing a water hammer.

Smoke Tintometer

This smoke tintometer consists of a tube *A*, having at one end an eye piece *D*. The opposite end of the tube has two object apertures and in front of one is fixed a revolving diaphragm *B*, having five circular openings of the same diameter as one of the object apertures of the instrument. Four of the apertures are glazed with tinted glass corresponding to, and graduated from the standard tints of the Ringlemann smoke scale, while the first aperture remains clear.



SMOKE TINTOMETER

When examining the smoke from any particular chimney, the observer turns the instrument so that the aperture which is fitted with the revolving diaphragm looks toward the windward side of the smoke so that through this aperture he sees past the side of the smoke to the clear light of the sky beyond; or the same light which is illuminating the smoke column. Through the other aperture the observer sees at the same moment a circular patch which appears to be cut out of the column of smoke that it issues from the chimney. All that the observer has now to do is to revolve the diaphragm until both apertures appear to have equal illumination and a glance at the numbered scale on the instrument shows the number corresponding to "light gray," "drak gray," "black," etc., of the Ringlemann chart.

The tintometer is manufactured by John Lowdon, Reform street, Dundee, Scotland.

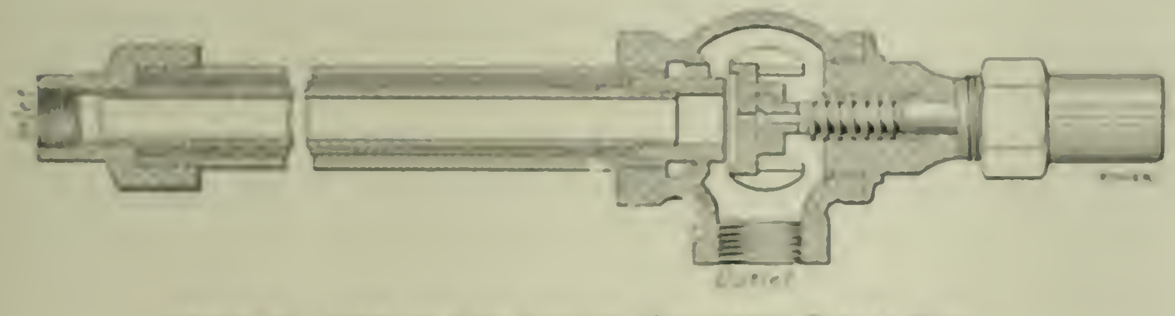
The Barton Expansion Steam Trap

The Barton trap consists of an inner and an outer expansion tube, into the inner tube of which the steam flows from the intake end. The inner tube at the outlet end supports the valve seat, which butts against the valve disk. When filled with live steam the inner tube is held by its expansion against this valve disk and is sealed. When condensation takes place the tube contracts and draws away from the valve disk, allowing the escape of the water, and closing again immediately after the discharge is made.

The outer tube, also an expansion tube, makes possible the use of the trap both with a vacuum or a gravity system, as follows: With a vacuum system there is maintained between the inner and outer tubes a vacuum, which insulates the outer from the inner tube, so that the outer tube is always cooler than the inner, and the inner tube takes care of the condensation, as already described. When the vacuum pump ceases to work, or where a gravity system is used, the outer tube is acted upon more directly by the steam flowing from the coil, and by its expansion opens the valve by drawing the valve disk away from the valve seat on the inner tube. The inner tube has a greater coefficient of expansion than the outer, so that when the water has escaped under these conditions the inner tube will expand sufficiently to reach the valve disk and close the outlet.

This trap is placed in a horizontal position at the lower end of the coils to be drained so that the water of condensation will flow to the trap. The end of the coil must be connected to the small opening in the trap marked "inlet."

This trap is manufactured by John W. Barton, 2707 Vestry avenue, Cleveland, O.



SECTIONAL VIEW OF THE BARTON EXPANSION STEAM TRAP

Idle boilers should be thoroughly washed out and dried. Trays with unslaked lime should be placed inside and the boilers should be closed air tight. If the boiler is to stand ready for immediate use it should be filled with water to which burnt lime has been added, but unless the boiler is one of a battery and is kept warm, it is likely to condense atmospheric moisture from outside and corrode if filled with water.—Ex.

Convention of the National Association of Cotton Manufacturers

The semi-annual convention of the National Association of Cotton Manufacturers was held in Boston on April 12 and 13 and was largely attended. A number of interesting papers were read upon textile matters and one upon "Power from Producer Gas" was of particular interest. The honorary medal was awarded to Charles T. Main, of Boston, in recognition of his services as a mill engineer and for his paper upon the "Choice of Power for Textile Mills," which was delivered at the fall meeting. Franklin W. Hobbs, of Brookline, Mass., was reelected president of the association.

Technology Congress

On April 10 and 11 the alumni of the Massachusetts Institute of Technology held a reunion at Boston to commemorate the fiftieth anniversary of the founding of their alma mater. The exercises were opened with an address by President Maclaurin, of the Institute, which was followed by the reading of a number of papers upon various engineering subjects, some of which will follow in a later issue.

The congress ended with a banquet in Symphony hall at which a number of men prominent in public, educational and engineering circles, responded to toasts.

The Institute was founded in 1861 by Professor Rogers, and from a small beginning with one building and only a handful of students, it has grown to be one of the leading technical schools with an enrollment of over fifteen hundred students and numbering among its graduates some of the most prominent engineers of this country.

Turin Exposition

In connection with the Turin International Exposition, which opens on April 29, 1911, there will be held an international competition for internal-combustion engines as applied to agriculture, entries closing on April 30. The object is to extend to various branches of agricultural work the use of petroleum motors, benzine motors, illuminating-gas motors, crude-oil motors, etc., in connection with plowing, sowing, harvesting, irrigating, etc. Various societies offer prizes, and the Italian government will purchase the articles winning first prizes in classes 1 and 2. Copies of the program for the competition in question may be obtained from the Bureau of Manufactures.

NEW PUBLICATIONS

ENGINEERING DIRECTORY, 1911. Compiled and published by the Crawford Publishing Company, Chicago, Ill. Leather; 1381 pages, 4x6½ inches. Price, $5.

This is the eighteenth annual publication of this work which was formerly known as the "Domestic Engineering Directory." The book aims to be a complete directory of the plumbing, heating, lighting, power plants and mill-supply industries in the United States. It contains a list of wholesale dealers in plumbing, heating and lighting supplies, a list of jobbers and dealers in mill, steam, mine and railway supplies, tools and machinery and, in addition, mailing lists of water works and gas companies, power plants, wholesale dealers in hardware and electrical supplies and purchasing agents of railroads, besides a classified list of the products of these various manufacturers. The various directories appear to be complete, and the book as a whole should prove of value to those interested in the fields mentioned.

STEAM TURBINES. By Walter S. Leland. Published by the American School of Correspondence, Chicago. Cloth, 120 pages, 6x9½ inches. Illustrated. Price, $1.

The book was written for the practical man who, though perhaps less interested in the finer points of theory than in the results and the way in which they are secured, is still deeply interested in the fundamental principles, both of construction and operation. No comparisons have been made between the designs of the different types. Facts have been stated and the reader has been left to draw conclusions on all points where a difference of opinion might occur.

The first five pages are devoted to the history of the turbine and a discussion of the kinetic principles upon which it is designed.

All types are accurately described and illustrated, making with its practical discussion of various installations and their respective performances, a comprehensive and valuable standard of reference. Turbine speed regulation is intelligently and thoroughly treated in the last chapter.

THE TEMPERATURE-ENTROPY DIAGRAM. By Charles W. Berry. Published by John Wiley & Sons, New York, 1911. Cloth; 410 pages, 5x7½ inches; 127 illustrations. Price, $2.50.

This is the third edition of Professor Berry's excellent little textbook, which is now expanded into a treatise on graphical thermodynamics, within the limits set by the title. In this edition the chapter on the Θ-Φ diagram for the flow of fluids has been expanded nearly four pages by a discussion of the total heat of dry saturated steam, based on Doctor Davis' classic determinations. The chapter on gas-engine cycles contains twenty additional pages devoted to the effect of different methods of speed regulation upon the efficiency at underloads and an analytical comparison of the several gas-engine cycles; the one on the nonconducting steam engine (Rankine cycle) has been improved by elaborating the tables of Rankine efficiency and specific steam consumption and extending their range downward to cover steam-turbine conditions. The old chapter of 16 pages on refrigeration and the Kelvin warming engine has been developed into two chapters covering 36 pages, one on each subject. An entirely new chapter on entropy analysis in the boiler room has been added and there are also short tables of Napierian and common or Briggsian logarithms at the end of the book.

For the benefit of those who are not familiar with previous editions it may be well to say that the book is an ideal college text but not at all adapted to "home study" or useful as a practical reference book.

Solenoids, Electromagnets and Magnet Windings. By Charles R. Underhill. Published by D. Van Nostrand Company, New York, 1910. Cloth; 350 pages, 5x7½ inches; 221 illustrations; many tables. Price, $2.

This is the first adequate exposition of the principles and practice of electromagnet design and construction thus far published, unless one has been brought out by the Chinese, Turks or Russians. It is a pity, therefore, that the author did not either omit the purely academic phase of the subject or submit his work to a competent editor. Some of his fundamental definitions are obscure and some statements based on them are absolutely wrong. His style is neither lucid nor fluent.

The practical formulas and data contained in the book are priceless to anyone who has much to do with making electromagnets. Unfortunately, some of the charts are so small and poorly reproduced as to be useless, notably those on pages 314, 315 and 316.

Notwithstanding the weak points, the book is highly praiseworthy in general. It could be improved by condensation and the omission of didactic material. A man who needs a practical manual on this subject has passed the strictly elementary grade.

At the recent exhibition held by the Physical Society, of London, A. C. Cossor showed an improved form of W. R. Cooper's patent speed indicator. A glass tube, branched below like the traditional anchor, is partly filled with mercury and is turned together with its vertical spindle within the cup, which holds it, by the flexible drive. The liquid above the mercury in the long, central tube falls when the device is rotated; should the maximum speed that can be recorded be exceeded, no harm would be done; the liquid would simply not descend more. The motion is taken from a shaft through a friction wheel. The new type of X-ray tubes of A. C. Cossor is provided at the anode with several radiating disks of aluminum intended to cool the anode. The bulb is further fitted with a branch tube, which serves as a regulator. This tube contains a length of a smaller glass tube wrapped with asbestos, over which aluminum wire is coiled; inside the tube is a strip of aluminum, and wires from this strip extend outside to near the terminals of the bulb. The idea—first applied by Gundlach, we believe—is that too strong currents will liberate an air bubble from the asbestos lagging as soon as a spark passes from a terminal to the branch circuit; the liberated air would enter the main bulb.—*Engineering.*

SOCIETY NOTES

The second annual meeting of the American Association of Refrigeration will be held in the "east room" of the La Salle hotel, Chicago, Ill., on May 9 and 10, 1911. The first session will be called to order at 10:30 a.m., Tuesday, May 9.

On Thursday evening, April 13, J. C. Jurgensen delivered a paper on the "Economic Aspects of the Institute of Operating Engineers," before the New York branch No. 1 of district No. 2, in the Engineering Societies building. The meeting was attended by some 70 members and friends.

On Saturday evening, March 25, the members of the Institute living on Long Island, met at the rooms of the Modern Science Club and organized the Isherwood branch No. 2 of district No. 2. The officers elected were: F. L. Johnson, chairman, and Frank Martin, secretary-treasurer. This branch starts out under extremely favorable circumstances as it is made up largely of the men interested in the education at the Modern Science Club during the past winter.

On Thursday evening, May 11, at eight o'clock, the second monthly meeting of the New York branch No. 1 of the Institute will be held in the Engineering building. F. L. Johnson, associate editor of Power, will deliver a paper on the "Necessity for Industrial Education."

PERSONAL

A. Bement, consulting engineer, has moved from the Fisher building, Chicago, to 206 South La Salle street.

Alex. Crawford has been appointed purchasing agent for the Hyatt Roller Bearing Company, of Newark, N. J., and assumed the duties of the office on April 17.

Rodman Gilder, secretary of the Crocker-Wheeler Company, of Ampere, N. J., has resigned to become associated with the brokerage house of Dick Brothers & Co., 30 Broad street, New York. His seven years' experience in a high-class industrial concern should be of value to him in the analysis of bonds of industrial and other corporations.

BOOKS RECEIVED

Current Railway Problems. By Samuel O. Dunn. Railway Age Gazette, New York. Paper; 85 pages, 5x6¼ inches.

The Ignition Handbook. By H. R. Van Deventer, Sumter, S. C. Paper; 73 pages, 4¾x7½ inches; 40 illustrations. Price, 50 cents.

The Principles of Scientific Management. By Frederick W. Taylor. Harper & Bros., New York. Cloth; 77 pages, 6x9 inches.

Engines and Boilers. By W. McQuade. D. Van Nostrand Company, New York. Cloth; 87 pages, 5¼x8¼ inches; 62 illustrations; indexed. Price, $1.50.

Three-Phase Transmission. By William Brew. D. Van Nostrand Company, New York. Cloth; 178 pages, 5¼x8½ inches; 82 illustrations; tables; indexed. Price, $2.

Machine Shop Mechanics. By Fred H. Colvin. McGraw-Hill Book Company, New York. Cloth; 172 pages, 4¼x6¾ inches; 116 illustrations; tables; indexed. Price, $1.

The Temperature-Entropy Diagram. By Charles W. Berry. John Wiley & Sons, New York. Cloth; 393 pages, 4¾x7¼ inches; 125 illustrations; tables; indexed. Price, $2.50.

High-Efficiency Electrical Illuminants and Illumination. By Rollin W. Hutchinson, Jr. John Wiley & Sons, New York. Cloth; 278 pages, 5x8 inches; 147 illustrations; indexed. Price, $2.50.

POWER

NEW YORK, MAY 2, 1911

THE baseball season is now at hand and everybody is alive to the relative merits of the various teams.

Did you ever stop to consider what goes to make up a successful team? Is it individual playing or the earnest co-operation between all the members, each affording the other active support?

In answer to this question, it might be said that both are desirable, although the latter is the more important; in fact, it is absolutely essential to success. A collection of individual stars, each playing his own game without regard to the other or without any definite system, would be at the mercy of a well balanced team in which each member actively supported the others.

In short, the keynote to success is team work.

This holds true not only in athletics but in all business enterprises. To insure success all must work for the common cause.

Applied to the power plant it means that from the general manager down to the fireman all must strive toward producing better and more economical service.

Frequently, the men of one watch are detected in an attempt to let things slide over for the next watch, or if anything goes wrong they will sometimes attempt to shift the responsibility for it to the preceding watch. Such practice is sure to promote dissension and petty jealousies spring up which have no place in the operation of any plant.

Another important factor in economical operation is that of co-operation between the office and the operating force in the matter of purchasing supplies.

The motto, "A dollar saved is a dollar gained," does not always hold true in the power plant. The purchasing agent is apt to look to the price of an article without due regard to its adaptability, hence it may prove more expensive in the end.

On the other hand, if the purchasing agent, or general manager, and the engineer get their heads together and consider the subject from both points of view, that of price and that of durability and adaptability, they are very apt to effect a compromise which will prove satisfactory to all concerned and cheaper for the company.

Moreover, it will be found advantageous to acquaint the entire operating force with the cost of supplies.

If the oiler is appraised of the sum which the small daily waste in oil amounts to annually, he will take more pains to eliminate this waste. And if the fireman is impressed with the saving he can effect by more economical methods of firing, much will be saved in this respect.

Similarly, the engineer will be able to reduce the yearly packing bill.

It is the small losses that add up to an amazing figure at the end of the year. But by proper treatment of employees and system on the part of the management, reciprocated by team work on the part of the employees themselves, the losses can be cut down to a comparatively small figure.

Comparing Steam Turbine Tests

By A. G. Christie

When it is desired to compare the performances of two or more turbines operating under different conditions of pressure, superheat and vacuum, it is first necessary to reduce them to a common basis. This involves the determination of the "efficiency ratio" of each machine. By this is meant the ratio of the heat converted into useful work, per pound of steam, to the heat available through adiabatic expansion from the initial to the final pressures.

Anyone who has endeavored to compare the results of various steam-turbine tests understands the difficulty in making a fair comparison, especially when the tests have been performed under widely differing conditions. For instance, suppose turbine *A* has been tested at 200 pounds gage pressure, 150 degrees superheat and 28.9 inches vacuum, referred to a 30-inch barometer, and showed a steam consumption of 11.1 pounds per electrical horsepower-hour. Turbine *B* was tested under practically the same load with steam at 150 pounds gage pressure and 98 per cent. quality and with a vacuum of 27.8 inches and produced one electrical horsepower with 14.6 pounds of steam. A comparison of the steam consumptions per electrical horsepower-hour of these two turbines would require certain corrections to be made in the results of turbine *A* due to the steam pressure, superheat and vacuum being higher than in the case of turbine *B*. These corrections can be found only from the results of a long series of special tests under varying conditions of steam pressure, superheat and vacuum. Should such a series of tests be run on turbine *A*, the results might be misleading, for this turbine may have been designed to operate at its maximum efficiency under the conditions of the first test; hence, tests under other conditions would be in error to the extent of the variations in efficiency. As a rule, the results of such a series of tests are not at hand for every class of turbine and engineers have not agreed upon any standard corrections to be applied to any one class of turbine.

In the case of the test of turbine *B*, a correction must be made for the quality of the steam. The correction for dry steam would be as follows: The dry steam per electrical horsepower-hour equals

$$0.98 \times 14.6 = 14.308$$

It is generally agreed that turbines do not operate as efficiently with steam of 98 per cent. quality, as with steam at 100 per cent. quality, as the presence of moisture increases the friction and reheating effects, hence lowers the efficiency. For the purpose of illustration let it be supposed that turbine *B* is designed for maximum efficiency with dry steam at 150 pounds gage pressure and 28 inches vacuum, referred to a 30-inch barometer.

From the foregoing it is evident that the usual method of correcting the results of steam-consumption tests does not provide a satisfactory means of making comparisons which are fair to all turbines. On the other hand, there is a method of comparing the results of such tests which can be applied readily to any set of tests and is not liable to errors in the correction factors. This method involves the determination of the "efficiency ratio" of each machine; and, although not new in this country, it has not been used to the extent that it has in Europe.

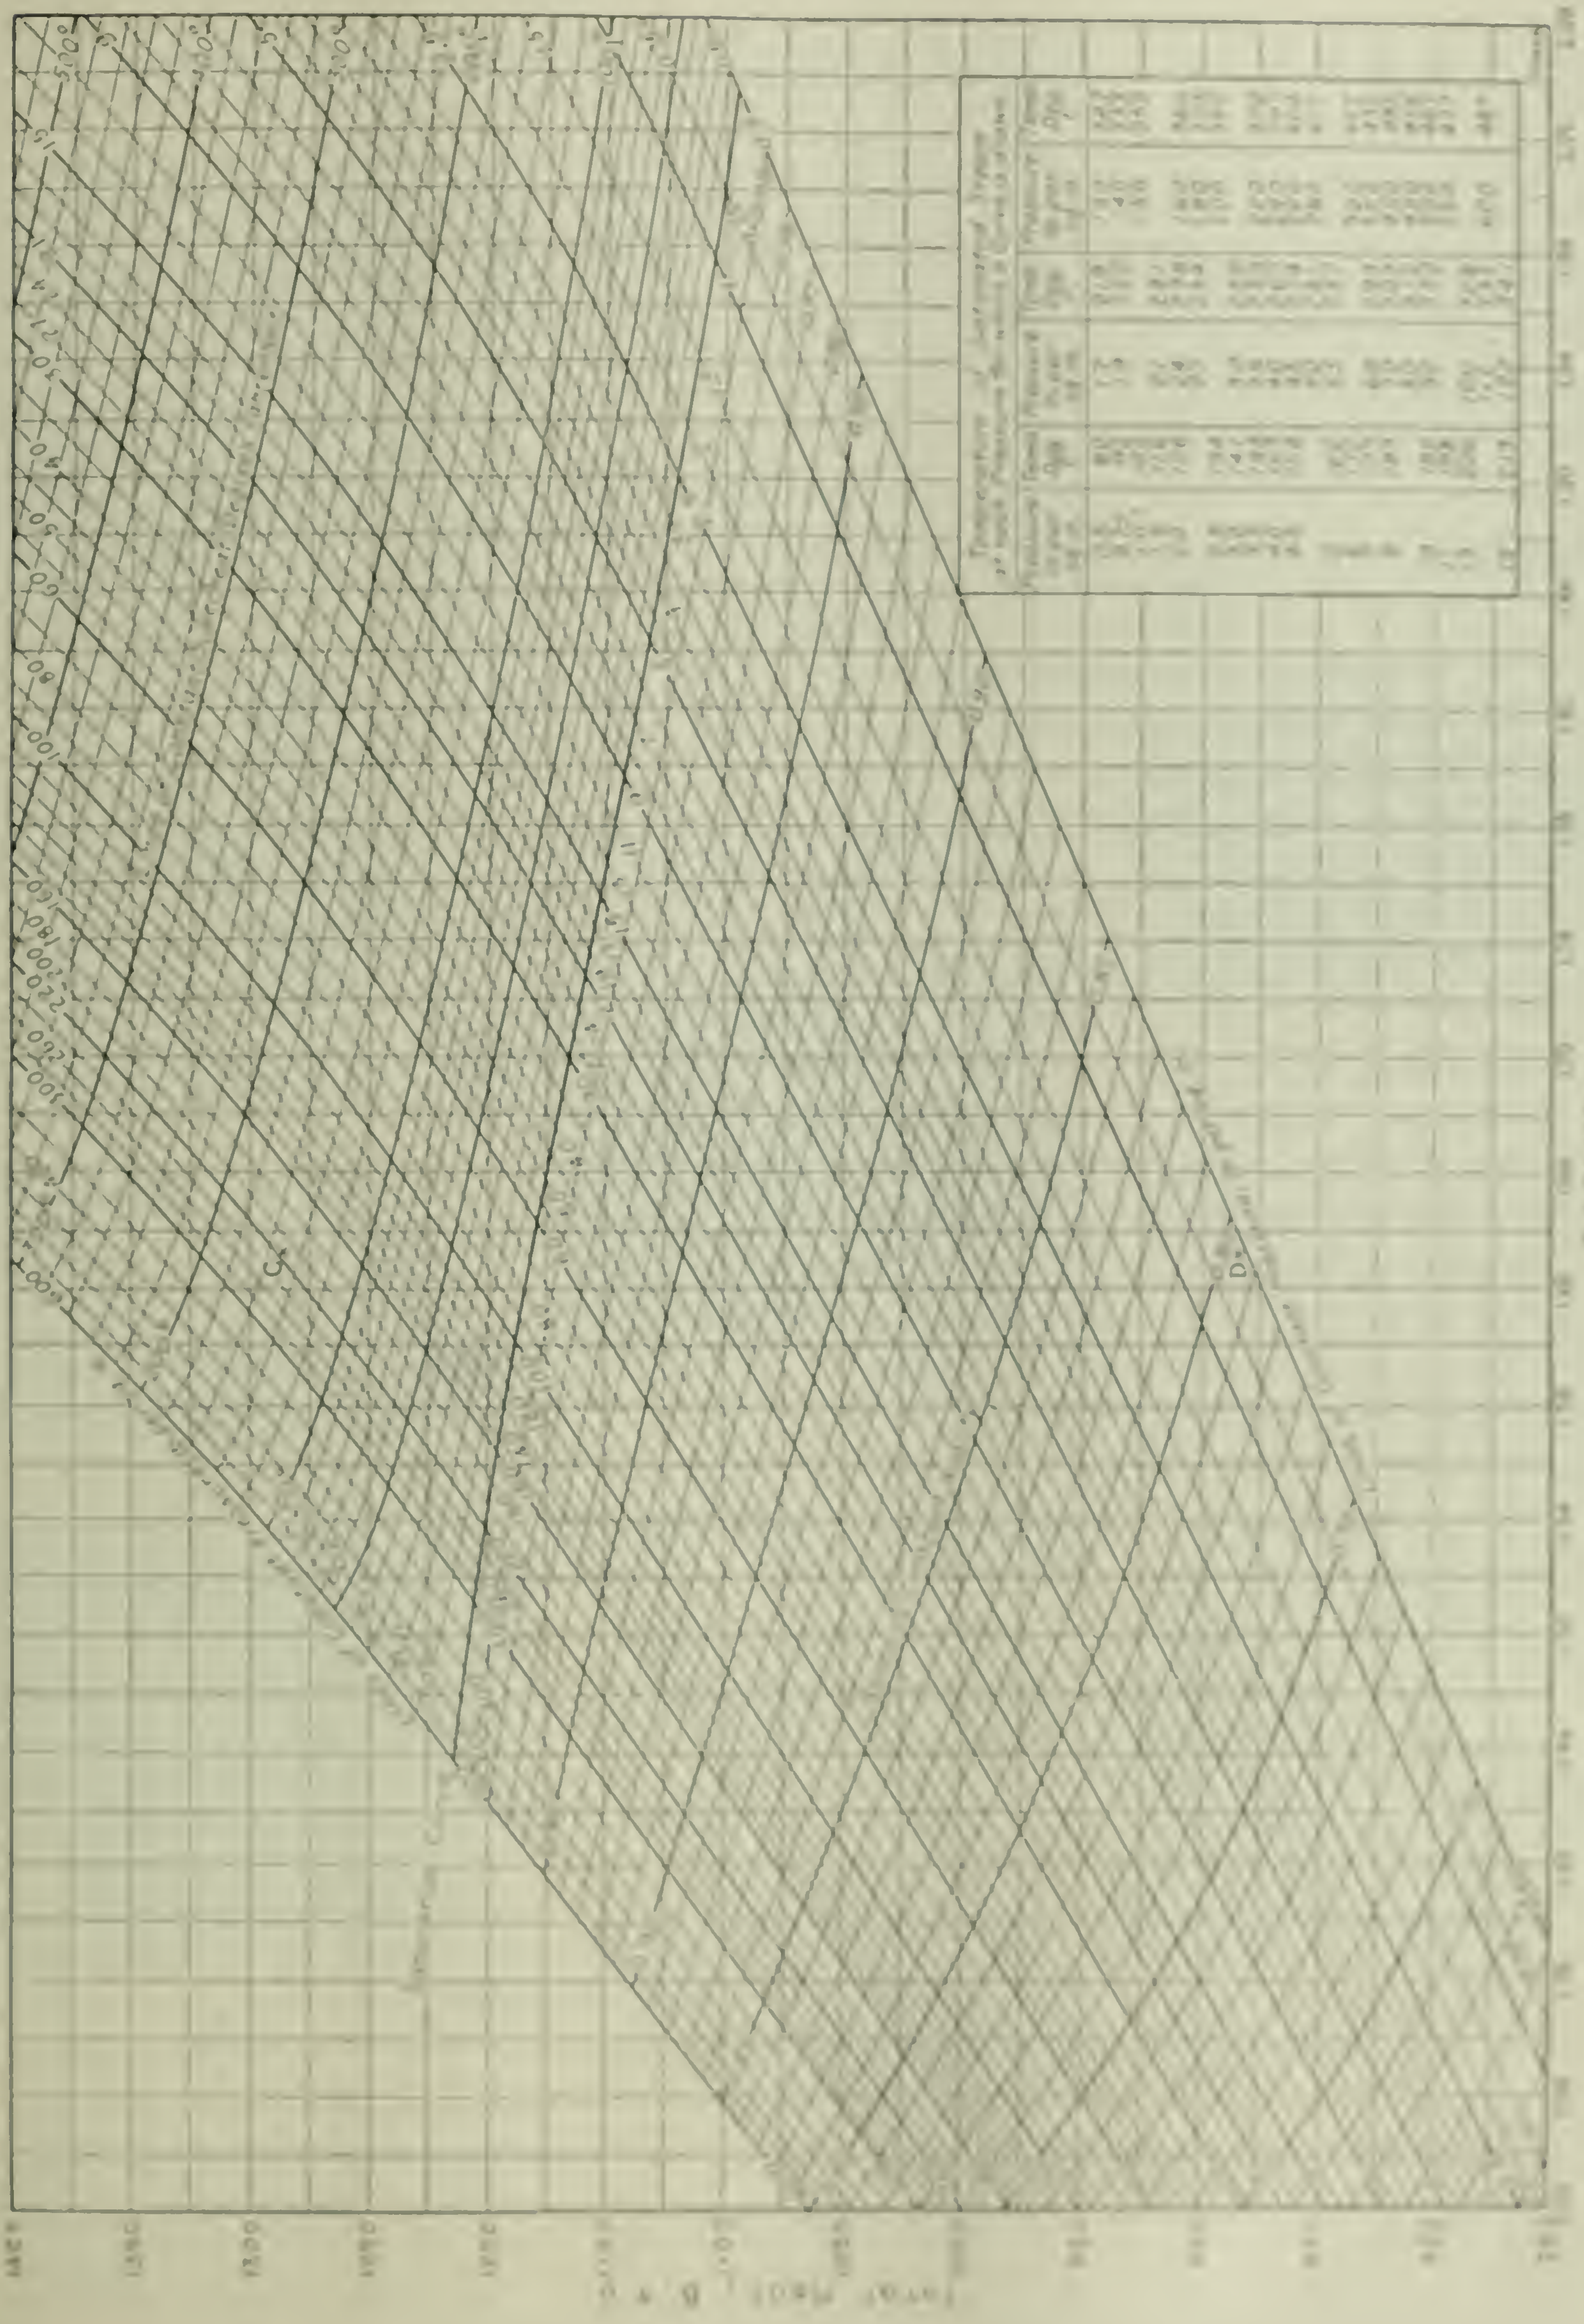
By "efficiency ratio" is meant the ratio of the heat converted into useful work, per pound of steam in the turbine, to the heat available through adiabatic expansion of the steam from its initial conditions of pressure, superheat and quality to its final pressure in the condenser. This may appear at first to be a complicated determination but, as will be shown later, it can be made very simple by the use of the heat charts which are now available.

A vapor is said to expand adiabatically when it neither receives heat from, nor gives up heat, except as work, to any outside body during expansion. All heat appearing as work must be supplied from the total heat in the vapor at the beginning of expansion. Hence, the heat, available as work, can be measured as the difference in the total heat in the steam at the beginning and at the end of expansion. In other words, with a given initial quantity of heat, the adiabatic expansion represents the maximum work that can be gotten out of a pound of steam in expanding from one condition to another. It represents the condition of maximum efficiency in all heat engines which depend for power upon the expansion of a vapor or gas, for there are present neither radiation nor internal losses. This forms a standard of efficiency with which actual results can be compared. The ideal turbine can be considered as working by adiabatic expansion of the steam and with neither radiation nor internal losses.

In the preceding discussion work has been referred to as a quantity of heat. Ordinarily, work is reckoned in foot-pounds of energy or in horsepower when the rate of its accomplishment is involved; but all these various units of work or power can be resolved into foot-pounds. It has been shown experimentally that 778 foot-pounds equal one B.t.u.; hence, work measured in foot-pounds, in horsepower or in other units can be readily transformed into equivalent B.t.u.

On a temperature-entropy diagram, an adiabatic expansion is represented by a line of constant entropy; for if the entropy increases during expansion, heat must have been added to the vapor or if the entropy decreases, heat must have been given up by the vapor. But, as adiabatic expansion is possible only when all the heat units given up during expansion are transformed into work, this condition occurs only when the entropy is kept constant. The term "isentropic" means equal or constant entropy and may be used instead of "adiabatic." There are several forms of entropy diagrams, the most convenient of which employ entropy and total heat per pound of steam as coördinates; of this type the Mollier diagram is the most widely known. This, which is here reproduced within the limits of the problem under discussion, contains curves of constant absolute pressure, constant quality and constant superheat. Such diagrams upon larger scales can be found in Stodola's *Steam Turbines*, Marks & Davis' *Steam Tables* and Thomas' *Steam Turbines;* Peabody's *Temperature-Entropy Tables* also give the values of such a diagram in tabular form.

To use the diagram for the determination of the heat available from adiabatic expansion, follow along the curve of constant absolute pressure to its intersection with the curve of constant quality or constant superheat, representing the initial conditions of the steam. The total heat in one pound of steam at that condition, can be read from the scale of coördinates at the left of the diagram. Note this amount of heat. Next, from this initial condition follow down the vertical ordinate of constant entropy until it intersects the curve representing the absolute terminal pressure of the expansion. Note the total heat at this condition. The difference in heat contents at the initial and the final conditions of the steam represents the heat available as external work per pound of steam due to the adiabatic expansion between the given limits. The absolute pressures are found in every case by adding the pressure corresponding to the barometer to the observed gage pressure.



Mollier Diagram

In a steam turbine, the expansion is not strictly adiabatic, owing to the internal losses and radiation. The radiation loss is usually small, but the internal losses are the real measure of the efficiency of a turbine and vary somewhat with different machines. These losses are often designated by such terms as blade friction, windage, eddying, etc., but all are manifestations of fluid friction. This may be due to the friction of the steam against the walls of the steam passages, to the friction between particles of the steam, or to leakage past the diaphragms and over the tips of the blades.

When friction losses occur in a vapor, a cycle of events occurs as follows: With steam flowing at a given velocity over a curved surface, such as a turbine blade, friction is set up between the steam and the blade and some of the energy due to the velocity of the steam is converted into heat. This heat increases the temperature of the metal surface. The next instant a cooler particle of steam comes in contact with this surface and absorbs this heat. Hence the heat loss due to this friction is returned to the steam itself, increasing the quality in the case of saturated steam and the temperature in the case of superheated steam. This increment of heat does not increase the capacity of the steam for doing work, as may be demonstrated by throttling steam from boiler pressure to atmospheric pressure. The volume at atmospheric pressure would then be many times greater than that at boiler pressure and the steam would probably be superheated. However, it would be useless to attempt to use this steam in a noncondensing turbine or engine for, although the heat in the steam may exceed that of dry steam at atmospheric pressure, no flow can occur until a drop of pressure is provided; therefore, no work can be done. Hence, internal friction of the steam in a turbine is a loss unless this steam is used for heating purposes. In most cases, this reheating of the steam in a turbine, through friction, has one beneficial effect in that it reduces the friction loss in later stages by supplying these stages with drier steam. It is well known that moisture in the steam materially increases the losses due to friction. The loss due to blade and diaphragm leakage is similar to that of throttling previously referred to.

When the heat available from adiabatic expansion has been determined, all that remains is to find the heat equivalent to work per pound of steam.

The results of the tests on any turbine will show the pounds of steam per electrical horsepower-hour or per brake horsepower-hour. If the turbines to be compared are both connected to electric generators, then it is necessary only to compare them on the basis of electrical horsepower, for as a rule, one contractor supplies both the turbine and the generator and makes his guarantee on the combined unit. If brake tests have been made on both units, comparison on a brake-horsepower basis is satisfactory. If one set of tests have been made with an electric generator furnishing the load and the other set with a brake load, then it will be necessary to reduce these to a common basis, in which case the efficiency of the electric generator must be known.

Assume that the tests have been made with electric generators as stated for turbines A and B. One horsepower equals 33,000 foot-pounds per minute, or

$$33{,}000 \times 60 = 1{,}980{,}000 \textit{ foot-pounds per hour}$$

Also, one B.t.u. equals 778 foot-pounds. It follows that

$$\textit{One horsepower} = \frac{1{,}980{,}000}{778} = 2545 \textit{ B.t.u. per hour}$$

Test results show for turbine A that 11.1 pounds of steam were required to produce one electrical horsepower of work which is equivalent to 2545 B.t.u. Hence, the heat per pound of steam actually converted into work equals

$$\frac{2545}{11.1} = 229.2 \textit{ B.t.u.}$$

From the Mollier diagram it will be found that there are 402 B.t.u. available per pound of steam due to adiabatic expansion from 214.7 pounds absolute and 537.8 degrees Fahrenheit to 0.54 pound absolute. This is found by first locating the point C at the intersection of the 214.7-pound pressure curve with the curve representing 150 degrees superheat; that is,

$$537.8 - 387.8 = 150 \textit{ degrees superheat,}$$

the 387.8 being the temperature of saturated steam at 214.7 pounds. Next, locate point D vertically below C and on the curve representing 0.54 pound. Referring to the scale on the left of the diagram, point C will be found to lie on the abscissa representing 1285 B.t.u. and D on the line representing 883 B.t.u.; therefore, the heat drop is

$$1285 - 883 = 402 \textit{ B.t.u.}$$

This shows an efficiency ratio of

$$\frac{100 \times 229.2}{402} = 57 \textit{ per cent.}$$

In the same way it can be shown for turbine B that the heat equivalent to work per pound of steam is 174.6 B.t.u. and the heat available from adiabatic expansion from 164.7 pounds absolute and 98 per cent. quality to 1.08 pounds absolute is 315 B.t.u.; hence, the efficiency ratio is

$$\frac{100 \times 174.6}{315} = 55.4 \textit{ per cent.}$$

Thus the efficiency ratio is a correct measure of the absolute efficiency of each turbine as it represents the ratio of the heat equivalent of useful work to the heat available, were the steam to expand freely with absolutely no losses in an ideal turbine.

Suppose, however, that one turbine has been tested with an electric generator and the other with a brake and it is desired to compare results on the basis of efficiency ratios. As stated before, the generator efficiency must be known. This can be obtained usually from the manufacturers and should include iron losses, copper losses, windage and friction. Assume that the tests of two 500-kilowatt turbines are to be compared. One is connected to an electric generator whose efficiency is 93 per cent. at full load; and in the test with a load of 670 electrical horsepower this unit required 9514 pounds of steam at 148 pounds gage pressure, 99 per cent. quality and 27.4 inches of vacuum, referred to a 30-inch barometer. The equivalent brake horsepower equals

$$\frac{670}{0.93} = 721 \textit{ b.h.p.}$$

and the steam consumption is 13.19 pounds per brake horsepower-hour.

The heat available through adiabatic expansion from 162.7 pounds absolute and 99 per cent. quality to 1.275 pounds absolute, is found from the chart to be 307 B.t.u. The heat utilized per pound of steam is

$$\frac{2545}{13.19} = 192.9 \textit{ B.t.u.}$$

and the efficiency ratio is

$$\frac{100 \times 192.9}{307} = 62.83 \textit{ per cent.}$$

The second turbine was tested with a brake. When running under steam at 155 pounds gage pressure and 98 per cent. quality, with a 28.5-inch vacuum, referred to a 30-inch barometer, the results showed a steam consumption of 13.05 pounds per brake horsepower-hour. The heat available from an adiabatic expansion from 169.7 pounds absolute and 98 per cent. quality to 0.737 pound absolute is found from the chart to be 330.5 B.t.u. The heat utilized per pound of steam was

$$\frac{2545}{13.05} = 195 \textit{ B.t.u.}$$

and the efficiency ratio is

$$\frac{100 \times 195}{330.5} = 59 \textit{ per cent.}$$

Hence, it would appear that the turbine tested with the generator is the more efficient unit.

By means of "efficiency ratios," a standard, varying only within the limits of the steam pressures used, can be determined; to this each turbine can be referred and an absolute efficiency ratio determined. A comparison of these efficiency ratios for several turbines will determine which is the most efficient regardless of the steam conditions under which they have been tested.

Friction Clutches and Their Use

By H. A. Jahnke

A continuation of the clutch descriptions appearing in the April 11 number, including clutches for gas and oil engines.

Dodge Clutches

Figs. 20, 21, 22 and 23 show the Dodge clutches. The Dodge clutches are of the disk type and are made in both split and solid patterns. The split clutch, Fig. 20, has one disk plate and is filled with hard-maple blocks the end-grain faces of which are pressed against the driving and clamping plates. The driving plate is keyed to the shaft while the outside clamping plate, by means of the levers shown, brings the wooden blocks in contact with the driving plate. When the clutch is in full, the wood-filled disk is securely clamped between the plates. The adjustments are made by tightening or loosening the locknuts on the draw bolts. A desirable feature of this clutch is its interchangeability. A pulley, sheave or gear used in connection with it may be of any size within the capacity of the clutch. Where much power is to be transmitted by the Dodge clutch, it is recommended that a sleeve be used which is long enough to permit the rise of two bearings, one on either side of the pulley. This will prevent all bending stress in the shaft due to the weight of the pulley.

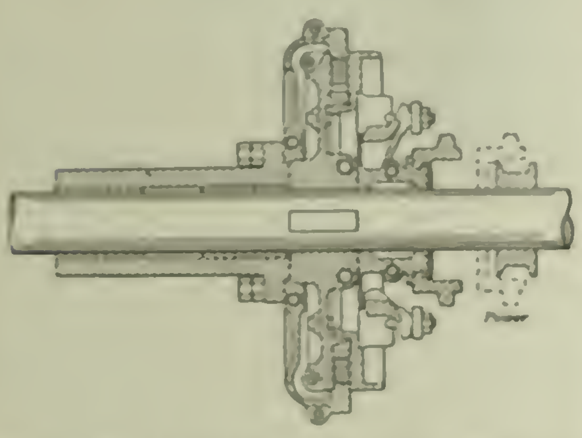


Fig. 20. Section of Dodge Friction-clutch Cutoff Coupling

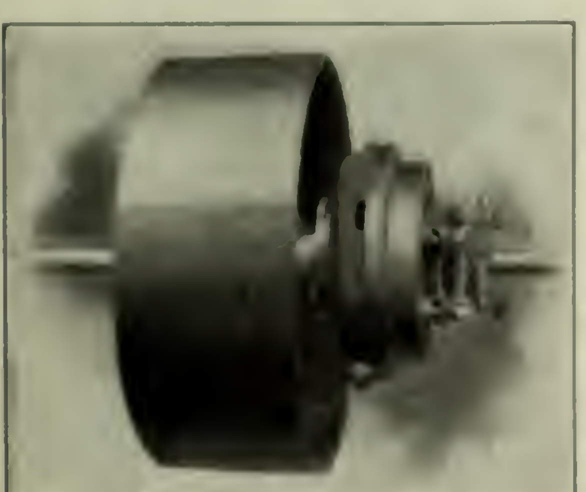

Fig. 21. Dodge Clutch with Steel Pulley

These clutches are made by the Dodge Manufacturing Company, Mishawaka, Ind.

The Hunter Clutch

Fig. 24 shows the Hunter clutch, which may be used as a friction-clutch cutoff coupling, or in connection with a pulley. A novel feature of the Hunter clutch is that when not in use the friction hub can be withdrawn; thus, should the shaft get out of line there would be no contact between the friction surfaces, thereby avoiding all unnecessary wear.

Fig. 22. Dodge Clutch with Wood Pulley

This clutch is made by the James Hunter Machine Company, North Adams, Mass.

The Medart Clutch

All of the operating mechanism of the Medart friction clutch, Figs. 25 and 26, is in full view, and self-locking. The clutch can be thrown in or out without shock or jar. All of the Medart clutches are furnished with stop bolts to limit the throw of the slide collar, making a set collar unnecessary. All clutch pulleys over 30 inches in diameter are fitted with V-shaped friction shoes as shown in Figs. 25 and 26.

The Medart Patent Pulley Company, St. Louis, Mo., manufactures this clutch.

The Lemley Clutch

Figs. 27 and 28 show the Lemley clutch. The Lemley clutch is provided with two or more sets of toggles, depending on the size of the clutch. The clutch has a universal adjustment which makes it necessary to move only one part to adjust all toggles. In this way equal pressure is secured on all friction surfaces.

The friction blocks are made of hard maple. These are riveted to the friction plate with copper rivets. The blocks are supported on both sides by flanges on the friction plate.

The Lemley clutch is made by the W. A. Jones Foundry and Machine Company, Chicago, Ill.

The Davis Clutch

Figs. 29 and 30 show the Davis clutch. This clutch is made with a friction ring or hub with a sleeve on which a pulley or gear can readily be mounted. On the body piece there are hinged two friction wings which extend all the way around the hub, and are operated by compound levers acting against set screws. The wings terminate in two sets of lips through which are passed steel bolts through springs; this arrangement assures plenty of clearance when the levers are dropped. The clutch is perfectly balanced and, therefore, vibration is practically absent.

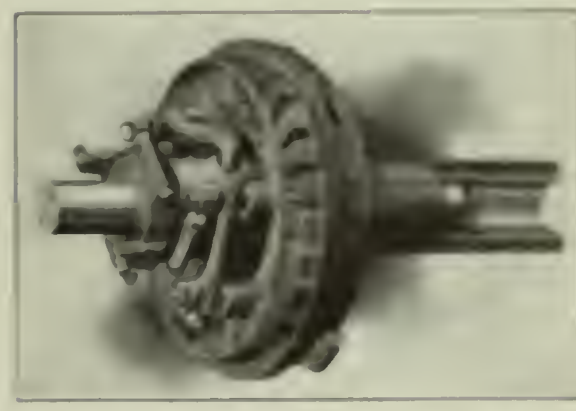

Fig. 23. Part Phantom View of Dodge Clutch, Showing Contact Blocks

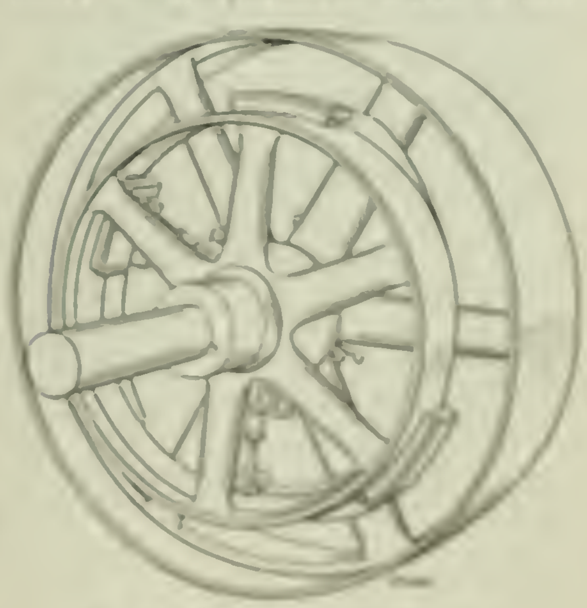

Fig. 24. The Hunter Clutch

The adjustment of this clutch is very simple and of almost unlimited range.

The Davis clutch is made by the Worcester Machine Company, Worcester, Mass.

The Reeves Clutch

The Reeves clutch is shown in Figs. 31 and 32. Extreme simplicity is one of the claims made for this clutch.

The metal friction wheel is clamped solidly to the shaft; the power is delivered by means of the wooden friction shoes,

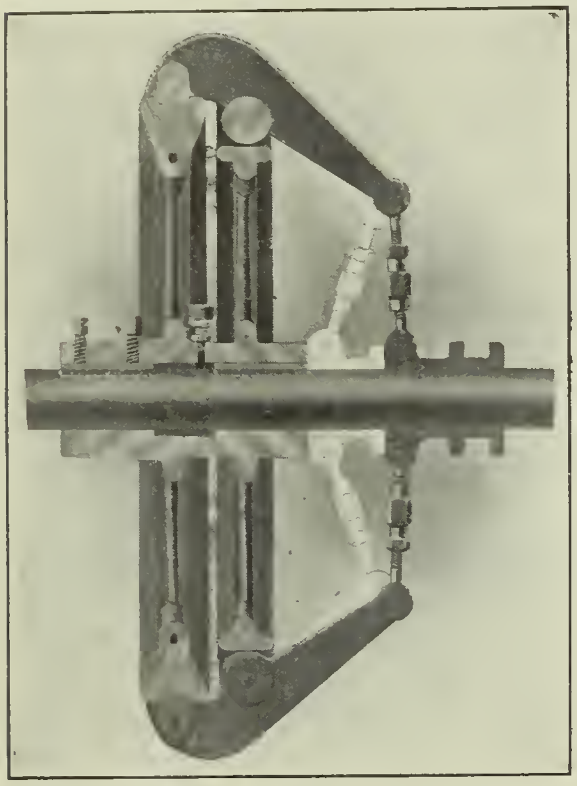

Fig. 25. Sectional View of the Medart Clutch

which are connected to the belt wheel, and which, when the clutch is thrown in, bear upon the face of the friction wheel.

The pulley is fitted with a babbitted bushing and when the clutch is thrown out all of the working parts and the

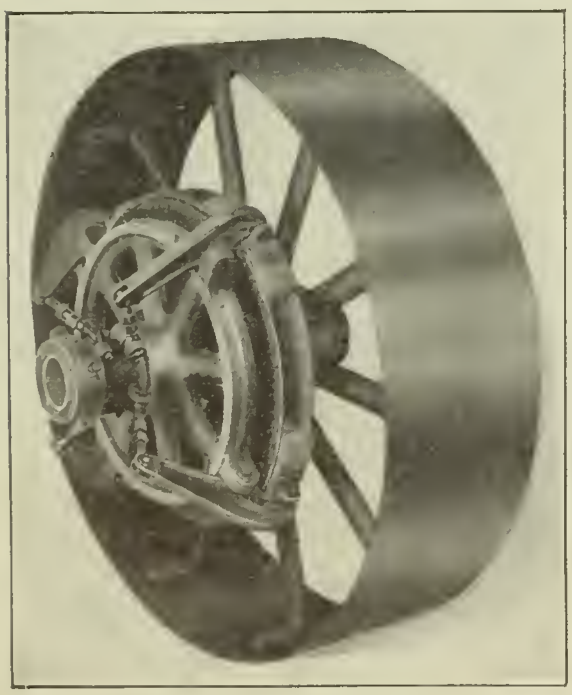

Fig. 26. Medart Clutch Attached to Pulley

pulley stand still. The friction shoes are operated by a toggle joint. The manufacturers of this clutch, the Reeves Pulley Company, Columbus, Ind., claim that, to the best of their knowledge, this is the only clutch which combines a wood split pulley with the clutch mechanism.

The Frisbie Clutch

The simple design of the Frisbie clutch is shown by the sectional view in Fig. 33. The pulley runs loose on the shaft; the

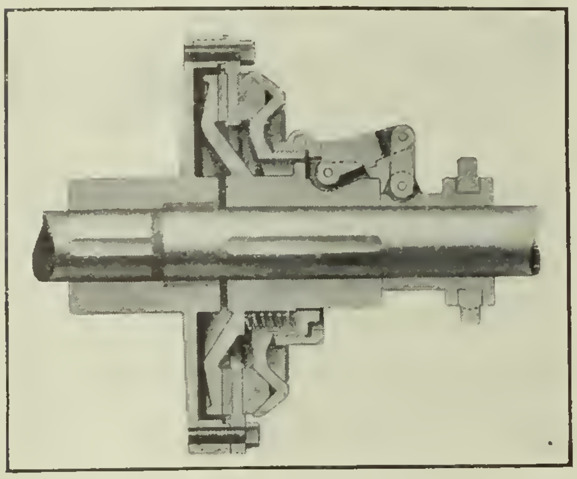

Fig. 27. Sectional View of the Lemley Clutch

hub of this pulley has a renewable bushing which takes all of the wear. The V-shaped friction ring is cast onto the arms of small pulleys and bolted onto those of the larger ones. The system of levers in the clutch spider, which is keyed solidly to the shaft, together with the friction shoes inside of the ring, forms the

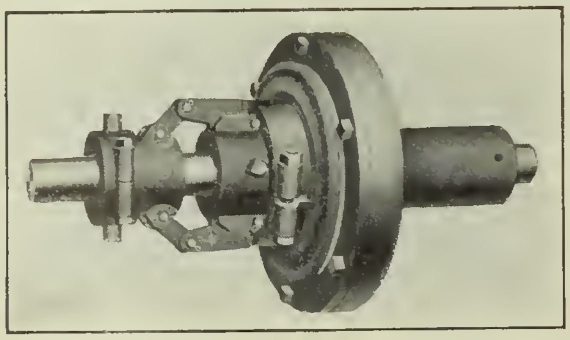

Fig. 28. Exterior View of Lemley Clutch

operating mechanism. Movement of the sliding sleeve operates the latches which move the heavy dogs, and by means of the shoe bolts draws the four friction surfaces of the pulley and spider together in position and powerful contact. The amount of pressure is regulated by the clamp nuts on the shoe bolts, which also take up lost motion caused by wear. The shoes and spider are fitted

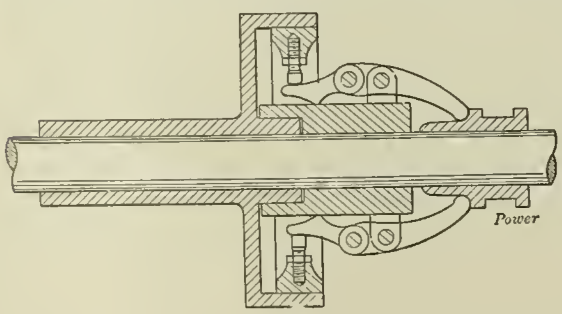

Fig. 29. Section of Davis Clutch

with thoroughly seasoned maple contact blocks.

The Frisbie cutoff coupling is shown in section in Fig. 34. Both of these devices are made by the Eastern Machinery Company, New Haven, Conn.

The Warner Clutch

Fig. 35 shows the design of the Warner clutch. This clutch has two or more crucible spring-steel rings or bands which

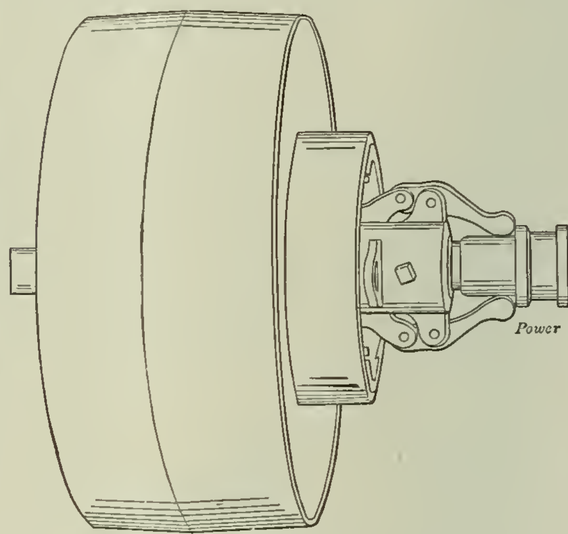

Fig. 30. Davis Clutch with Pulley Attached

are forced into frictional contact with the polished surface of a chilled-iron drum. The clutch mechanism is inclosed in a dust-proof case, and runs in an oil bath; the steel rings are practically unbreakable. The wear, which is very slight, occurs on the steel rings. The rings act one after another, thus insuring smooth engagement. When the clutch is used in connection with a pulley or gear it is fitted with a sleeve to which the pulley or gear can be keyed.

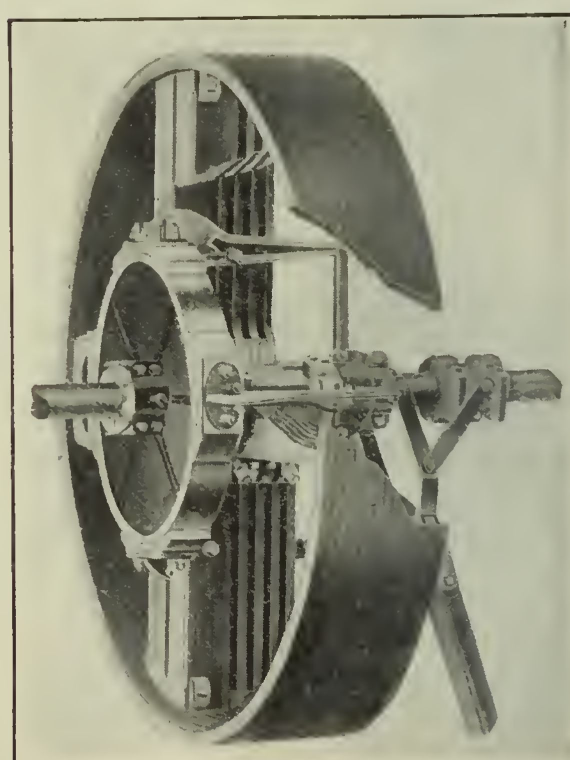

Fig. 31. Part Sectional View of Reeves Clutch with Pulley

When the clutch is used for a cutoff coupling, it is furnished with a hub, the driving shaft being keyed to the hub, while the driven shaft is keyed to the drum.

The Warner Clutch Company, Chicago, Ill., makes this clutch.

The Plamondon Clutch

A sectional view of the Plamondon clutch is given in Fig. 36. This clutch

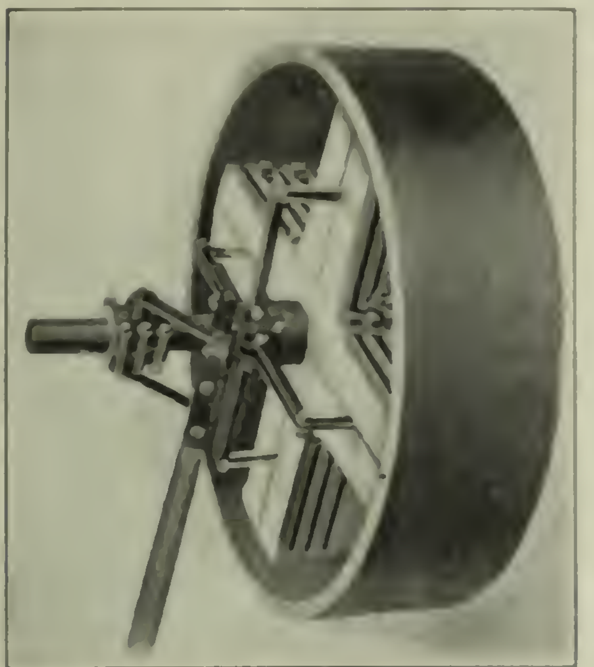

Fig. 32. Reeves Clutch and Pulley, Showing Mechanism

is powerful and simple, has few parts, contains no springs or bolts and is of such design as not to be affected by cen-

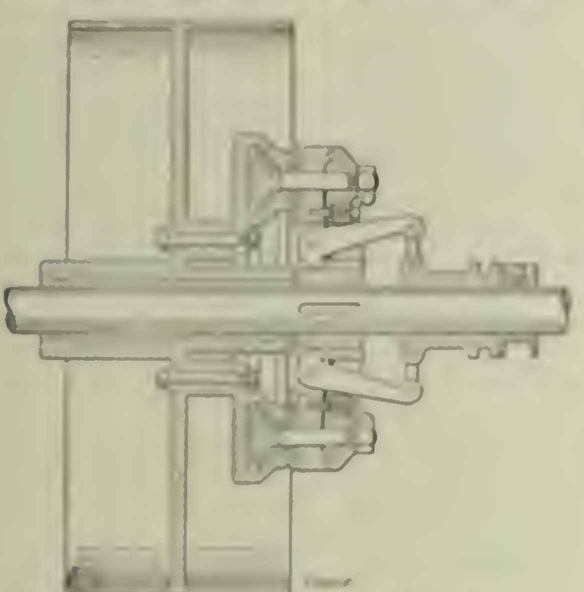

Fig. 33. Sectional View of Frisbie Clutch

trifugal action. Further, it is proof against dust and dirt, which fact makes it valuable for service in cement mills and the like.

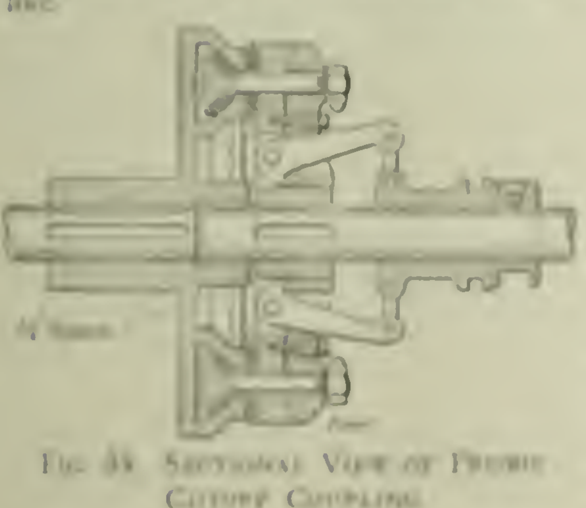

Fig. 34. Sectional View of Frisbie Cutoff Coupling

The friction plate C is lined on both sides with hard-maple segments, and is made in halves so that it can be removed for relining. In operation, the disks A and B are pressed against the plate C by means of the compound toggle arrangement G, H and I.

This clutch is made by the Plamondon Manufacturing Company, Chicago, Ill.

The Moore & White Clutch

Fig. 37 shows a sectional view of the Moore & White friction-clutch pulley, and

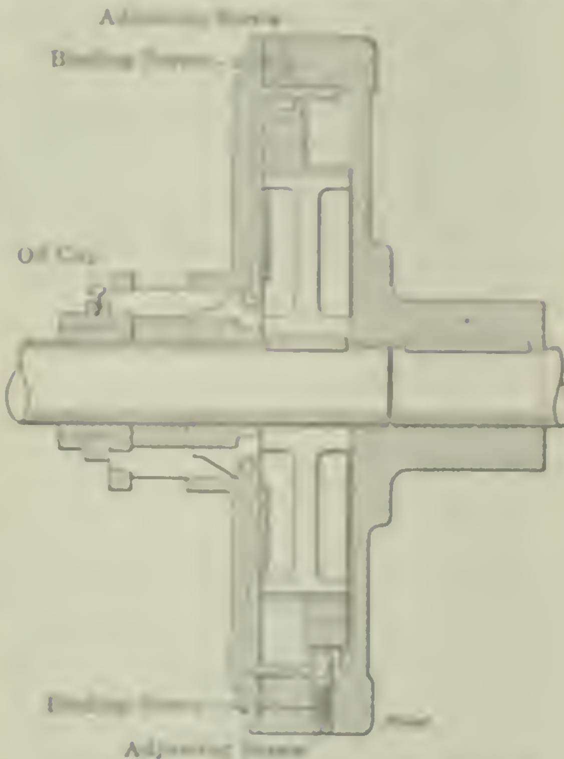

Fig. 35. Design of Warner Clutch

Fig. 38 shows the friction disk used in this clutch. The pulley is made with a long hub to give ample wearing surface. To the hub of the pulley is keyed a collar with lugs on one side which engage with lugs on the friction disk;

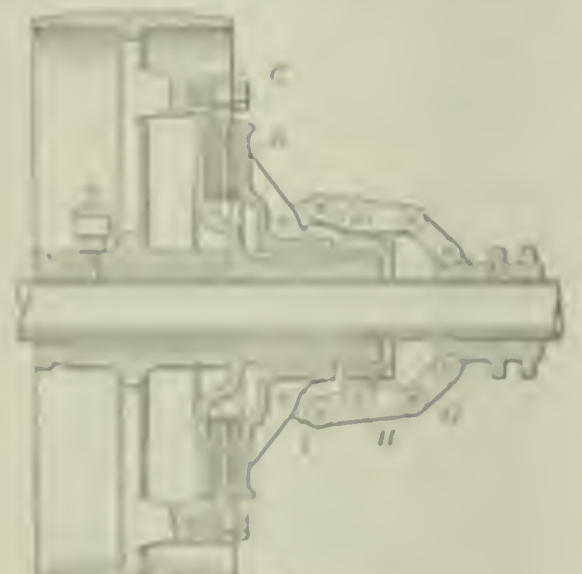

Fig. 36. Sectional View of the Plamondon Clutch

this causes the disk that fits loosely on the hub of the pulley to revolve with the pulley and at the same time leaves the disk free to take up wear if necessary. The advantage of the disk being loosely connected to the pulley in this manner becomes manifest when the pulley wears loose on the shaft, or when the shaft, pulley or hub falls to run true. With this design wear of the friction surface is prevented when the clutch is disengaged.

The friction disk is filled with hard

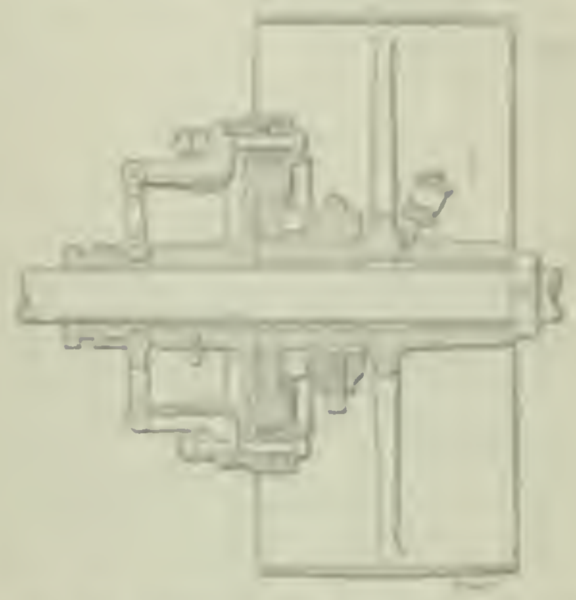

Fig. 37. Section of Moore & White Friction-clutch Pulley

wood and presents two end-grain wood surfaces for contact with the two iron surfaces. The iron surfaces are drawn into contact with the wood surfaces of the disk by a powerful mechanism. The

Fig. 38. Friction Disk of the Moore & White Clutch

clutch can be made in halves if necessary, and applied to wood pulleys, gearing and sprocket wheels. It can also be applied as a cutoff coupling for stopping

Fig. 39. The [illegible] Friction-clutch Pulley

and starting parts of line shafts. This clutch is manufactured by the Moore & White Company, Philadelphia, Penn.

The Falls Clutch

Figs. 39 and 40 show the Falls friction-clutch pulley, and Fig. 41 shows the

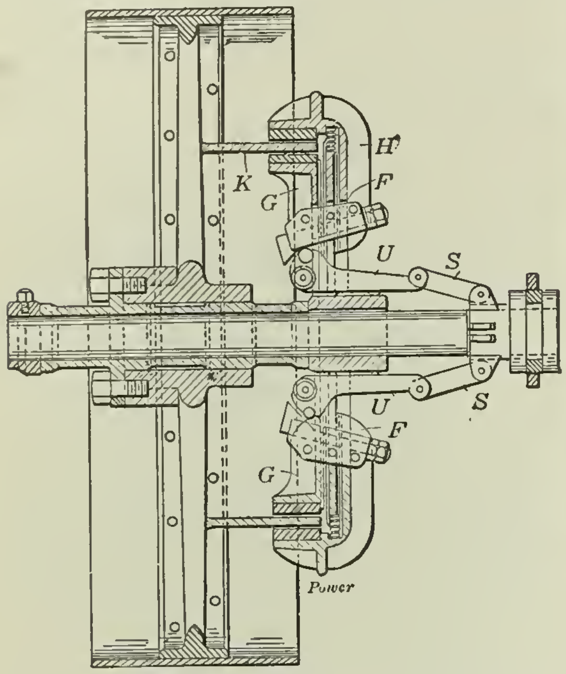

Fig. 40. Sectional View of the Falls Friction-clutch Pulley

friction-clutch cutoff coupling. These clutches are made with four or six arms according to the amount of power to be

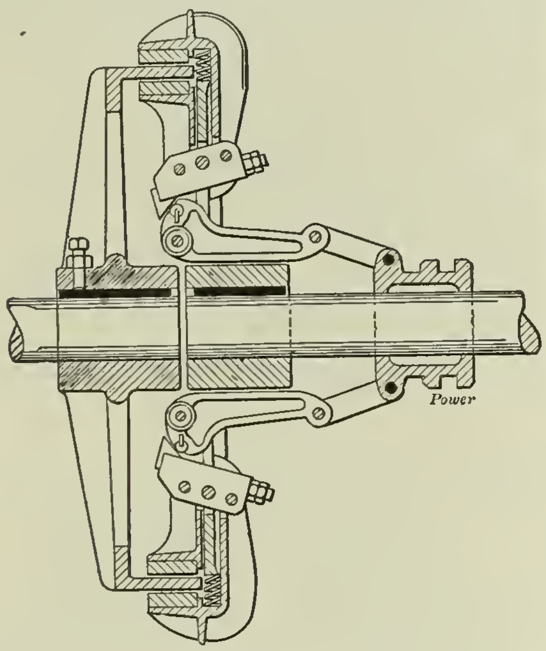

Fig. 41. The Falls Cutoff Coupling

transmitted. The pulleys are furnished with babbitted split sleeves for bearings; they are turned on the outside to fit the

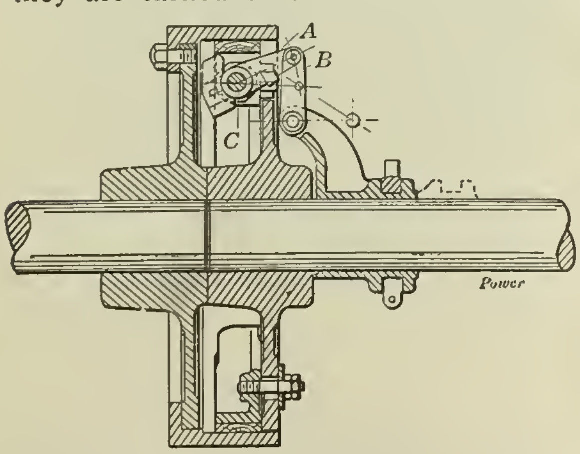

Fig. 44. Section of A. & F. Brown Friction-clutch Pulley

hub of the pulley and bored on the inside to fit the shaft. The sleeves are held in position by two cap screws.

The clutch ring *K*, Fig. 40, is generally made one-half the diameter of the pulley onto the arms of which it is cast.

Fig. 42. Allis-Chalmers Friction-clutch Pulley

The inner jaw *G* of the clutch arms is forced outward, and the outer jaw *H* inward, by means of the toggle levers *S*

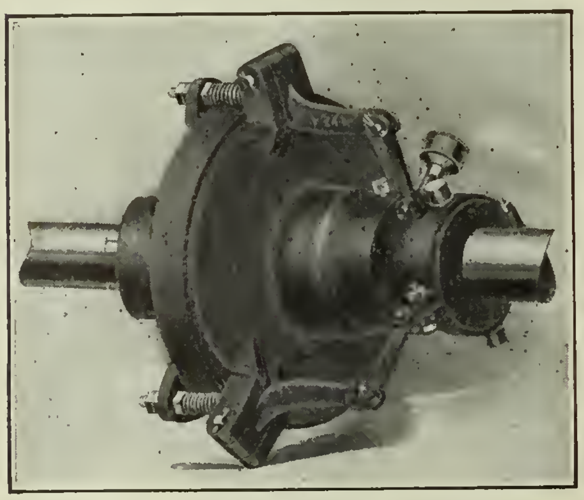

Fig. 43. Allis-Chalmers Friction-clutch Coupling

and *U* which act upon the lever *F*. The clutch jaws are adjusted by means of the steel wedges in the lever *F*. Seasoned maple is used for the clutch shoes.

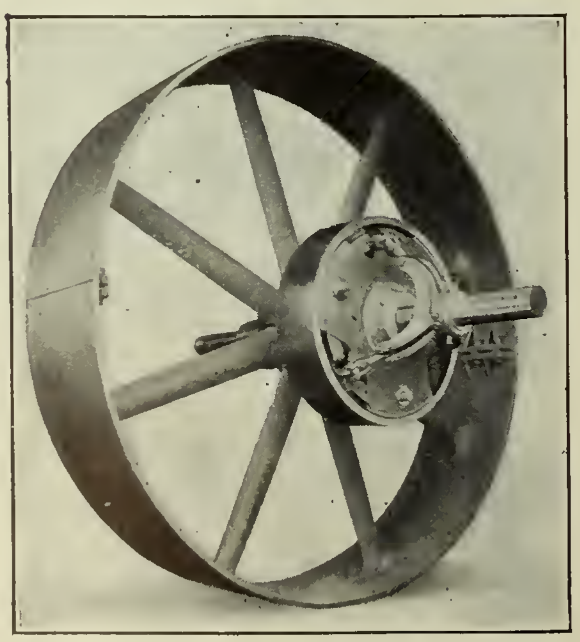

Fig. 45. A. & F. Brown Clutch with Pulley Attached

The Falls Rivet and Machinery Company, Cuyahoga, O., makes the clutch.

The Allis-Chalmers Clutch

The Allis-Chalmers friction-clutch pulley is shown in Fig. 42 and the friction-clutch coupling in Fig. 43. These clutches are of the disk type. Although they are designed to be capable of carrying very

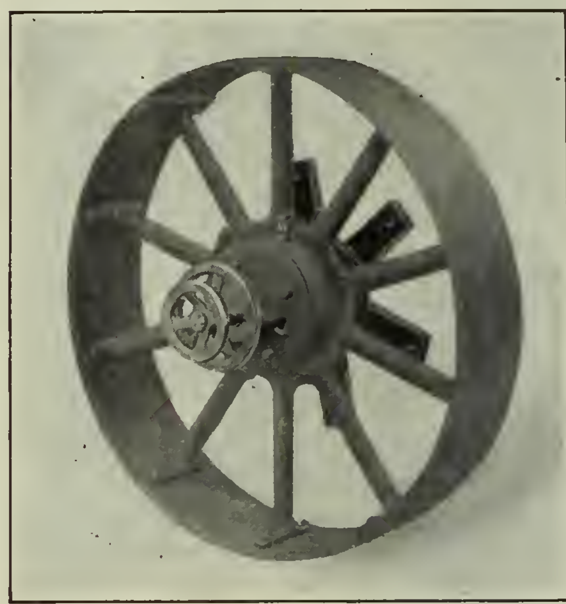

Fig. 46. The Springfield Clutch for Gas Engines

heavy load, they are made in sizes adapted for use in any place where power is employed.

The adjustment of two set nuts compensates for any wear of the friction surfaces. The cast-iron driving disk is clamped between two continuous wood surfaces. The clutches are made with either three or six arms, and, as the pressure is distributed uniformly over

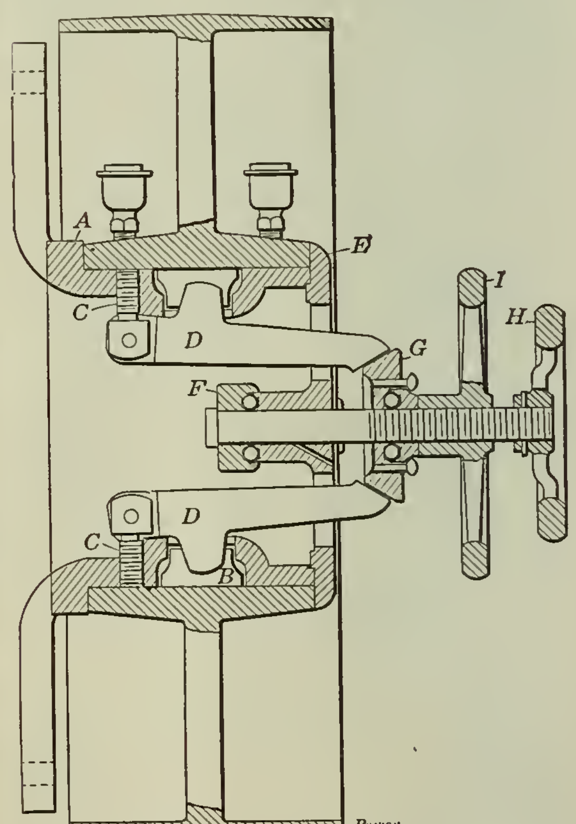

Fig. 47. Section through Springfield Clutch

the entire friction surfaces, the clutches do not have to carry any one-sided strains. There are no springs in the mechanism. The pressure is regulated according to the load the clutch has to carry, by means of adjusting nuts on the eye bolts.

These clutches are made by the Allis-Chalmers Company, Milwaukee, Wis.

The A. & F. Brown Clutch

The A. & F. Brown clutch is shown in Figs. 44 and 45. This clutch is simple in construction and durable. The shifter collar, Fig. 44, operates the counterweighted lever *A* through the link *B*. The pin *C* carries a worm which, when the clutch is thrown in, forces the frame carrying the wood shoes against the friction hub. The object of the counterweight on the lever *A* is to prevent centrifugal force from influencing the action of clutch.

Fig. 45 shows a three-arm clutch with split pulley attached.

The A. & F. Brown Company, New York City, manufactures these clutches.

Clutches for Gas, Gasolene and Oil Engines

There are many points in favor of placing a friction clutch on gas and gasolene engines, especially where the load is heavy. One advantage is that the engine may be started slowly and gradually speeded up before any load is thrown on the engine. Another desirable point in having a friction clutch on the engine is that in case of an accident it is not necessary to stop the engine; the machines can be stopped or started by the friction clutch, thereby saving time and expense.

Springfield Clutch

Figs. 46 and 47 show the Springfield clutch pulley ready to be attached to the flywheel of a gas or gasolene engine. The pulley proper is mounted on a hollow bearing or spider *A*, Fig. 47, having arms which bolt to the flywheel. In the bearing is a recess or groove in which lies a friction ring *B* which is divided into two parts. Attached to the bearing by means of studs *C* are two levers *D* having wedge-shaped lugs extending between the ends of the friction ring. A faceplate *E* is bolted to the bearing or spider and provides a journal for the spindle. The inner end of the spindle is fitted with a ball-bearing thrust collar *F*. Mounted loosely on the spindle is a cone *G* which also forms part of the ball bearing.

To engage the clutch the handwheel *H* is held stationary and the wheel *I* is turned down on the spindle. This causes the cone *G* to force apart the ends of the arms *D* so that lugs enter the openings between the halves of the friction ring *B* and force it into contact with hub of the bearing.

The Springfield Gas Engine Company, Springfield, O., manufactures the clutch.

Lemley Gasolene-engine Clutch

Fig. 48 shows the Lemley gasolene-engine clutch pulley. The upper part of the figure shows the clutch designed to be bolted to the flywheel arms and the lower part shows the clutch as it is built to be keyed to the shaft.

The friction blocks are made of hard maple riveted to the clutch plate and make a continuous friction surface around the plate. To engage the clutch the handwheel is pulled out; to release, it is pushed in.

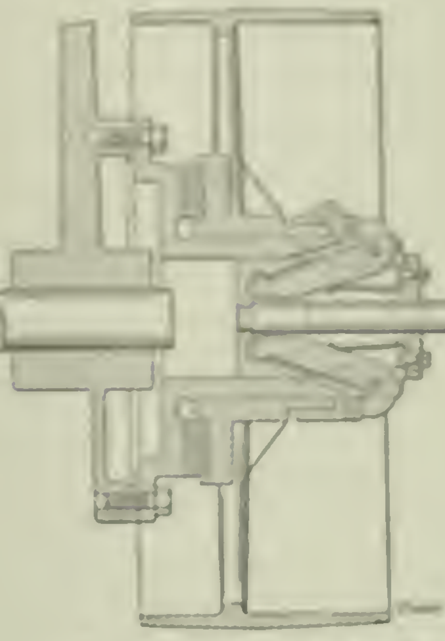

Fig. 48. Lemley Clutch

The Lemley gasolene-engine clutch is made by the W. A. Jones Foundry and Machine Company, Chicago, Ill.

Notes on Power Plant Betterment*

By H. H Hunt

A consideration of the work of the engineering expert, who, through specialization in economic plant management, is able to introduce new methods which minimize waste and cut down operating expenses. To be effective, the regular operating force should be trained in these methods, which should be carried on with zeal after the expert leaves.

The general tendency toward consolidation has extended to power plants, and many of the smaller ones have been replaced by large central stations of modern design, operated by high-priced men and with great refinement. There are, however, many of the smaller plants which for good and sufficient reasons are still in operation and which must be operated in the future. In the face of the upward tendency of wages, cost of apparatus and materials and the downward tendency of rates and increasing demands for improved service, the public service company of today is in a position where the question of economy all along the line, and particularly in that most important part of the property—the power plant, is one of vital importance.

A casual inspection of one of these small power plants often reveals a more or less heterogeneous collection of apparatus and machinery, some of which date back to the early days of the business. This, together with the fact that such a plant is usually operated by a force of engineers and firemen of only ordinary intelligence and ability, might naturally lead to the conclusion that, even under most favorable conditions high power costs are to be expected.

On the other hand, a careful and detailed examination by an expert in power-station operation will almost invariably reveal many features which are capable of marked improvement, enabling him to report recommendations which, if properly carried into effect, will result in material reductions in costs.

In undertaking the betterment of operating conditions, attention should first be given to the personnel of the operating force. The chief engineer should be a man of both operating and executive ability, and capable of enforcing strict discipline. He must be capable of receiving instruction, as must also the other members of the force. Each man who does not possess the possibility of becoming a thoroughly efficient and alert member of the force should be replaced as soon as possible. Careful study is required in arriving at correct conclusions in reference to each individual of the operating force in order that justice may be done. It not infrequently happens that certain men develop unexpected ability as they gradually become familiar with the methods by which actual improvements are brought about. Furthermore, every reasonable opportunity should be given the existing employees to measure up to the new requirements in order to avoid the demoralization to the organization which would be caused by the needless discharge of men.

A thorough physical examination of the plant should be made and immediate steps taken to correct such defects as can be remedied without excessive cost. Starting with the fire room, for instance, the boilers should be thoroughly overhauled and cleaned, leaky tubes replaced,

*From a paper presented at the Congress of Technology, at Boston, April 11, 1911.

blowoff cocks and valves made tight, gage glasses and dampers put in order, air leaks in boiler settings stopped, furnace linings, bridgewalls and grate bars put in order, safety valves adjusted, steam gages calibrated, etc. The work should be continued, in like manner, to the engines, paying particular attention to valve setting, steam piping, pumps, condensers, heaters, oiling systems and electrical machinery.

In connection with this general overhauling of the machinery, all gages, meters and measuring instruments should be calibrated and tested, so as to give accurate information regarding the operation of the plant. Attention should also be given to the matter of tools, and it should be seen that a suitable assortment is provided, both for the engine room and the fire room. Finally, the station should be thoroughly cleaned.

All the firemen should be individually instructed in handling the particular kind of coal used, in the use of the proper fire tools, the operation of the dampers and control of the draft. A thorough course of training along these lines will usually be found necessary, and it will be further necessary to instruct the chief and watch engineers in every detail of the proper handling of the fires in order that they may be able to maintain intelligent supervision over the room.

Special attention should be given to maintaining the necessary boiler pressure and feed-water temperature, in order to avoid the usual fluctuations which so largely affect station economy. Recording pressure gages and feed-water thermometers and a bulletin board in the boiler room, on which are posted the coal consumption and pressure records of each watch, will serve a useful purpose in exciting rivalry among the men.

Presumably, the engineers understand such matters as the starting and stopping of their engines and generators; nevertheless, the expert should give some attention to the engine room. In this connection a most careful study of the load conditions should be made and charts prepared which will show clearly just what combinations of apparatus and machinery should be used to meet the various conditions of the load, the idea being to so arrange the schedules that each piece of apparatus, when in use, will be operated as nearly as possible at its point of maximum efficiency.

A carefully arranged station log should also be provided which will contain the daily operating data of the plant, recorded in a systematic manner. In such a station log it is desirable that the main factors, such as coal consumed per kilowatt-hour, water evaporated per pound of coal, etc., be shown so clearly that the manager of the company, by spending a few minutes daily in perusing the station log, may become fully acquainted with the daily operation of the plant and be in position to intelligently discuss matters with his chief engineer.

The coal problem is one of the most important, and at the same time one of the most troublesome, which is encountered in power-plant operation. The quality of coal depends, to a certain extent, upon the location of the power plant as related to the sources of coal supply. It will be found profitable to have a careful investigation made of the possible sources from which coal may be secured at reasonable prices. Full data should be gathered regarding the analysis of the various coals available, and that coal selected which will meet local conditions with the best results. While not always practicable, it is desirable to purchase coal on the analysis basis under specifications which provide for a penalty or bonus according to whether the coal falls short of or exceeds the requirements of the contract. Under such a contract an analysis of each shipment of coal is necessary. Where the annual consumption is comparatively small, however, it is not practicable to purchase coal on the analysis basis, in that event the best that can be done is to buy it of responsible dealers who handle the best coal to be had under the circumstances.

To account for the coal purchased, while seemingly simple, proves in practice more or less troublesome. Coal is frequently purchased and paid for according to bill of lading weights. The consumer is apt to suffer shortage under this method of purchase and to start out with substantially less coal in than is called for by his books. It is obvious that ultimately the cost of the coal consumed must check with the cost of coal purchased, and in order to bring about this agreement, frequent checks between station records, coal on hand and fuel accounts are necessary. It will be found desirable to arrange proper scales for weighing in bulk the coal which is delivered to the yard; and if a contract can be so arranged as to make payments on the basis of the company's weights, one question of coal shortage will be removed. Bins should be provided which will permit the coal supply to be accurately measured at any time. Also the coal passing into the fire room must be carefully weighed and these weights recorded. With these precautions there should be no excuse for coal shortage.

Low cost of maintenance does not always indicate thorough or economical maintenance, for while it may be possible to run for months on abnormally low maintenance costs, the time will come when the accumulation of deferred maintenance will produce a condition of affairs which will require excessive expenditures, if not for new apparatus, certainly for the overhaul and repair of the old apparatus. Therefore, it is desirable to prepare a proper maintenance schedule which shall be carefully and conscientiously followed by the operating force. Such a schedule will set forth definite dates for the inspection of all apparatus; the schedule to be so arranged that each and every part will receive periodical attention as often as is necessary to keep it in good operating condition.

As to what may be expected as a result of this power-plant betterment work, it may be summed up as follows: first, accurate knowledge of the maximum efficiency of which the particular plant under consideration is capable; second, the securing of this efficiency through the efforts of a well trained and efficient operating force; third, systematic and economical maintenance producing maximum life of all apparatus and continuity of service; fourth, in case of failure to continue to produce the desired results, it is possible to trace the cause.

Experience has shown that the saving in power costs, resulting from power-station betterment work, will cover the cost of the necessary expert services in a comparatively short time, depending upon the amount of saving effected.

The continued operation of a power plant under the conditions established by successful betterment work, by which maximum economy in operation and maintenance are secured, calls for most active and energetic work on the part of the operating force. In fact, from the manager of the company all along the line down to the coal passers, every man must work under high pressure. After the novelty of the improved condition wears off, the operation of the plant becomes not only monotonous but exceedingly strenuous. It is so much easier to slip back a little than to maintain the required pace, that frequent checking of the plant operation is necessary. The manager must give his personal attention to this matter, and he will doubtless be surprised to note the effect of his failure to carefully follow up the matter of daily checking of the plant, if for any reason it becomes necessary for him to temporarily discontinue his critical study of the daily station log.

In spite of all reasonable efforts, it is quite likely that the economy of a plant will gradually decrease because of a combination of little things which creep into the operation unnoticed by the engineers. This has been noted in actual experience and has led to the belief that a periodical power-plant audit by a competent expert is necessary just as it is found necessary to periodically audit the accounting department. Such an audit will require much less time than the original examination, especially if both examinations and audits are made by the same man, and should not, therefore, be very expensive.

Limitations of Scientific Efficiency

By Henry G. Bradlee

While recognizing that the efficiency engineer can improve operating and manufacturing methods in certain instances, the author calls attention to the limitations in this line and cites cases where the cost of reorganization and the introduction of new methods far exceed the benefits derived therefrom.

During the past year much has been said and written about "efficiency," and, in fact, quite recently the public was startled by the statement that the steam railroads of this country are wasting a million dollars a day—three hundred and sixty-five million dollars a year—which might be saved through the adoption of so called scientific methods of management.

This whole question has recently jumped into prominence because a group of men, who have been doing some very excellent and successful work, have been tempted into the realm of prophecy, and have possibly allowed their enthusiasm to outstrip their judgment.

In view of the statements which have been made it certainly seems reasonable to consider whether there are not some practical limitations which have prevented a general adoption of these methods in the past and which may prevent the wholesale overturning of present industrial systems.

Stripped of technicalities the method of the modern efficiency engineer is simply this. First, to analyze and study each piece of work before it is performed; second, to decide how it can be done with a minimum of wasted motion and energy; third, to instruct the workman so that he may do the work in the manner selected as most efficient. There is nothing fundamentally new in this method. The underlying principle is being used today to a greater or less extent in all industries and has, no doubt, been used at all times in the past.

The method as employed by the modern efficiency engineer is distinctive, not because it is new, but because it is carried to much greater detail. He is not content to plan work along broad general lines, but proposes to attack it in a more scientific spirit and obtain maximum efficiency through preventing waste and loss at each and every point. With this in view he watches every motion of the workman's hands and body. If any unnecessary movement is made he tries to change the conditions under which the work is carried on or gives instructions to the workman so that the wasteful act may be avoided in the future.

The form of organization adopted naturally has the same end in view. The number of overseers, supervisors, experts and specialists, in proportion to the number of workmen, is materially increased. Special accounting systems are adopted to show at a glance what proportion of the cost of a piece of work is necessary and what proportion is caused by wasted energy. The information so obtained is used as a guide to prevent waste in the future. The workman is often encouraged to coöperate through the use of a bonus system which aims to give the highest pay to the most efficient worker.

These methods in certain cases have produced surprising and satisfactory results, but it is by no means a necessary conclusion that they can be universally applied with equal success.

Upon considering these methods of careful study and analysis, and of detail instructions to workmen, one is first impressed by the fact that such study and instruction must be expensive; it must be performed by men of considerable ability, and consequently high pay, otherwise it will not be effective. Such methods, therefore, can be used to advantage only where a material saving can be made.

If a piece of work is to be performed but once the manner in which it is to be done may be planned in a general way, but should one attempt before starting the work, to decide the exact manner in which every detail is to be handled the cost of planning may exceed any possible saving in the cost of labor. If the work is to be repeated several times, but each time is to be performed under new conditions, the same difficulty will be found. On the other hand, if the work is to be repeated a number of times under uniform conditions, instead of only once, it may be profitable to carry out the preliminary planning in greater detail. But not until the work is to be repeated over and over again should the full program of the efficiency engineer be adopted.

Next, consider the territory covered by the work of any industrial organization. Imagine a factory employing a thousand men under a single roof. Then imagine an industry employing an equal number of men distributed through forty different cities, an average of twenty-five men in each city. Can there be any doubt that the introduction of the methods of scientific efficiency would be fraught with a hundred difficulties in the second case for every one in the first?

To what class of work, then, may efficiency methods be successfully applied? Work of this character will presumably be found in certain large mills, factories and shops and in some special departments of other industries. In fact, from the examples quoted by these engineers it is in just such places and under such conditions that the best results have been secured.

But this is only one side of the problem; further study will show that even where conditions are favorable to efficiency methods, limitations often exist which will prevent their adoption.

Low cost of operation or of manufacture, is, after all, only one factor out of many to be considered in measuring industrial efficiency. It frequently happens that the lowest cost can only be secured through sacrificing other and more important factors, for example:

Steam railroads increase their operating costs per ton mile by operating express service. By doing this they have helped to build up industries which could not otherwise exist. People are glad to pay this extra cost so that they may no longer be dependent upon a local supply of fruits and other perishable goods.

In construction work methods are frequently adopted which might be considered extravagant if the advantages which come from completion of the work by a certain date were overlooked. Delay in completion is often far more serious than a considerable increase in the cost of the work.

An electric lighting company will spend a large amount of money to purchase and maintain a storage battery solely to prevent momentary interruptions in service. Continuity of service, even at increased cost, is necessary to retain public good will and patronage.

It is often more economical for a street railway to attach trailers to its regular cars to handle rush hour business than to operate additional cars. The public, however, do not like trailers and here again, the railway decides that public good will is more important than a slight saving in expense.

These few examples illustrate that diversified industries, public health, safety and welfare, speed of service, time of completion, quality and quantity of service, public good will and patronage, all enter into the measurement of success and efficiency.

Moreover, an attempt to increase economy in one detail of operation often decreases it in another. This may be illustrated by the fact that one of the first steps taken by an efficiency engineer is

*From an address delivered before the Congress of Technology, and also the National Association of Cotton Manufacturers.

to establish an elaborate system of cost accounting; a second step is to increase the number of supervisors and specialists employed to oversee and direct the work of the laborers. This increased cost is deliberately and intentionally incurred for the purpose of saving a greater amount in other items of expense. If the accounting department were considered by itself without reference to the rest of the business, or if the number of supervisors and specialists were compared with those employed by some other concern doing a similar business, it might appear that the efficiency engineer is most extravagant and uneconomical. However, to be fair and just to the engineer, one must consider the results of his work as a whole and not condemn him because of increased expenses in certain departments.

It has always been recognized that there is an element of danger in fixing one's attention too closely on detail economies, which is in line with the "man who was penny wise and pound foolish." The writer once knew the manager of an electric lighting company who directed his business with the greatest economy. He frequently remarked that he would much rather save a dollar in operating expenses than secure a dollar of new business because, when he had saved a dollar in expense he had saved the whole dollar, but, when he had obtained a dollar from new business he had to spend half of it in serving the customer. In due course of time this manager resigned and a new man was appointed in his place. The new manager was not very economical, but he was a hustler for new business and he kept in very close touch with his customers. As a result the business immediately began to grow and increased very rapidly, and the public received more and better service at slightly lower rates. The dividends of the company increased, but the cost of operation per kilowatt-hour increased also. Measured by operating costs only, the efficiency was less than under the old manager, but the efficiency of the business, as a whole, was greatly increased.

The question will naturally be asked—why not secure a manager who will push the development of the business, keep the public satisfied, maintain a high quality of service, and, at the same time, direct his organization and business along the lines of maximum economy? There is no doubt that men of this kind would be desirable but, unfortunately, they are few and far between.

Flow of Water in Clean Iron Pipes

By Albert E. Guy

The method of developing and plotting a chart showing the flow in gallons per minute for any size of pipe between 2 and 72 inches with a velocity anywhere between 0.5 and 25 feet per second. An introductory discussion and a similar chart, applicable between different limits, appeared in the April 4 issue.

It is not possible for an investigator to cover in experiments the complete range of conditions with which the practical engineer has to deal at some time or another; this is particularly true with hydraulics. Prior to Darcy's investigations of the subject, many experiments on the flow of water in pipes had been conducted, but the results were not coherent until Prony, of the Prony brake fame, took up the problem, and finally succeeded in establishing a complex formula with constant coefficients, which embodied approximately all the experimental results at hand at that time. Prony's achievement appeared to many engineers more as the result of an accidental compensation between all the causes of divergence than as the revelation of a positive law.* Darcy's experiments confirmed the deductions of Prony and enabled him to simplify the latter's formula.

More recent investigators, however, have endeavored to establish a formula still less complicated than Darcy's. This complication, so far as concerns the present treatment, lies in the fact that each pipe diameter is expressed in the complex form,

$$\frac{D}{\sqrt[6]{0.62\,(D+1)}}$$

It would be very desirable to have, instead of this, one of a simpler form D^n.

Several engineers have boldly cut across lots, and have each brought out a formula which, expressed by a graphical chart of the type described here, has for the diameters a continuous scale much easier to establish than that of chart No. 1.† Besides, the diameter function being continuous, it was possible to show on the same chart an additional scale, very much needed, giving the velocity per second corresponding to a given quantity of water passing through a pipe of certain diameter.

It is easy to so transform Darcy's formula that D becomes a continuous function; but in order to do this, an approximation must be introduced. Solving the expression $\left(\frac{D}{\sqrt[6]{0.62\,(D+1)}}\right)$ for a series of values of D ranging from 2 to 48 inches, and then considering each of the values obtained thereby as representing the corresponding diameter raised to a certain power, the expression may be written,

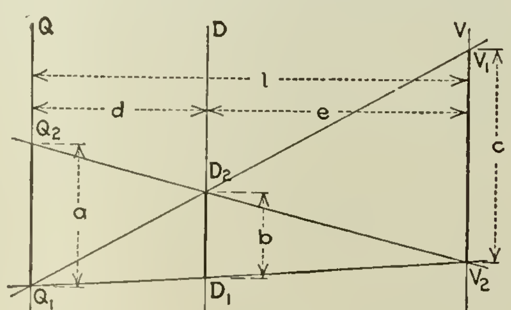

Fig. 2

$$\frac{D}{\sqrt[6]{0.62\,(D+1)}} = D^n$$

or, using logarithms

$$\frac{\log.\left(\frac{D}{\sqrt[6]{0.62\,(D+1)}}\right)}{\log.\ D} = n$$

For the range of diameters considered, n appears to be almost constant; that is, n increases from 0.851 for a diameter of 2 inches, to 0.864 for one of 4 inches, and then gradually decreases until it becomes 0.852 for a 48-inch pipe. The average value is 0.8567, which permits Darcy's formula to be written with a very close approximation, as follows:

$$\textit{Gallons per minute} = (D^{0.8567})^3 \sqrt{h} \quad (13)$$

or,

$$\textit{Gallons per minute} = D^{2.57} \sqrt{h} = D^{\frac{18}{7}} \sqrt{h} \quad (14)$$

However, the writer preferred to make chart No. 1 conform strictly to Darcy's original formula and to construct chart No. 2, showing the relation between the volume and the velocity of water passing through a given pipe.

Let

V = Velocity in feet per second;

D = Diameter of pipe, in inches.

The area of the pipe, in square feet, is:

$$\frac{\pi D^2}{4 \times 144}$$

The velocity in feet per minute equals $V \times 60$.

One cubic foot equals 7.48 United States gallons.

Substituting these values,

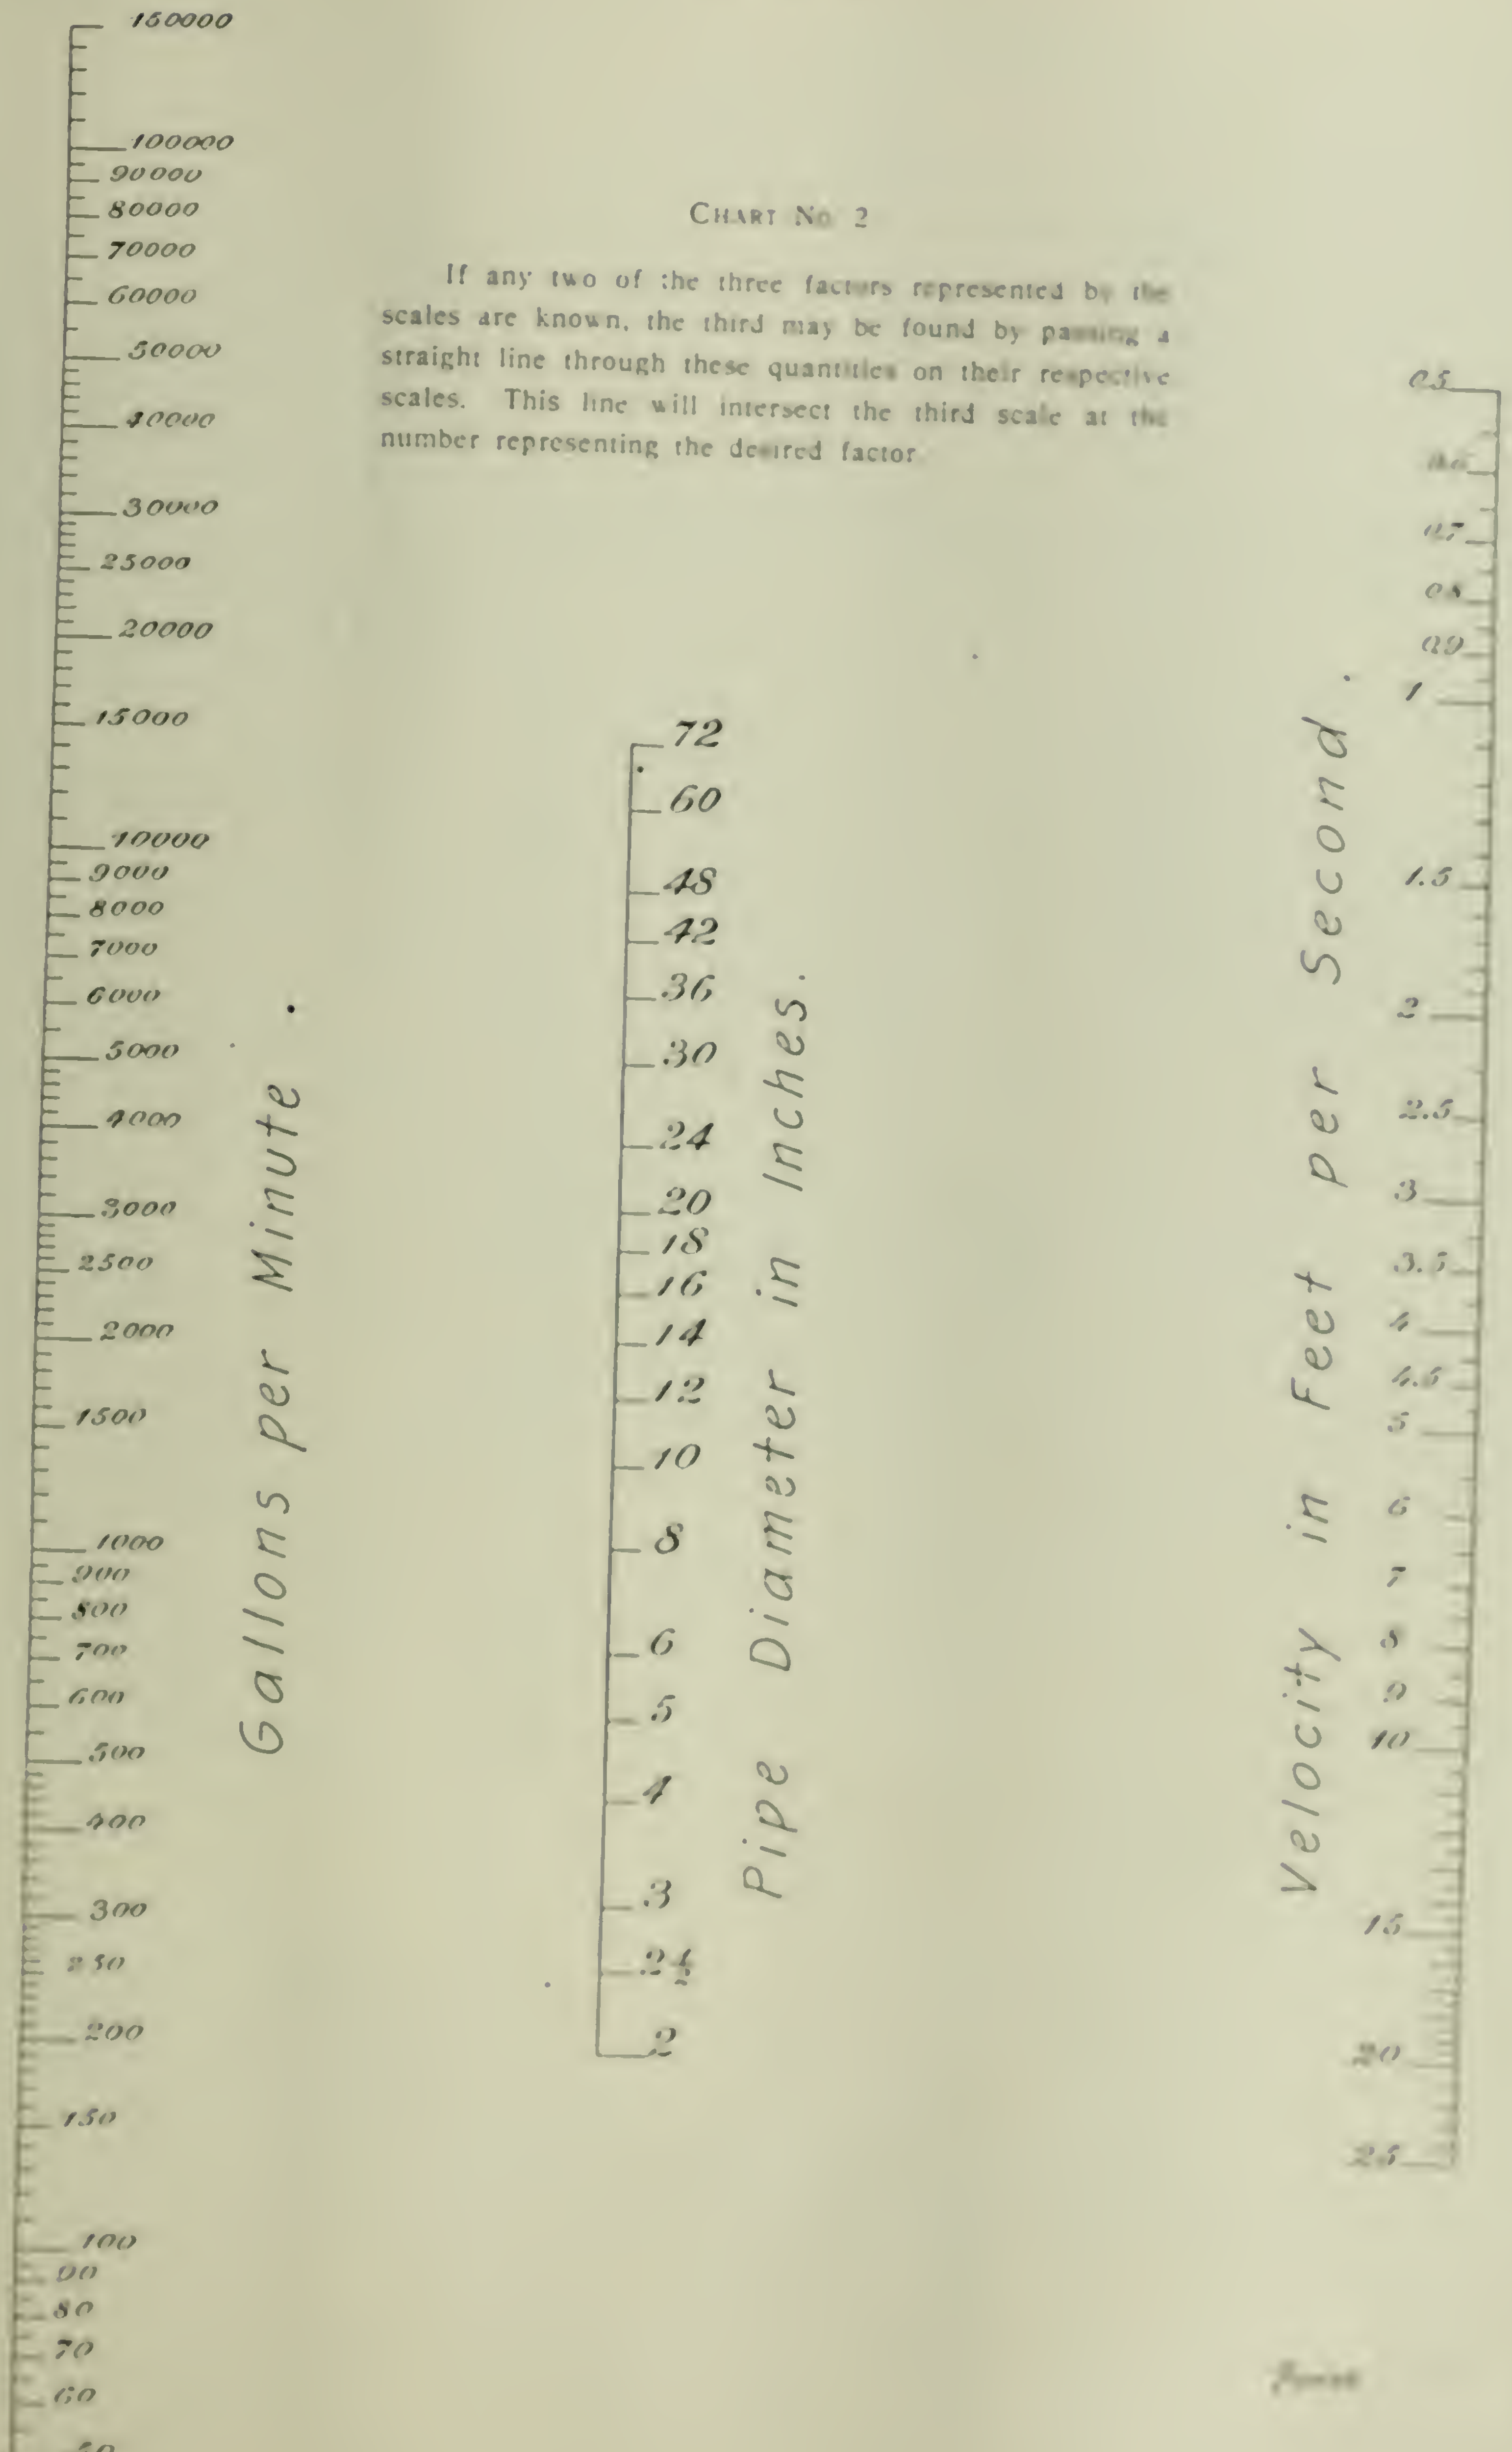
$$\textit{Gallons per minute} = \frac{\pi D^2}{4 \times 144} \times 60 \times V \times 7.48 = \frac{D^2 V}{0.4085} \quad (15)$$

*E. Collignon, "Hydraulique."

†Chart No. 1 appeared in the April 4 issue of Power.

CHART No. 2

If any two of the three factors represented by the scales are known, the third may be found by passing a straight line through these quantities on their respective scales. This line will intersect the third scale at the number representing the desired factor.



The chart is intended to cover a range of volume from 50 to 150,000 gallons per minute, for pipe diameters from 2 to 72 inches, the velocity ranging from ½ foot to 25 feet per second.

Proceeding as with chart No. 1, let Fig. 2 represent the chart to be established. On three parallel lines *Q, D, V,* it is proposed to lay off scales such that on *Q* will be read gallons per minute; on *D,* the diameter of the pipe in inches, and on *V,* the velocity in feet per second. Now, any straight line such as $Q_1 V_1$ placed across the three scales is to indicate that a quantity Q_1 in gallons per minute, will pass through a pipe of diameter D_2, with a velocity of V_1 feet per second.

Assume that the scale of numbers on a slide rule measures exactly 10 inches. Such a length may be understood to represent the value of the number 10. The values of the numbers 2, 3, 4, 5, would be represented, according to logarithmic tables, respectively, by 3.0103, 4.7712, 6.0206 and 6.9897 inches. Adding the lengths representing 3 and 4, the result is

$$4.7712 + 6.0206 = 10.7918 \textit{ inches}$$

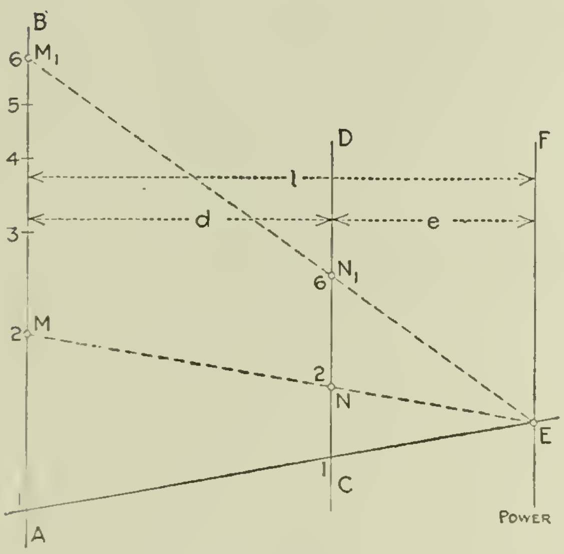


FIG. 3

This length represents the value of the number 12.

In Fig. 3, the three parallel lines *A B, C D* and *E F* represent scales of the same kind as used on the slide rule, the origin of each scale being at the intersection with the datum line *A E.* The three scales being fixed, if the line *A E* is made to pivot about point *E* and occupy successively the positions represented by the dotted lines *M E* and $M_1 E$, it will cut on *C D* the lengths *C N*, $C N_1$, respectively proportional to *A M*, $A M_1$; and if the length *A M* represents the logarithm of the number 2 and $A M_1$ that of 6, the lengths *C N* and $C N_1$ will represent these numbers respectively on a smaller scale.

The logarithm of 10 may be drawn on *A B* with a modulus, or length in inches or millimeters equal to m_1; on *C D* with a modulus equal to m_2, and on *E F* with a modulus equal to m_3. Let *A M* represent the logarithm of 2, and $A M_1$ the logarithm of 6; then,

$$\log. 2 \times m_1 = A\,M$$
$$\log. 6 \times m_1 = A\,M_1$$
$$\log. 2 \times m_2 = C\,N$$
$$\log. 6 \times m_2 = C\,N_1.$$

But,

$$\frac{A\,M}{C\,N} = \frac{l}{c} = \frac{\log. 2 \times m_1}{\log. 2 \times m_2}$$
$$\frac{A\,M_1}{C\,N_1} = \frac{l}{c} = \frac{\log. 6 \times m_1}{\log. 6 \times m_2}$$

Hence,

$$\frac{l}{c} = \frac{m_1}{m_2}$$

When pivoting the straight line *A E* about point *E* it was first stopped at *M,*

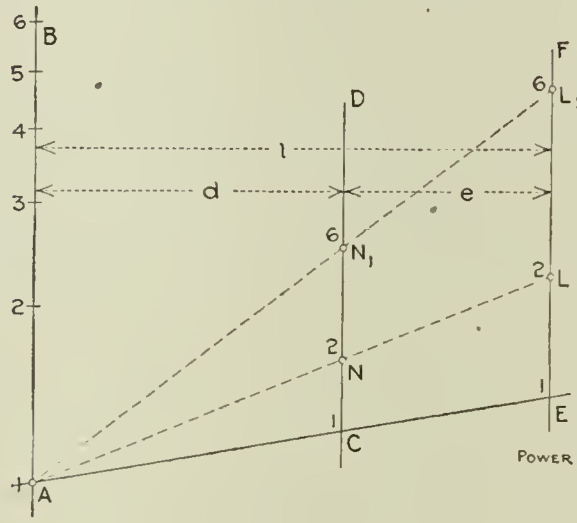

FIG. 4

determining on scale *A B* a length *A M* equivalent to the logarithm of 2; at the same time determining on scale *C D* a length *C N* also equivalent to the logarithm of 2, but of length

$$C\,N = c \times A\,M$$

If *A M* represents the logarithm of 2, and $A M_1$ represents the logarithm of 6, then $M M_1$ represents the length of the log-

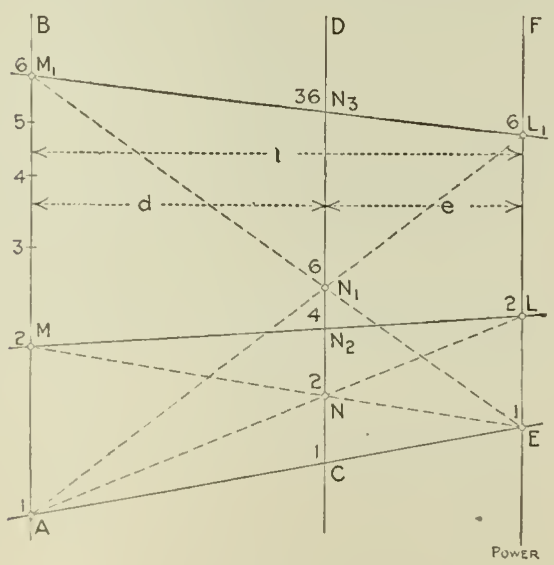

FIG. 5

arithm of 3. Hence, just as with the slide rule, when different lengths are added on one scale, the total length represents the product of the numbers represented by these lengths.

Fig. 4 has the same and similarly placed scales as Fig. 3. By pivoting the straight line *A E* about point *A* and stopping first at point *N,* the length *E L* is determined on *E F.* It is evident, from the foregoing, that *E L* represents, on a large scale, the same logarithm that is represented by *C N;* hence:

$$\frac{E\,L}{C\,N} = \frac{l}{d} = \frac{\log. 2 \times m_3}{\log. 2 \times m_2}$$

whence,

$$\frac{m_3}{m_2} = \frac{l}{d}$$

The same reasoning holds true for points N_1 and L_1.

Fig. 5 is a combination of Figs. 3 and 4. Here, the straight lines *E M* and *A L,* starting respectively from the origin of the scales *E F* and *A B,* and intersecting at a common point *N* on *C D,* determine on the three scales the lengths *A M, C N, E L,* which represent the logarithm of the same number. Similarly, lines $A L_1$, $E M_1$, intersecting at N_1 on *C D,* determine the three lengths $A M_1$, $C N_1$, $E L_1$, each representing the logarithm of the number 6. By joining *M* and *L* a length,

$$C\,N_2 = C\,N + N\,N_2$$

is cut. But *C N* is the logarithm of 2, and obviously $N N_2$ is also the logarithm of 2, for

$$\frac{E\,L}{N\,N_2} = \frac{E\,L}{C\,N} = \frac{l}{d}$$

therefore,

$$C\,N_2 = \log. 2 + \log. 2 = \log. 4.$$

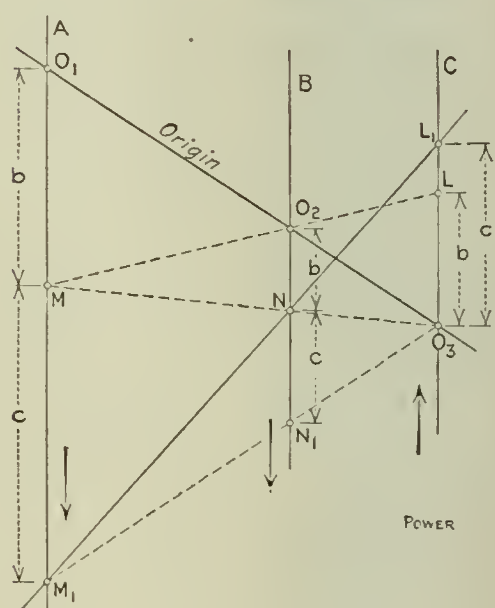

FIG. 6

By joining M_1 and L_1 the length

$$C\,N_3 = C\,N_1 + N_1 N_3$$

is cut on *C D.* But,

$$C\,N_1 = N_1 N_3,$$

and

$$C\,N_3 = \log. 6 + \log. 6 = \log. 36.$$

However, the scales do not always run in the same direction; they may run in opposite directions. Generally speaking, a three-line diagram is intended to solve an equation of the form:

$$a = constant \times b \times c$$

where *a, b* and *c* are the variables. Passing to logarithms, and neglecting the constant,

$$\log. a = \log. b + \log. c$$

If *b* is on the first scale and *c* on the third, *b* added to *c* must equal *a* (as read on the middle scale). In this case, as shown by Fig. 5, the three scales are graduated in the same direction.

If a is on the first scale, b on the second, and c on the third, the problem seems, at first, a little more complex. These scales are shown in Fig. 6. Line O_1M cuts O_2N on scale B, and O_1M on scale A; each of these two lengths, as measured on its own scale, represents the same number, b. Similarly, length O_3L, determined on scale C by line ML, represents the same number b. Let O_3L equal c, then line LM, passing through N, cuts on scale A the length O_1M equal to $O_1M + MM_1$; or, as stated before, O_1M represents $log.\ b + log.\ c$, or the product $b \times c$. In this instance, the two scales, A and B, are graduated in the same direction, while the other, C, is inverted. The position and direction of the scales depend obviously upon the conditions of the problem at hand which they are intended to solve.

Reverting now to Fig. 2 and equation (15), let

$Q_1 = 1000$ *gallons per minute;*

$Q_2 = 10{,}000$ *gallons per minute;*

$D_1 = 8$ *inches.*

Neglect the constant factor (0.4085) for the present. The formula then becomes

$$Q = D^2 V$$

$$Q_1 = 1000 = 8^2 \times V$$

$$V_1 = \frac{1000}{64} = 15.625 \text{ feet } (log = 1.19382)$$

With this value of V_1

$$Q_2 = 10{,}000 = D_2^2 \times V_2 = D_2^2 \times 15.625$$

$$D_2 = \sqrt{\frac{10{,}000}{15.625}} = 25.298 \text{ inches}$$

$$(log = 1.40309)$$

To obtain V

$$1000 = 25.298^2 \times V_2$$

$$\frac{1000}{(25.298)^2} = V_2 = 1.5625 \text{ feet } (log = 0.19382)$$

It is then possible to write:

$a = (log.\ Q_2 - log.\ Q_1)\ m_1 = (4 - 3)\ m_1 = m_1$

$b = (log.\ D_2 - log.\ D_1)\ m_2 = (1.40309 - 0.90309)\ m_2 = 0.5\ m_2$

$c = (log.\ V_1 - log.\ V_2)\ m_3 = (1.19382 - 0.19382)\ m_3 = m_3$

Because of the similarity of the four triangles,

[illegible]

whence

[illegible]

There remains only to determine the moduli. For convenience m_1 was taken equal to the length of the scale of cubes on a 10-inch slide rule, and m_3 equal to the length of the scale of squares, that is, respectively 83⅓ and 125 millimeters. Then,

$$\frac{a}{c} = \frac{m_1}{m_3} = \frac{83\frac{1}{3}}{125} = \frac{2}{3}$$

whence,

[illegible]

[illegible]

$$m_1 = \frac{2}{3} \times 1.25\ m_2 = \frac{5}{6}\ m_2$$

With

$$m_1 = 83\tfrac{1}{3}$$

$$m_2 = \frac{83\frac{1}{3} \times 6}{5} = 100 \text{ millimeters}$$

In constructing Chart 2, the elements adopted were:

$m_1 = 83\frac{1}{3}$ millimeters, d = [illegible] millimeters

$m_2 = 100$ millimeters, $e = 102$ millimeters

$m_3 = 125$ millimeters, l = [illegible] millimeters

One point on the diameter scale was figured out for a given quantity and a given velocity, taking then the constant factor into account, the location of the origin of the scale was thereby determined. This scale of the modulus equal to 100 millimeters was laid out by projecting an ordinary slide-rule scale of a modulus equal to 125 millimeters.

The attention of the reader is called to the fact that, although Chart 2 is correct, and correctly drawn according to the foregoing calculations, it does not seem to meet the requirements exemplified by Fig. 5. The trouble seems to be with the D scale. However, the discordance is more apparent than real; it exists because the pipe diameters themselves, such as 6, 8, 10 and 12 inches, are marked, but it ceases when it is known that the exact numerical values represented by each of these sizes is really its square. Thus, 6, 8, 10 and 12 inches represent respectively 36, 64, 100 and 144. With this correction the chart agrees entirely with Fig. 5. The point raised, however, is so important that it will be taken up again in Part III, where the general formulae applying to this kind of diagram will be shown and demonstrated.

Gears for Steam Turbines

The Hon. Charles A. Parsons, in a recent lecture before the Royal Institution, spoke interestingly regarding the use of gears upon steam turbines, and exhibited the pinion which had been used to transmit 900 horsepower to the propeller of the "Vespasian" while making over 12,000 miles. The evidences of wear were very slight, and it was said that the drive had been entirely successful. As compared with the original machinery, the geared turbine had shown an economy of 22 per cent. with the same boilers and propeller. The turbine is run at 1400 revolutions per minute, and the speed is reduced by gearing to 70 at the propeller. The efficiency of the gear is very high. Measurements of the rate at which heat is generated indicated that it is over 98.5 per cent., and the friction is too small to be satisfactorily measured with a transmission dynamometer. In marine use the geared turbine is very effective in preventing racing, as the inertia of the swiftly rotating parts prevents a material increase of speed, even when the propeller is raised out of the water.

German Market for Lubricants

According to Consul General Robert P. Skinner, of Hamburg, in the *Daily Consular and Trade Reports*, there is an extensive demand in Germany for lubricating materials of every description. Such as are obtained from the residues of the distillation of mineral oils containing paraffin, or are of a tarry or pitchy nature, the latter provided that they do not sink in water, are dutiable in Germany at the rate of $1.428 per 220 pounds. Other lubricants manufactured with fats or oils, liquid or solid, molded into shapes or not, are dutiable at the rate of $1.785 per 220 pounds.

Some difficulty attends the importation of lubricants manufactured from fats or oils, for the reason that such products must be denatured, upon arrival, with petroleum.

Various American concerns are engaged in all branches of this business, usually having well organized Hamburg branches to handle the trade at first hand, and apparently with successful results.

The introduction of a new American grease would be difficult, but by no means impossible. Quality, special advantages and price might sell it, if energy and perseverance were manifested by the exporters in entering the market, and intending exporters should ascertain whether an identical or very similar article is not already on sale in Germany.

It would also be advisable that the intending exporter obtain samples and prices of different lubricants of the same class manufactured or sold in Germany and study the comparative merits of each. The exporter should send a competent representative to the German market to work out the practical details of securing a sale for his product for himself. An article of this kind is almost impossible to place by means of ordinary correspondence.

The imports into Germany of lubricating oil, paraffin, vaseline and vulcan oils during the first 11 months of 1910 amounted to 202,052 tons, valued at $6,550,280, as compared with 191,300 tons, worth $6,212,270, for the corresponding months of 1909. Of the quantity imported in 1910 the United States supplied 90,894 tons, Asiatic Russia 60,327 tons, Austria-Hungary 29,000 tons, European Russia 10,063 tons and Belgium 1614 tons. The German imports of lubricants manufactured from fats and oils during the first 11 months of 1910 amounted to 7419 tons, valued at $797,480, against 7003 tons, worth $713,442, for the same period of 1909. Of the quantity imported during 1910 the United States supplied 5008 tons, an increase of 208 tons over 1909. Thus in 1910 the United States supplied 45 per cent. of the mineral oils imported by Germany and 70 per cent. of the oils made from fats.

A Difficult Case of Parallel Operation

By H. R. Mason

The parallel operation of 60-cycle alternating-current generators, especially of the older types, often presents very interesting problems to solve. The station in which the following difficulties were encountered is of about 12,500 kilowatts capacity, about 3500 kilowatts being in 600-volt direct-current railway generators and the others 60-cycle 2300-volt alternators supplying rotary converters to a capacity of about 4500 kilowatts and an alternating-current lighting and power system of about 4500 kilowatts.

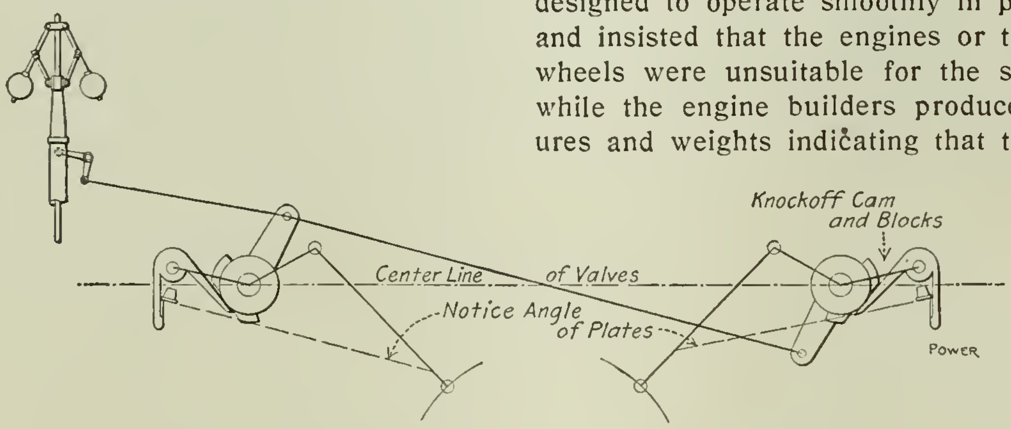

Fig. 1. Original Arrangement of Valve Gear

There are two 1500-kilowatt alternators, one driven by a 36 and 60 by 60-inch cross-compound Corliss engine and the other by a 36x60-inch twin Corliss engine; also, two 3000-kilowatt turbine units. It was found impossible to secure satisfactory parallel operation of the engine-driven units with each other or with the turbines and it was accepted as an impossibility for some years, as the load was not so heavy that parallel operation was absolutely necessary. There was no difficulty in getting the two turbines to operate in parallel with each other and, as there are two sets of busbars, the load could always be divided so that the two turbines were on one set during the peak while one engine unit on the other set carried the city arc lamps and enough rotary converters to take care of the remainder of the load. This was often troublesome and expensive, as it resulted in an unsatisfactory engine load at times and required close attention in balancing the load between the two sets of busbars.

The load recently increased to such an extent that it became imperative either that the alternators be made to operate in parallel, or that a third set of busbars be installed so that the remaining engine could be operated, which meant considerable expense and undesirable complication. The builders of the alternators maintained that the machines were designed to operate smoothly in parallel and insisted that the engines or the flywheels were unsuitable for the service, while the engine builders produced figures and weights indicating that the engines were not to blame and claimed that the generators were deficient in synchronizing ability.

Upon trial, it was found that no matter how carefully the generators were got into synchronism they would set up enormous cross currents within a revolution or two after being connected to the same busbars and it had happened a number of times that rotary converters were caused to flash over and interrupt part of the service in the brief time required to change the switches in transferring the load from one alternator to another.

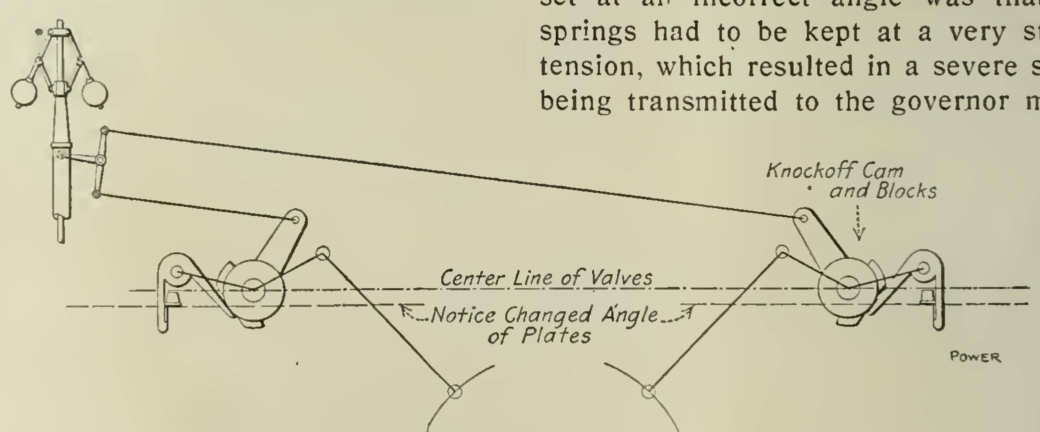

Fig. 2. Corrected Arrangement of Valve Gear

Indicator diagrams were taken, which disclosed some serious faults in the steam distribution, due to unequal cutoff and unequal and excessive compression. In this connection, there is a point which seems never to have been taken into consideration in all of the endless arguments for and against compression, and that is its effect upon the angular velocity of the flywheel. In this case the compression figured up to nearly 600 horsepower, which seemed an unreasonable amount even for a 2000-horsepower engine, and as this energy was necessarily absorbed from the flywheel near the end of the stroke, it was thought to be at least partly responsible for the trouble in operating the units; therefore, the eccentrics were moved so as to give much less compression and the cutoff was equalized as far as possible.

After taking additional indicator diagrams it was found that the governor rods were connected to the knockoff cams at unequal angles, the undesirable method of connection shown in Fig. 1 being used. With this kind of connection, it is impossible to adjust the cutoff of the crank-end valve without disturbing the adjustment of the head-end valve, and in this case the unequal angles of the knockoff cams caused the point of cutoff to change at different rates on the two ends of the cylinders, which also added to the trouble in paralleling the generators.

Upon still closer examination of the valve gear it was observed that the latch plates were set at an improper angle, as also represented in Fig. 1, frequently causing the block to slip off the hook before the tail of the hook struck the knockoff cam; although this could scarcely be observed by watching the engine, it showed on the indicator diagrams and resulted in unequal crank efforts. Another effect of the latch plates being set at an incorrect angle was that the springs had to be kept at a very strong tension, which resulted in a severe shock being transmitted to the governor mechanism every time the hook encountered the knockoff cam. These defects were all corrected and the valve gear changed to the arrangement shown in Fig. 2, which gave reasonably good indicator diagrams.

After this was done, determined efforts were made to operate the units in paraldrives under all conditions. I believe that there are places, and a large number of them, where the belt or rope drive is more economical than the electric drive. I believe that there are places, and many of them, where it is cheaper for the factory owner to purchase power than to generate it. I believe, too, that there are places, and many of them, where the factory owner can generate his own power and use it through electric motors more cheaply than he can either buy it or operate by belt drive. Every plant must stand on its own merits and no factory owner can say because "John Jones operates his plant more cheaply by belt drive than Tom Smith does his by electric drive, I can put in belt drive and operate more cheaply than I can by electric drive."

HENRY D. JACKSON.

Boston, Mass.

The Giddings Engine Valve

Allen J. Stocks illustrates an engine valve in the issue of March 28 and asks if anyone ever saw anything like it. This is the well known Giddings valve and was used very successfully for many years by several engine-building concerns prominent in the manufacture of high-speed engines.

Fig. 1 shows a section of the valve and valve face. It will be observed that the valve takes the form of the Allen valve with the difference, however, that the steam enters the middle of the valve through the port *S*. With this arrangement there would be a tendency to throw the valve from its seat unless it were

FIG. 1. SECTION THROUGH GIDDINGS VALVE

counterbalanced by a pressure on the back of the valve. This pressure was secured by means of a needle-hole port from the steam inlet of the valve. In order to keep the pressure within certain limits, there was a needle-hole port of slightly larger area communicating with the exhaust chamber of the valve. It usually took about 15 per cent. of the boiler pressure to keep the valve from slapping on its seat.

One remarkable feature of this valve was the supplementary passage or carry-over port which increased the volume into which the steam was compressed without increasing the clearance space from which the steam was exhausted as this port was never in communication with the exhaust.

Fig. 2 shows a pair of indicator diagrams from an engine with this type of valve. The compression curve starts to rise when the edge of the valve covers the exhaust port and it continues to rise until communication with the supplementary port is established, increasing the volume into which the steam is compressed and enlarging the area of the diagram over that shown by the dotted lines.

The engines built at the time when this valve was used were of comparatively long stroke, the sizes ranging as follows: 6x10 inches, 8x12 inches, 10x16 inches, 12x18 inches, 14x20 inches, etc. As single-valve engines they were hard to beat in the matter of economy. The large sizes could be run on 30 pounds of steam per indicated horse-

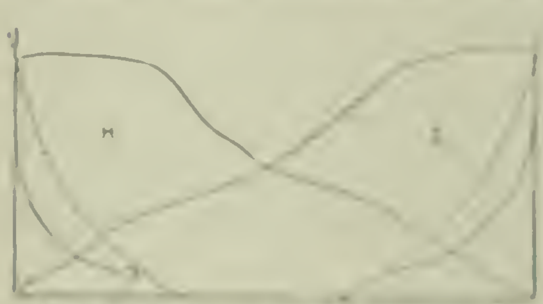

FIG. 2. DIAGRAMS FROM ENGINE WITH GIDDINGS VALVE

power with a pressure of 100 pounds at throttle, noncondensing. They were much more economical than the high-speed engines at that time with the so called piston valves (which were simply a plug in a hole) which leaked scandalously, or the many forms of flat valve balanced by a pressure plate.

CHARLES A. CAHILL.

Milwaukee, Wis.

In POWER for March 28 Allen J. Stocks has a letter, some diagrams and a cut of an engine valve about which he seems to be puzzled. I operated a Russell engine for three years that was fitted with this valve. The valve is balanced; there are two needle-hole ports in the top of the valve, one that admits steam from the face to the back of it and the other, which is a little larger, forms a communication between the back of the valve and the exhaust of the engine. These small ports retain enough steam back of the valve when the engine is running to balance the valve and keep it on its seat.

By means of an angle valve in a ½-inch pipe, steam may be admitted from above the throttle to the back of the valve when starting and stopping the engine; this keeps the valve from slamming on its seat.

The valve takes and exhausts steam at its face. I cleaned the burned oil from the face of the valve and found fine lines to correspond with the edges of the ports on the face of the valve by which the valve could be set.

If Mr. Stock's engine is a Russell he will find that there is an adjusting nut where the rod connects with the eccentric and that the length of the rod can be changed either way.

The diagrams show all events of the valve to be early, also the valve to be one sided, although not very much so.

The engine mentioned had a Giddings governor which is quite complicated and if taken apart is liable to be put together wrong, which might leave the valve setting off.

This may be the trouble in Mr. Stocks' case as a long rod would make the events early on one side and late on the other.

JAMES W. BLAKE.

New York City.

The Position "Higher Up"

In the issue of March 21 there are two articles under the above heading. The one by L. F. Wilson is right to the point and contains some very good advice.

I wish to call special attention to what Mr. Wilson says about "blind advertising." Only a few weeks ago I ran a blind advertisement for a position and I got two answers. One came from Philadelphia and one from Boston. The one from Boston asked me to "call around" and see a certain party! Perhaps I might have secured a good position, but it is not an easy matter for me in New Orleans to call around in Boston!

The other letter in the March 21 issue, written by Edward Adams, tells how the writer stepped out of the fire room into his first job as chief. All this may be interesting but it is of little value to the man trying for the position "higher up" unless he is in the same fire room that Mr. Adams left. But his first paragraph hits the nail on the head.

In the first-page editorial of POWER for March 21 there is more horse-sense concerning this matter than can be found on any other page of POWER. It says "Pick out your goal, keep your eye on it and work to get there." Everyone who expects to better his position should read this article over and over, and study it.

He who says "There isn't no chance these days for a fellow to get along" will never get any higher. Turn to the first-page editorial of the March 28 issue and read that carefully. Do you fully grasp its meaning? No, not at a first reading. This editorial you should be studying. Do you realize that "there are more opportunities than ever going a-begging for lack of men to see and make use of them?" But who tells of that? "These are wonderful times," times of progress, and a fellow must keep up with this progress. He cannot "wish" himself into the position "higher up"; he must go after it.

of fire on the outside and mud (sediment) on the inside of the plate. The cover of the cleaning nozzle (the nozzle is connected to the lower front part of the boiler) can be taken off and the sediment scraped and washed out. A lamp can be brought into the boiler through this opening and nearly the whole of the bottom sheet and the bottom part of the lower row of tubes can be inspected. The boiler is set with an inclination toward the front; the blowoff valve is placed on the cleanout cover, oftentimes the feed valve too.

JOHN ZEUERLUND.

Eskilstuna, Sweden.

Belt versus Electric Transmission

In the March 21 issue, Franklin Van Winkle takes exception to my article in the February 14 issue on central-station versus factory-plant service, making the statement that the friction in many hundreds of plants has been found nearer 10 than 20 per cent. of the total power required.

This does not agree with the results of tests of many of the plants that we have investigated, nor the results that are reported in many of the papers and which are mentioned in connection with the shafting losses in a number of handbooks. In many factories the friction loss amounts to considerably over 60 per cent. of the total power generated at the engine and these plants are pretty fairly operated. There are, of course, many textile mills and many mills in which the shafting is laid out accurately and carefully and in which recent additions have not been made to disturb the operating conditions, where the shafting losses are very small, but such conditions do not hold for any considerable length of time, nor are such conditions possible except through excessive waste of space in belt- or power-transmission towers or wells.

It is interesting to study what the actual losses are in a plant using belt drive, starting with a pretty small loss from shaft to shaft and from floor to floor until the engine is reached. Suppose, for instance, it is assumed that on the top floor of a four-story factory 20 horsepower is required, divided between four lines of shafting. On the next floor assume the same conditions and requirements and so on down to the lowest floor, where the main jack shaft is situated. This is an arrangement very frequently found. If 5 per cent. loss from shaft to shaft is allowed, the losses are cumulative and the power required at the engine is to a very considerable extent larger than would ordinarily be required if the shafts were driven direct from the engine. The following table shows to what extent this cumulative friction increases and it will be noted that 5 per cent. is used as the average loss of power for each transmission belt; this is by no means a figure accomplished under average conditions.

Top floor, 20 horsepower; 4 shafts, 5 horsepower each; 5 per cent. loss between shafts.

	Horsepower.
Power required at the main shaft on 3d floor for top floor	22.06
Power required, 2d floor for 3d floor	45.22
Power required, 1st floor for 2d floor	69.54
Power required to operate 1st, 2d and 3d floors from engine	97.33
Total power required at shafting	80.00
Loss	17.33

or 21.7 per cent., which is quite different from the loss that would exist with individual drives to each shaft. It should be noted also that this loss is to a considerable extent represented by slip, so that the speed of the shafting is continually dropping from what would be expected on pulley ratios, materially influencing the production factor of the machinery. As vertical drives are of frequent occurrence in a factory of this character, figures of 5 per cent. loss on an average between shafts is considerably below that met with in practice, although it is not below what could be accomplished by proper arrangement in many cases.

In machine shops the conditions are radically different and so are they in many types of plant where the machinery is not constantly in operation so that the power lost in driving the shafting may be, and frequently is, a very heavy item of expense. Under such conditions the power required to operate with belt drive would be much larger than that required to operate with electric drive. Each plant has its individual characteristics, and it is necessary to make a careful study of each plant to determine what is the proper type of drive. It not infrequently happens that with a plant already installed, a rearrangement of belting is much cheaper than the installation of electric drive, and that a belt-driven plant can be operated more cheaply than electrically driven, either by power purchased or power generated in the plant itself.

When motor drives are installed, they should be installed with a thorough knowledge of the influencing conditions so that the motors will be adapted to the purpose in hand and every precaution should be taken to reduce the friction losses to the minimum. The efficiency of the motors is an important consideration, also the efficiency of the drives connecting the motors to the shafting. It frequently happens that unless the engineer installing the drives is thoroughly conversant with the motors and the machinery to be operated, very much larger motors are installed than are necessary. It also happens that in order to save first cost, the owner and engineer install motors which are of far too high a speed to operate satisfactorily or install the motors on too short centers with too large ratio of driver to driven pulley. All of these things militate strongly against the success of the electric drive. On the other hand, similar mistakes work against the belt drive; there is just as much danger of a poor layout in a belt-driven plant as there is in an electrically driven plant and there are quite as many belt drives throughout the country which are failures, if their owners and engineers but knew it, as there are electric drives.

Mr. Van Winkle's statement that he was called in to consider a case where the proprietor of a plant was greatly disappointed is exactly in line with conditions which are frequently met. The electric motors in this case were probably not installed properly and the central-station salesman was probably thoroughly onto his job as a salesman and very far from onto his job as an engineer. The factory owner who bites at the salesman's figures of operating cost in his plant as driven by belts and at the economies which are likely to accrue from the installation of electric motors and makes no further investigation, usually gets stuck and there is every reason why he should expect to get stuck. This same factory owner would not allow the agent for some company supplying him with materials to estimate what it would cost him to get materials from half a dozen of his competitors but he would actually get competitive prices. Why, then, should not this man take the same precaution when it comes to the matter of power? If he is not capable of making up his own figures as to what power costs him, why should he take the figures of the central station and buy material of which he knows nothing?

The electric drive has many advantages over the belt drive. So, too, has it many disadvantages unless properly installed. Mr. Van Winkle leaves out one item in his tabulation of advantages, which is of very considerable importance, that is, uniformity of speed, resulting in a considerable increase in production. This production factor alone, if properly looked into, is, in many cases, a sufficient cause for the introduction of the electric motor and, further, is very often a sufficient explanation for a considerable increase in the cost of power. In a number of cotton mills in the South where electric drive is installed, under the first year's operation the factory owners were very much disappointed to find that the total cost of power during the year was considerably greater than the cost of power during preceding years. Their engineer, however, was far-sighted enough to go a little bit into the figures for output during those years, with the result that he discovered that the total cost per unit of goods manufactured was less than in previous years.

While I am strongly in favor of the electric drive where it is suited to conditions, I am not a believer in electric

Questions Before the House

Comment, criticism, suggestions and debate upon various articles, letters and editorials which have appeared in previous issues

Operating Cost of a Small Water Works

Having read the editorial, "Publicity of Operating Costs" in the issue of March 7, I will do the best I can to give the readers of POWER the actual running costs of the station of which I am in charge.

This is a small town of about 6000 inhabitants. It has a direct-pressure system with a standpipe located at the highest point in the village. We pump from a receiving basin fed by gravity from springs. The average suction lift is 20 feet and the discharge head averages 160 feet.

The pumping station contains two horizontal return tubular boilers, 60 inches by 16 feet. These are used alternately and are in fairly good condition considering their age which is 24 years. They were operated for 13 years at their full capacity for during that length of time electric current was generated for use in the town. They are of the lap-seam design and since reading the recent articles and editorials in POWER I am sure that they have seen their best days although they are given a pretty good standing and are allowed 85 pounds pressure by one of the leading boiler insurance companies.

The pumps are Worthington direct acting, one is a compound 12 and 18½ by 10½ by 10 inches in size and the other is a simple 16 and 10½ by 10 inches (this one is held in reserve for emergencies). There is one boiler-feed pump 5¼ and 3½ by 5 inches, delivering water through a Baragwanath heater to the boilers at a temperature of 210 degrees.

We operate, on an average, 10 hours out of the 24 and, being subject to a fire call at any time, have steam up with banked fires between. The night engineer reads the service meters monthly. We use run-of-mine coal which costs $2.05 per ton delivered in the coal bin.

The cost of operating the station for the year ending Feb. 28, 1911, was as follows (Not including interest and depreciation):

310 tons coal @ $2.05	[illegible]
Oil and waste	[illegible]
Packing	[illegible]
Repairs	[illegible]
Engineers and ...	[illegible]
	[illegible]

In the year we delivered to the mains 80,830,000 gallons of water against an average total head of 160 feet using 310 tons of coal. This shows the duty of the plant to be slightly over 21,000,000 foot-pounds of work per 100 pounds of coal. The cost of pumping was, then, 2.379 cents per 1000 gallons delivered.

The water end of the pump shows an efficiency of 90 per cent. and I think it will be of interest to some to hear how I find this as we have no meter on the delivery line.

When the receiving basin, which is 27 feet in diameter, is pumped down and we are not running I note the level of the water and the time. Taking the level again one hour after, it is easy to calculate the number of gallons running in per hour. On starting up I note the counter reading of the pump, the time and the water level in the basin, taking them again after the pump has run one hour.

The efficiency is then found by dividing the water actually delivered (which is the amount which runs into the basin plus the amount taken out by lowering the level) by the displacement of the plungers of the pump.

These figures are not given as models of economy but as actual running expenses of a small old-fashioned pumping plant and I should very much like to see them compared with those of a modern uptodate plant of about the same size running under similar conditions.

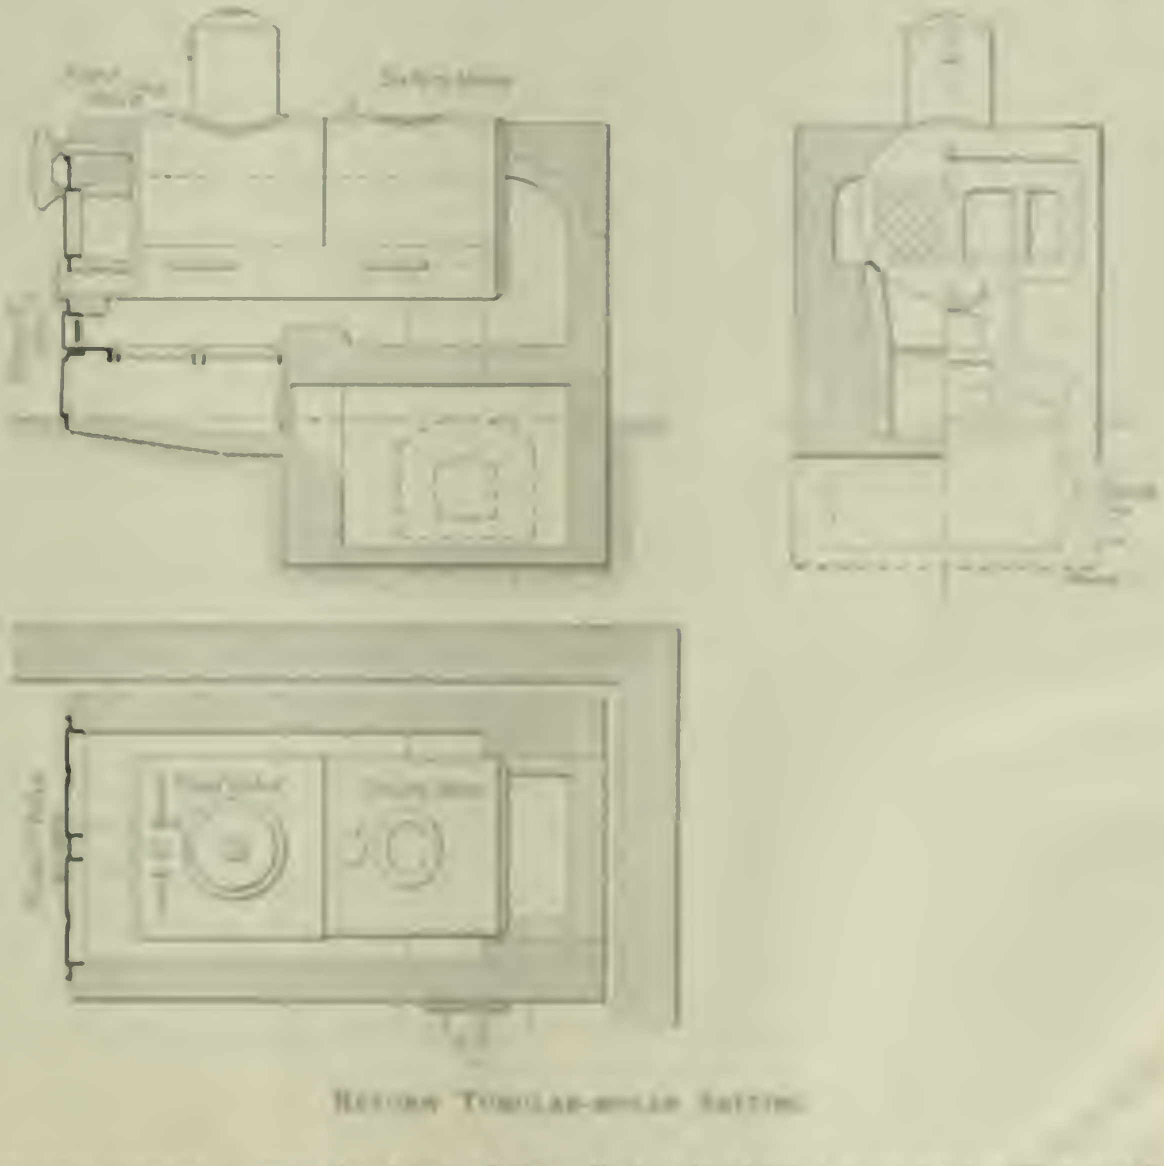
Boiler Setting

Some time ago there appeared in POWER a very complete paper by S. F. Jeter on "Setting Horizontal Tubular Boilers," which I have read with a good deal of interest.



RETURN TUBULAR-BOILER SETTING

Herewith is a design of a horizontal tubular boiler setting which is used very extensively in this country with satisfactory results. The bottom sheet of the boiler is in one piece; the sheets are ... bottom with rivets exposed to the ... [illegible] thority over their own force, and yet they were paid a good salary and were well thought of.

How is a man to make known his ability, beyond the more or less successful operation of his plant with what the employer chooses to give him, unless he is consulted and given an opportunity to show what he can do? Some may say, let him take his ability where he can get full value for it, but that is much easier said than done.

Regarding engineers preparing themselves for the demands made upon their ability, I think that if employers would give the engineers a chance to show whether they are worthy of the name and can operate more cheaply than the central station can supply electricity, it would be a simple matter to answer the question when the time comes. It would seem to be more of a question of coöperation between employer and engineer than one of whether the engineer can beat the central station. The engineer alone cannot beat the central station, so let the employer get busy as well as his engineer.

Brooklyn, N. Y.

Low Charge of Electrical Energy

When the first bonds were to be voted for the municipal plant at Pasadena, Cal., the Edison company, backed by $20,000,000 of capital and owning the electric-light plants in thirty-five cities, would not give out any information to the citizens of Pasadena as to the cost of producing electrical energy or what a profitable selling price would be. As a result, the city built its own plant which contains the very best of machinery, has been enlarged three times in four years and has made good.

The plant now furnishes electrical energy to 3650 private consumers and takes care of all the public and street lighting. There is a sliding scale of from 5 cents down to as low as 3 cents per kilowatt-hour for larger quantities of energy used for lighting purposes; for power the rate runs from 4 to 5 cents per kilowatt-hour. The plant with the distributing system reaching into every part of the city cost $450,000 in round numbers.

During the fiscal year ending June 30, 1910, the city plant paid out of its earnings the principal and interest on the bonded indebtedness incurred for its construction, in addition to all operating expenses, and had left for depreciation and new construction an amount equal to approximately 5 per cent. of the cost of the plant.

I am informed that it cost the Southern California Edison Company $0.0216 per kilowatt-hour to furnish electricity in the city of Los Angeles during the year 1909. During the same period the Pasadena municipal lighting plant produced electrical energy at an average cost of $0.020 per kilowatt-hour. The residents of Pasadena remember when they paid at the rate of 15 cents per kilowatt-hour for lighting their houses, and now the city plant furnishes them with light at a base rate of 5 cents per kilowatt-hour.

From the standpoint of the city as a whole, it may said that its people have, and are now, effecting a saving of not less than $100,000 per annum by reason of the difference in rates charged before the city built its plant and the rates which are now in effect.

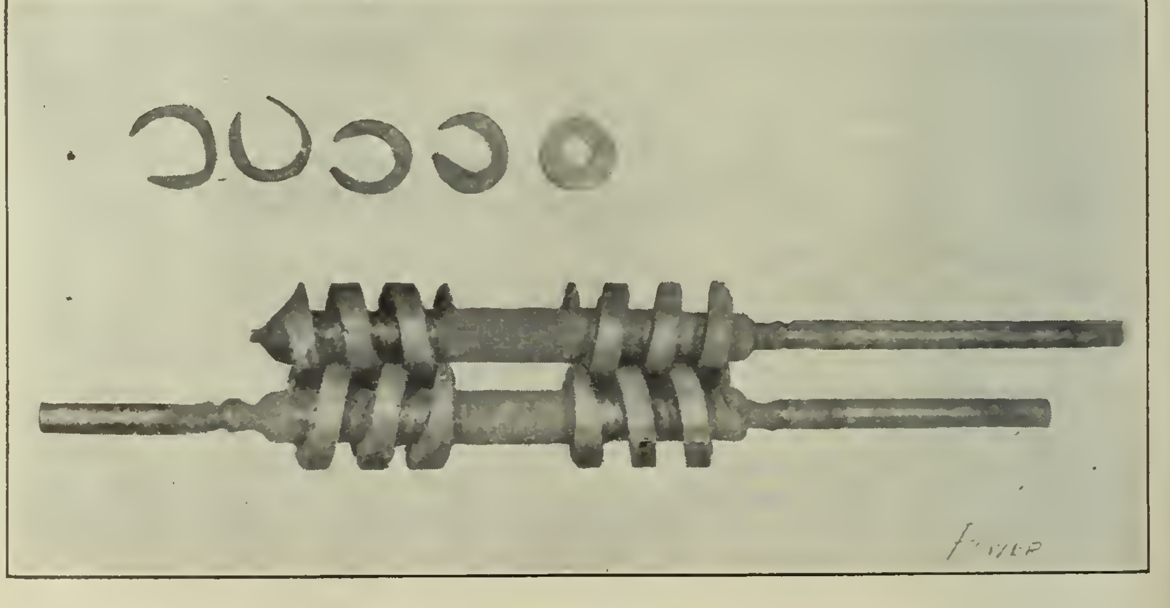
Worn Pump Worms

Readers of POWER may be interested in the long service that has been obtained from a screw pump. Nine years ago two screw pumps were installed in a 14-story office building to pump the water for four hydraulic elevators. The accompanying illustration shows the screws or worms which have been in continuous operation in No. 2 pump for eight years, operating ten hours a day, six days a week. In that time the pump has been idle about two months, due to motor repairs. The illustration shows the shafts worn more than half way through and one end entirely worn off by the action of the water, thrust washers and packing. The pump was operated for six weeks after the missing end of the shaft had broken off, the screw guiding itself in the cylinder.



WORN PUMP WORMS

The four horseshoe-shaped rings at the left show all that is left of the illustration of the thrust washers; the tap ring shows how a new thrust washer looks.

After the screws were removed, the cylinders were measured and showed but 1/64 inch more than their original diameter, and this was at the end of the end where the loose screw with the broken shaft revolved.

The screws were 7 inches in diameter; the pump has an 8-inch suction and a 7-inch discharge pipe and is supposed to pump about 700 gallons of water per minute at 800 revolutions per minute.

Glenfield, Penn.

An Old Belt

Some time ago I read of a belt that had been run for 25 years.

At the plant where I am engineer, there is a 20-inch belt running 2827 feet per minute that has been in service 10 hours each working day for 45 years. It is a double belt and is shown in the illustration. The engine is a Putnam and runs at a speed of 90 revolutions per minute.

SHOWING PRESERVED CONDITION OF BELT

CHARLES E. HARRIMAN.

Concord, N. H.

any one of the push buttons *M*, the circuit is closed through the batteries *N* and magnets *O*, which pulls the armature *K* and the trigger *J* down, thus releasing the trip *I*, whereupon the lever *C* drops, and, in so doing, throws the link *A* off of the stud *B*. The lever *C* then strikes the adjustable stop *P*, thereby forcing the arm *Q* down to the rubber-cushioned stop *R* and at the same time the arm *V* comes to rest on the stop *S* and assuming the position indicated by Fig. 3. This moves the rods *T* in the direction shown by the arrows, thereby throwing the valve cam into such position that the knockoff blocks come in contact with the hooks and prevent the steam valves from opening, thus stopping the engine.

Passaic, N. J.

Carelessness Causes Accidents

A high-speed, center-crank engine pounded badly. The engineer, who was a new man trying to make good, had disconnected the crank-pin end of the connecting rod in order to ease away the brasses. He had then closed up the crank case and started up, but the engine began to pound and heat badly. Investigation showed that there was an accumulation of wood pulp, mixed with the oil inside of the case, and the connecting rod was also sprung, which caused the heating.

The engineer then remembered that he had used a piece of wood to block up the connecting rod while facing off his brasses and when connecting up again this block of wood had fallen down to the bottom of the crank case and he had failed to remove it. Just a little carelessness.

In another case a boiler-feed pump suddenly refused to feed enough water to the boilers. A small test gage was connected to the discharge line of the pump and upon starting the pump a higher pressure was obtained on the test gage than showed on the steam gage on the boiler, showing that there was an obstruction in the discharge, notwithstanding the pipe was new. Upon tracing up the pipe line it was found that in one out-of-the-way place the pipe went through a wall and a short piece of old pipe had been left in place, as it was difficult to get at. The new piping had been connected at each end and, as the old pipe was almost filled with scale, when the pump was started after the repair work had been finished a small piece of loose scale was forced into the small opening in the old pipe, partially closing the same and causing the trouble.

Failure to tighten the lock nut securely on the dashpot rod after making adjustments allowed the nut to work loose and the rod to lengthen, resulting in a bent rod.

In the case of a Greene engine, when putting new steel plates on the tappet the engineer failed to properly tighten the screws, which worked loose and allowed the plate to drop, breaking the tappet.

These accidents were all the result of carelessness and could have been prevented.

Dusty Engine Room

Can any reader tell me how I can keep dust from collecting on the walls and ceiling of my engine room. Dust is drawn in by the driving belts of three engines, each belt 20 inches wide and traveling at a speed of 3500 feet per minute. I have a hardwood floor and have it scrubbed once a week, but this dust spoils the looks of the engine room.

Has any reader any suggestions to offer as to how I can rig up a suction vacuum cleaner to remove the dust from the walls and ceilings, as sweeping it does not make a good job?

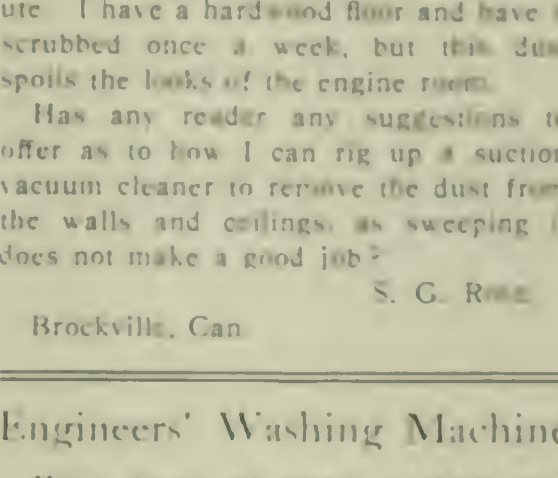
S. G. Ross.

Brockville, Can.

Engineers' Washing Machine

Many forms of steam washing machines for washing overalls, etc., have been made by the man on the job that have given more or less satisfaction.

The washer shown in the drawing herewith uses steam only, and will wash a garment, no matter how dirty, in two minutes. The garment is soaked in soapy water and, without wringing, is placed in the washer and the steam turned on. When the garment attains a speed of



Washing Machine

between 35 and 40 revolutions per minute, enough steam has been turned on. If one is particular the garment might be rinsed a little after washing.

The width of the front lid is two inches narrower than the opening. The sides of the washer, also the crosspiece through which the pipe to the jets enters, are made of 1-inch dressed lumber. A strip of galvanized sheet metal 14 inches wide and long enough to go around the bottom and circular sides of the machine is nailed to the edges of the wooden sides and crosspiece. The cover is made of the same material and is fastened by hinges to the crosspiece.

When the garment has been placed in the machine and the steam turned on, the garment follows a path shown by the arrows. The steam follows a circular path the same as the garment, but escapes through the opening in the front while the garment drops directly in the path of the jet of steam from the nozzles and is driven around again.

It is not necessary to construct the machine water-tight.

Pueblo, Colo.

Isolated Plant Engineering

The central station versus the isolated plant has become a very serious question for the consideration of the engineer who operates the latter plant. Engineers have been urged to keep records of the daily performance of their plants in such a way that they may be thoroughly understood by their employers and used to refute the very clever and persuasive statements made by the central-station solicitor.

This is all very well, but I would like to ask how the average engineer is to procure all these data? Suppose, for example, that an engineer is put in charge of a building where there is a heating and lighting plant and, as is generally the case, is under the supervision of a superintendent. The engineer carefully looks the place over for a while, taking note of the methods of the operating force, the kinds of fuel burned, lubricants used, when the boilers are cleaned and, in fact, makes a general survey of the plant and its operation. Discoveries are made and noted and the engineer decides upon some changes which in his best judgment will be to the benefit of the plant. Having the data in regard to this particular change he wishes to make, he goes to the superintendent and with all the confidence of a man who thoroughly understands his subject presents his plan.

It may be he will get recognition and he may get the necessary material to make the change, but in 99 out of 100 cases he will be turned down and gently but firmly sat upon.

Worse than this, at a later date an outside mechanic will appear with material and men to do the same job that the engineer suggested and he is told that the idea came from headquarters. Such methods are not conducive to a proper feeling on the part of the engineer, but yet such an occurrence is not an impossible or imaginary situation.

Another phase of this question which has always attracted my attention is the apparent lack of confidence of the employer in the engineer. I know of good engineers who were put in charge of plants and were not even given the au-

The Line Shafts Break

During the last two years there has been considerable trouble with the breaking of shafts, as nearly every shaft of any importance has broken during this time. A $2\frac{15}{16}$-inch shaft has let go three times, and three others of $2\frac{7}{16}$ inches have broken, all doing considerable damage. They all break in the hub of the driving sheave of the American system of rope drives. The sheaves are keyed to the shafts by a straight key with two set screws on top to hold the key firmly in place. The shafts are not out of line and are not overloaded. The $2\frac{15}{16}$-inch shaft drives but 50 horsepower, and the other shafts about 20 horsepower each.

The danger of maiming or killing employees is apparent. The expense of maintenance is great, as the ropes usually become tangled and the shaft comes down, taking everything with it before the power can be shut off. Good machinists have been employed for the repair jobs but the shafts keep on breaking. Can any reader of POWER suggest a probable cause or remedy?

Chicago, Ill. A. RATHMAN.

A Homemade Safety Stop

When I took charge of a certain steam plant, I recommended the installation of some kind of an automatic safety stop, so that in case of necessity the engine could be stopped by pressing a push button from various points in the factory without waiting to signal or telephone the engineer.

But as there was some delay in regard to the matter and feeling somewhat apprehensive that something might happen when none was near the engine to shut it down quickly, I came to the conclusion that I could make a safety stop, and it has proved reliable in every way. The accompanying illustrations will give a very clear idea of the construction and operation of the apparatus. The only parts that had to be purchased were the push button, batteries, wire and magnets. Any type of electric-gong magnet will answer the purpose; otherwise the rest of the material costs nothing, and the only expense is the machinist's time in making it. The method of making this safety stop is described herewith.

The brass knuckle on the end of the governor link *A*, Fig. 1, is slotted so that it can be disengaged from the stud *B*. The lever *C* is mounted upon the bell-crank bracket of the governor, and is secured by three set screws to the collar *D*, upon which it moves freely by means of the strap *E*. The link *A* passes between the grooved rollers *G*. The magnetic releasing mechanism is attached to the front of the governor column in the position indicated at *H* so that the lever *C* rests upon the trip *I*, Fig. 2. This trip is held down by the trigger arm *J*, which is secured to the top of the armature *K*, mounted between the two pivots in the top of the brass posts *L*. Upon pressing

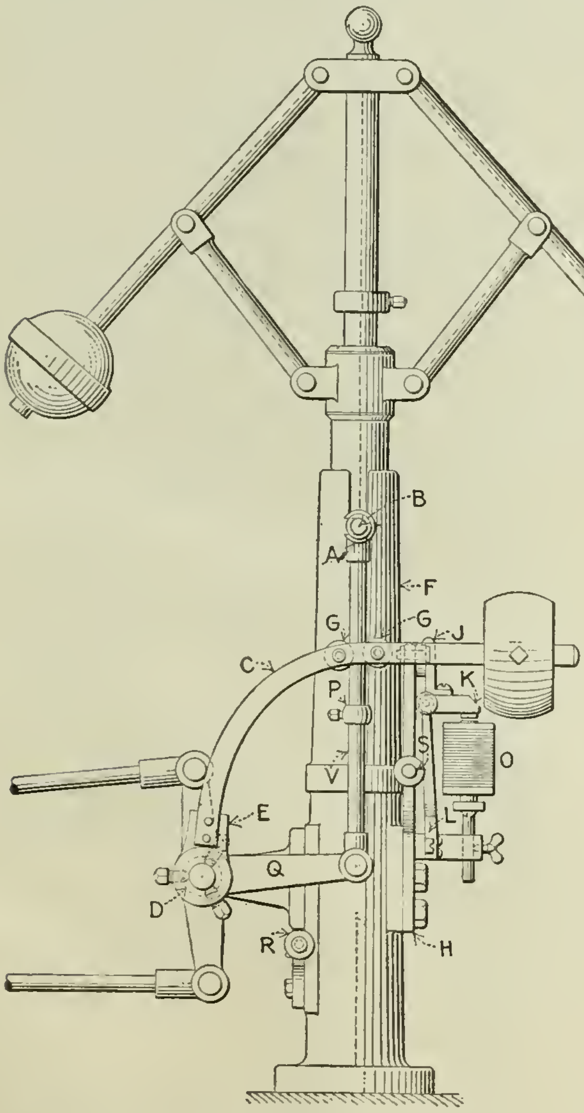

FIG. 1

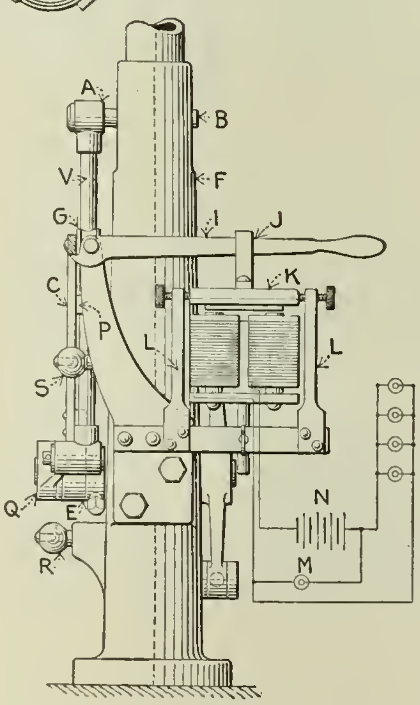

FIG. 2

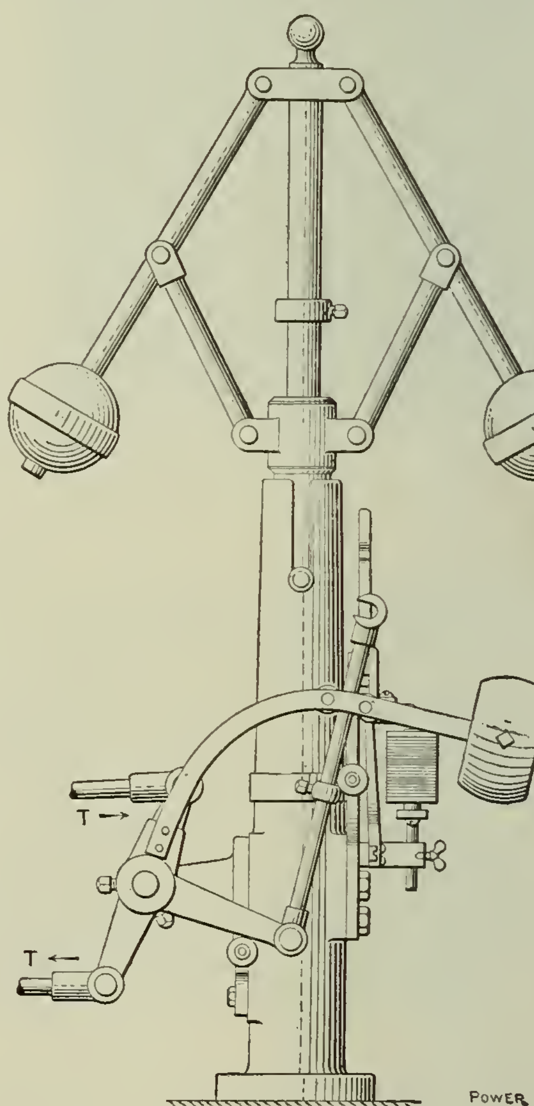

FIG. 3

DETAILS OF HOMEMADE SAFETY STOP

represent the cost of operating the whole system because, with the exception of the building and contents, no charges are made for interest, maintenance, depreciation and sinking fund for the general system. Office expenses, improvements, etc., are likewise not included, as these charges would remain the same with either gas or steam as the source of power. The cost of constructing the gas-power plant as compared with a steam plant of similar size, however, has been taken into consideration.

TABLE SHOWING COMPARATIVE COST OF PUMPING WATER BY STEAM AND PRODUCER GAS

Rate of pumping is 1,000,000 gallons per day.

	Steam Plant	Producer Gas Plant
Interest on cost of building and contents for one day, rate 4½%	$2.20	$2.86
Daily average charge for repairs and maintenance	0.35	0.41
Daily debit to sinking fund, interest at 4%, based on complete renewal in forty years	0.48	0.68
Daily cost of operation:		
(a) Labor, two men, 12 hours each, at $80 and $75 per month	5.10	5.10
(b) Fuel at $2.50 per ton	9.45	2.13
(c) Oil	0.30	0.25
(d) Waste	0.02	0.02
(e) Light, etc.	0.10	0.10
(f) Miscellaneous	0.20	0.20
Total daily expense	$18.20	$11.74
Estimated cost of pumping 1000 gallons water by steam		1.81 cents
Estimated cost of pumping 1000 gallons water by gas		1.17 cents
Estimated saving per 1,000,000 gallons water pumped	$6.40	

Producer Gas from Crude Oil*

By E. C. Jones

The production of gas from crude petroleum or its products is not sufficiently standardized to give figures necessary to exactly determine its economy. California with its immense deposits of petroleum is the natural and logical field for the exploitation and industrial use of oil producer gas. It is to be deplored that such an important subject was first considered by men not conversant with the manufacture of oil gas, who, in casting about for apparatus to make producer gas from oil, naturally gravitated to the old familiar methods of retorting the oil; any improvements that grew out of these methods seem to have retained the objectionable features of the retort system. Briefly stated, these features consist of the necessary shutdowns for the purpose of removing coke and frequently for burning out accumulated soot and lampblack. A typical analysis of gas made in this way is as follows:

CO_2	4.0	CH_4	12.8
CO	7.4	H_2	3.1
O_2	0.4	N_2	71.9

British thermal units per cubic foot, 172. Claimed thermal efficiency, 20 to 62 per cent. Operating thermal efficiency, 55 per cent.

*A paper presented at the San Francisco meeting of the American Society of Mechanical Engineers.

This gas has been applied to the operation of small gas-engine units up to and including 100 horsepower. Owing to the abundance of petroleum in California, it has superseded all crude material in the manufacture of illuminating gas.

The first oil gas manufactured on a large scale in California has the following analysis:

Heavy hydrocarbons	6.2
Marsh gas	20.6
Hydrogen	62.4
Carbon monoxide	3.0
Carbon dioxide	2.2
Oxygen	0.4
Residual nitrogen	2.2
	100.0
Specific gravity	0.390

By improvements in apparatus and refinements of operation the hydrogen content of the gas has been reduced to less than 40 per cent.; the marsh gas has been increased to 34 per cent.; the carbon monoxide has been increased to 9 per cent.; the specific gravity to 0.485, and the heat value from 624 to 680 B.t.u. per cubic foot. The oil gas generators used at present for manufacturing illuminating gas are so elastic in their operation that any of them can be immediately adapted to the manufacture of producer gas from oil, the chemical composition of the gas and its value depending only upon the manipulation of the generator.

The writer has carried on a series of experiments with oil producer gas, using a large generating unit, and the only change in equipment was the use of compressed air at from 35 to 40 pounds pressure for the injection of oil and to assist in the partial combustion of the oil. During these experiments producer gas was made having a thermal value as low as 103 B.t.u. per cubic foot and as high as 482 B.t.u. per cubic foot. Unfortunately no ready means was at hand for measuring the quantity of gas made and the amount of oil used to produce 1000 cubic feet. A typical analysis of this gas is as follows:

Carbon dioxide	4%	
Heavy hydrocarbons	2	or less
Oxygen	1	
Carbon monoxide	9	
Hydrogen	2	
Marsh gas	13	
Nitrogen	70	

This gas has a calorific value of 100 B.t.u. per cubic foot. To use this gas successfully in gas engines it is necessary that it shall be thoroughly cleaned by efficient scrubbing, and that it shall be uniform in calorific value and chemical constituents. This last can be readily accomplished in the operation of oil-gas generators, by careful measurement of the oil used and the air supplied for its partial combustion, and the maintenance of a fairly constant temperature in the generator.

This can be done as in oil-gas manufacture by a determination of the necessary temperature by the observation of color in the checker brick and the maintenance of this temperature by frequent observations through sight cocks by the gasmaker.

Making producer gas from oil in the ordinary gas generator has many advantages over any special process. The gas can be made in very large quantities and the amount made can be easily regulated to the needs. The operation is continuous and without interruptions for cleaning. This is essential in the manufacture of producer gas for power purposes. In any other known process the interruptions are not at stated intervals, but occur when the producer refuses to work, owing to the clogging up of its parts by coke or lampblack.

Oil-gas generators have no easily destructible parts, as the lining and checker brick are constructed with a view to resisting high temperatures and, although a much higher temperature is desirable in making producer gas than that employed in making oil gas in retorts, the checker brick are not seriously affected by the high temperature. In the decomposition of oil in the presence of air, there is complete disposition of all the gas-making constituents of the oil, so that producer gas can be made without a by-product of any kind. Any accumulation of carbon in the generator may be removed by adjusting the temperature and quantity of air supplied.

This method of making gas requires a small gas holder for momentary storage, and the process as at present understood could not be used as a suction gas producer. Producer gas made from oil and containing a small percentage of hydrogen possesses advantages over illuminating-oil gas inasmuch as it can be subjected to higher compression in gas-engine cylinders and, with a gas of uniform analysis, uniform piston speed can be obtained.

CORRESPONDENCE

Mr. Barker's Engine Speed

In the February 28 number, O. J. Barker asks if a speed of 300 revolutions per minute is too high for a vertical, single-acting engine of 9½-inches bore and 12-inches stroke, built with a crosshead. My opinion is that such a speed is too high for a single-acting engine. When the piston reaches the end of the expansion stroke it has no cushion against the open end to assist the sudden reversal of stress. At such a high piston speed (600 feet per minute) a sudden reversal of stress would most likely cause a pound at the end of the downward stroke. Especially is this true in this type of engine as the power stroke is downward and the inertia of the moving parts tends to increase the sudden reversal of stress.

Thomas H. Beckman.

New Orleans, La.

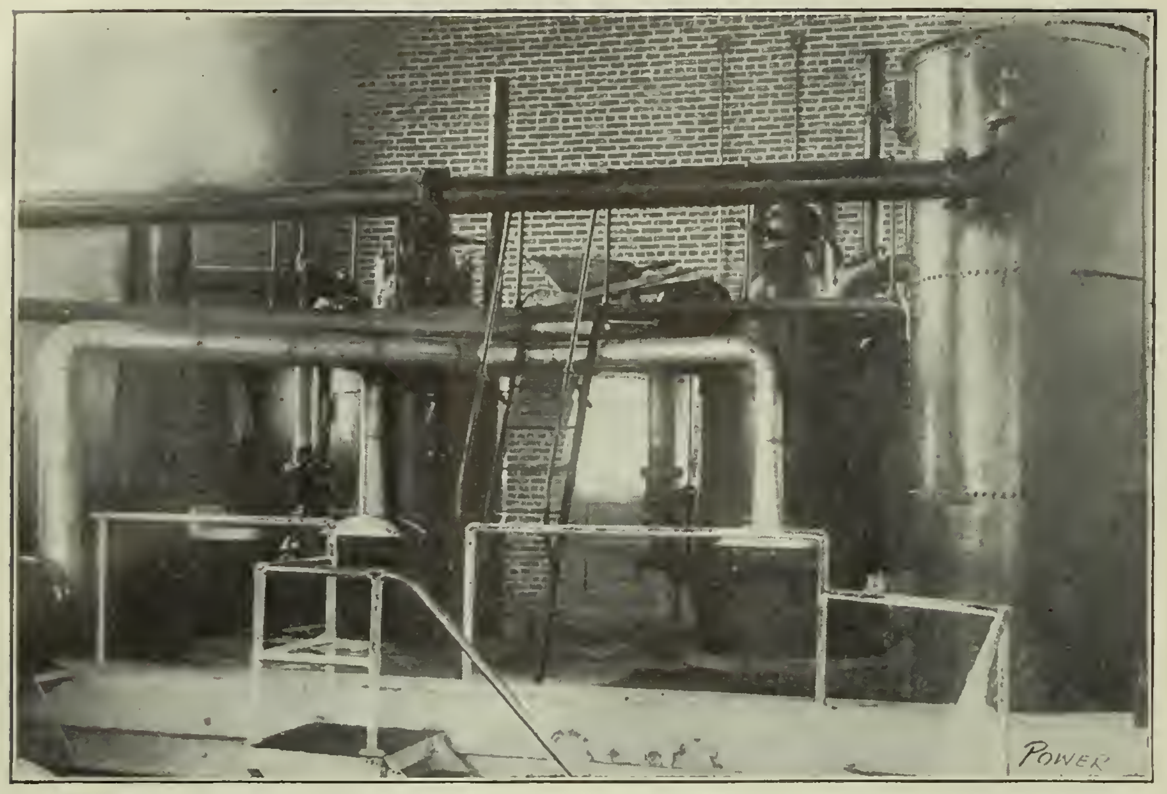

Fig. 4. The Producer Equipment

Whenever clinkers are drawn out of the fire, which is requisite only at intervals of several hours, the suction fan is started and draws all dirt away and discharges it outside the building. By this means the producer room is kept perfectly clean and no dust is ever carried over to the engines and pumps.

The supply of lubricating oil is kept in iron tanks with pipe connections leading outside to permit their being filled readily and without making any mess in the station.

As to the operation of the plant, the pumping units and gas producers are in complete duplicate; therefore, either set can be operated independently of the other or both may be operated at the same time. When the engines are not in operation, the fires in the generators are usually banked. While in this state, very little attention or coal is required for days at a time, but the plant can be placed in full operation on short notice.

a shutdown of several hours' duration. The compressor, blower and pump are all driven by the gasolene engine.

The suction pipes are laid beneath the floor in concrete channels which are covered by steel floor plates and the piping is so arranged and equipped with valves that either engine may be operated from either producer. A neat gage board, located on the east wall of the machinery pit, is in full view from both engines. Upon this board are mounted two sets of suction and discharge gages and a recording gage which indicates high and low water in the standpipe by means of an electric alarm and registers upon a paper disk the water pressure as it varies from hour to hour.

The operating engineer of the plant has installed an excellent system for removing the dust arising during the operation of stoking the fire at the grate level. As indicated in Fig. 3, a system of galvanized pipe extends from a suction fan to the fire doors of each generator, with a hood or extension over each door.

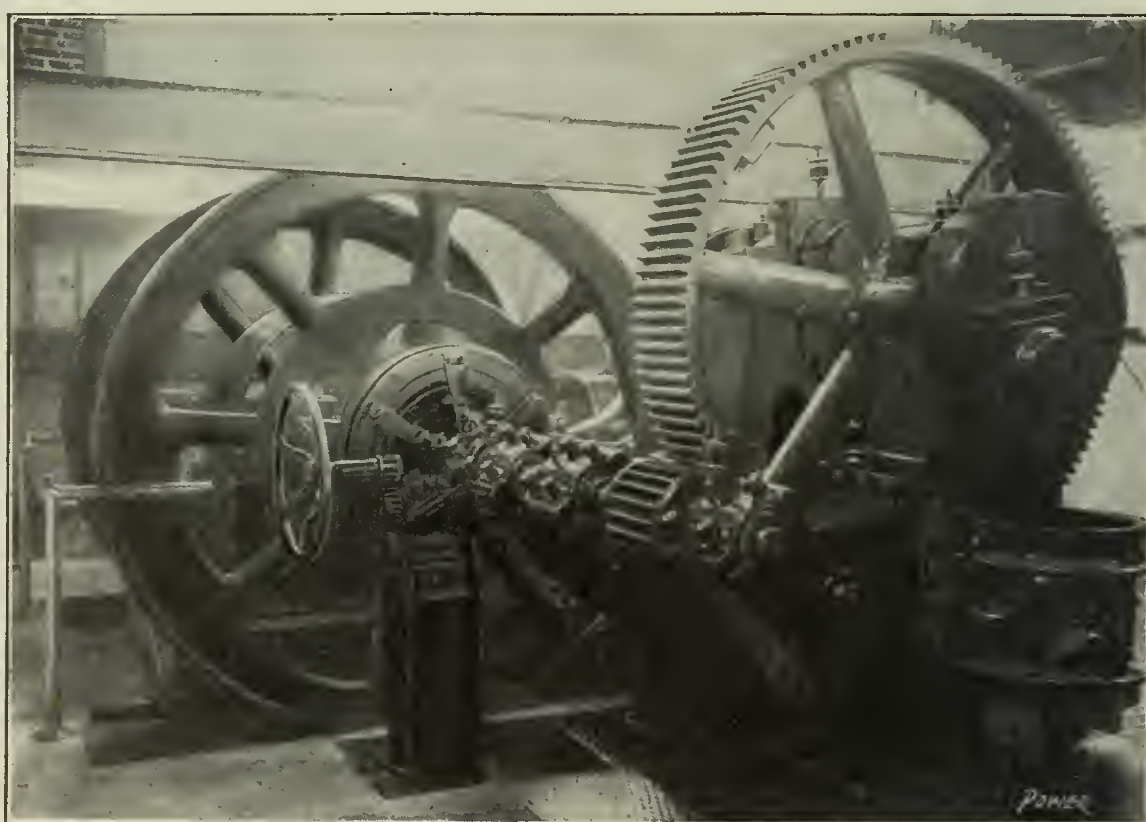

Fig. 6. One of the Pumps and Its Clutch Gear

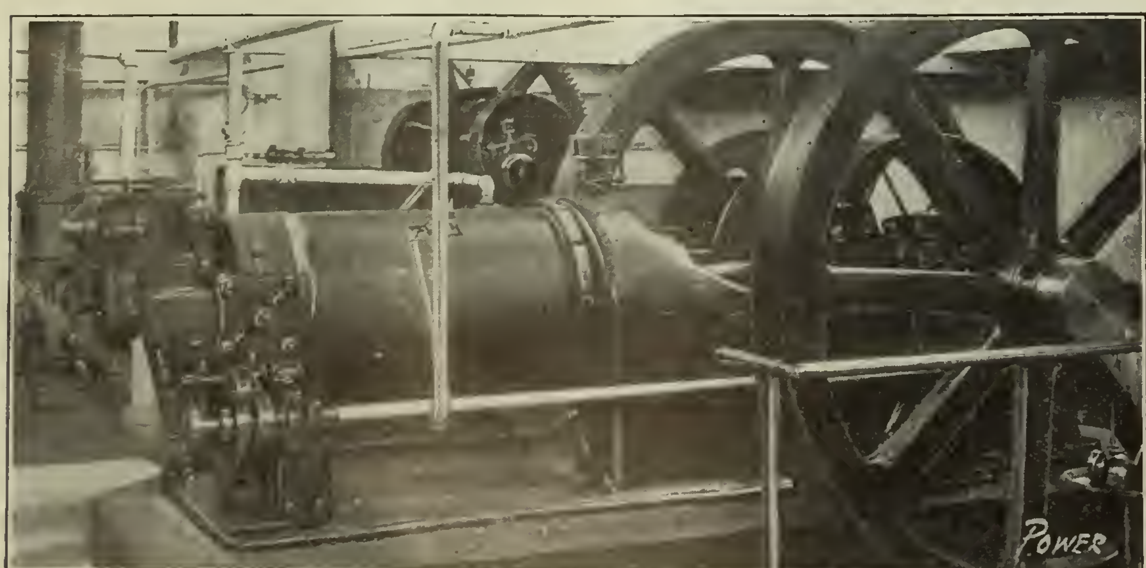

Fig. 5. One of the Engines

By actual experience it has been found that after a shutdown of seventy-two hours the engines could be started and water pumped within fifteen minutes. This is less time than would be required to get up steam from banked fires in ordinary boilers.

The accompanying table shows the cost of pumping 1000 gallons of water by producer gas as compared with the cost of pumping by steam. In making the comparison, data from steam pumping plants of similar size have been utilized to determine the cost of operation. The actual prices bid for a steam plant were used in determining the charges for interest, depreciation, sinking fund, etc. It should be understood, however, that the figures given do not pumping unit is composed of an 85-horsepower single-acting engine and a Deane triplex pump. Fig. 5 shows a view from the engine side of one of the units and Fig. 6 shows a view from the pump side. The engines are the standard heavy-duty single-cylinder machines built by the Otto Gas Engine Works and are direct-connected by friction clutches to the driving shafts of the pumps, to which are geared the pump crank shafts, as usual. The pumps are of the vertical single-acting type and each has capacity of one and a quarter million gallons in 24 hours against a head of 250 feet (108 pounds per square inch). The total capacity of the station is, therefore, 2,500,000 gallons per 24 hours.

On the basis of the figures just given, the water horsepower delivered by each pump is 54.3 and, with the ample allowance of 25 per cent. for friction in the pump and gears, the brake horsepower required from the engine is 72. This is only 85 per cent. of the rated power of each engine and as each of these has an overload capacity of more than 20 per cent. above its rating, the water pressure could be temporarily increased in case of fire to more than 150 pounds per square inch. This policy of operating a municipal pumping plant at moderate load and pressure, with a possibility of considerable increase in emergencies, is most excellent. It increases the life of the plant and insures its reliability, if well built.

The only auxiliaries required are a 3-horsepower Otto vertical gasoline engine, a compressor, a centrifugal blower and a drainage pump for the machinery pit. The compressor, together with a storage tank, is used to provide compressed air for starting the main engines. The blower provides a forced draft in brighting up the producer fires in the morning or after

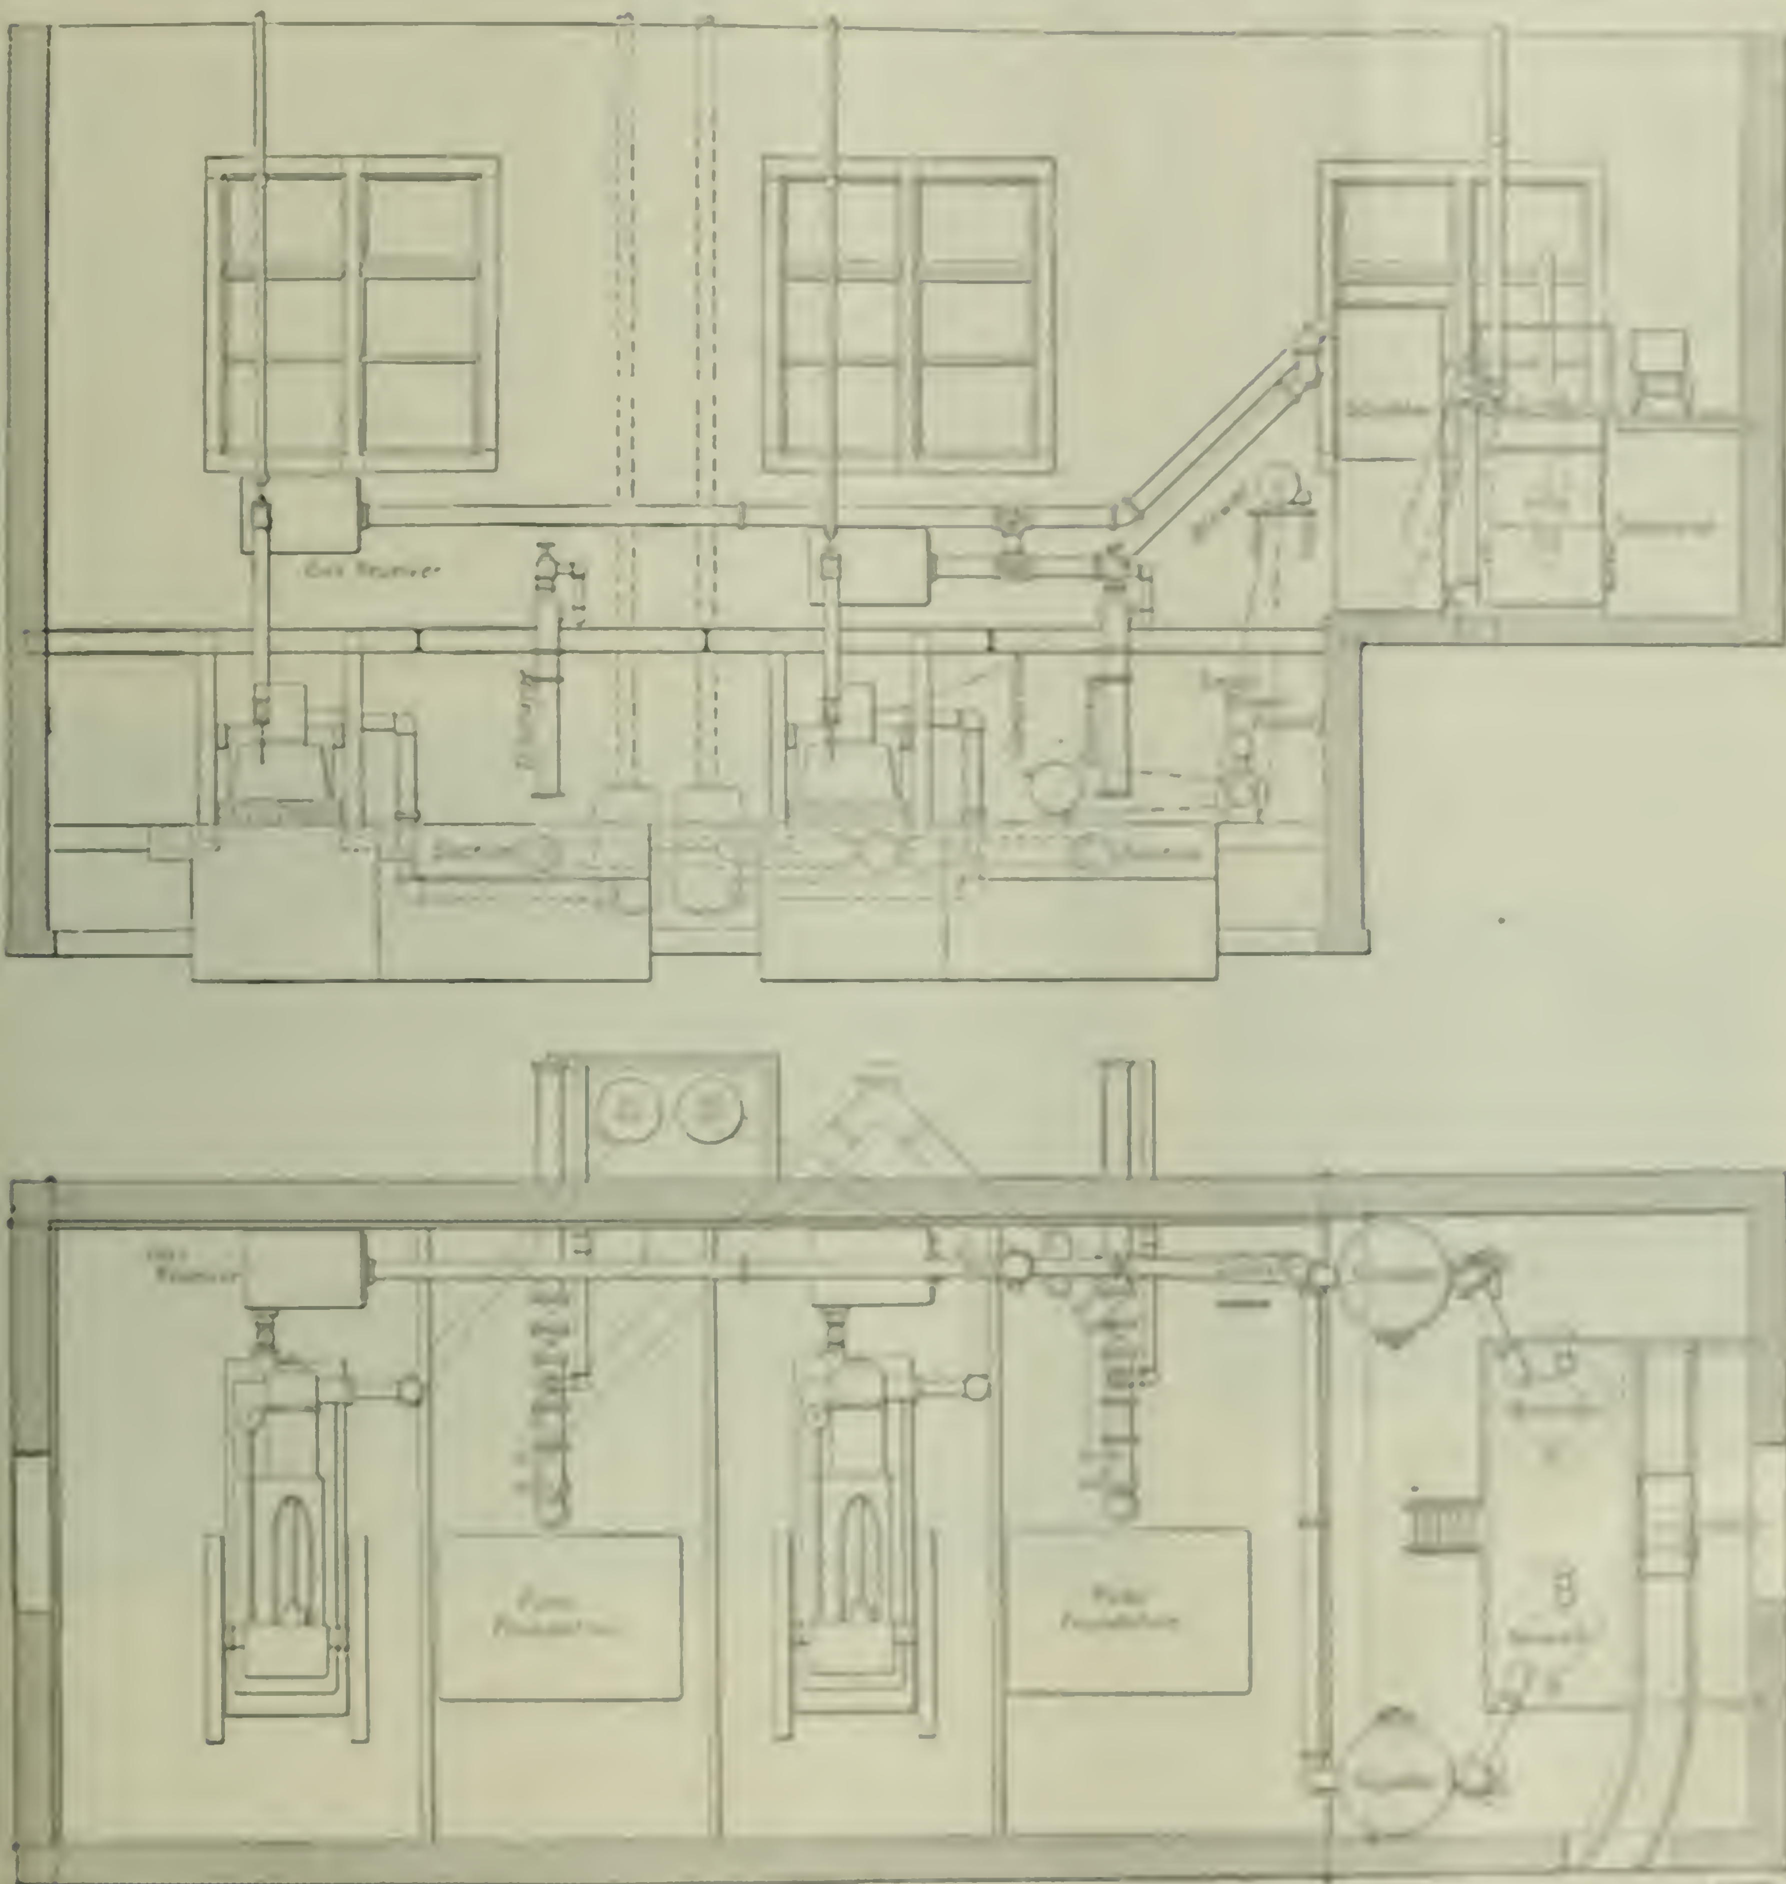

Fig. 3. Elevation and Plan View of Apparatus in Haddonfield Gas-power Plant

Gas Power Department

Everything worth while in the gas engine and producer industry will be treated here in a way that can be of use to practical men

A Municipal Gas Power Pumping Plant

By Thomas E. Butterfield

A striking example of municipal progressiveness is embodied in the gas-power service and fire-pumping station installed within the past year by the town of Haddonfield, N. J. The new water-works system derives its water supply from four artesian wells which extend down about 220 feet. From each well a 6-inch branch leads to a 12-inch main extending from the well field to an absolutely water-tight concrete cistern 20 feet in diameter and 42 feet deep. The 12-inch main extends about 30 feet down into this cistern and as soon as the pumps lower the water level in the cistern more water is siphoned out of the wells.

The power house is built of hard burnt brick and the foundation walls are of concrete, reinforced according to requirements. Large double-width windows located between each pair of pilasters provide ample light and ventilation for the interior. The building is located at the foot of a hill, as shown in Fig. 1, and at the edge of a basin or depression in which the artesian wells were driven. The railroad spur track is on the crest of the hill and coal cars are dumped into the chute shown in the picture, the coal passing by gravity down the chute to the coal shed, whence it is wheeled by barrow across the bridge to the producer platform in the power house.

Fig. 1. Coaling Arrangement

The interior of the building is divided into two parts, the main producer floor and the pump pit. The producer floor is at the ground level and the floor of the machinery pit is located eight feet below and reached by iron stairways from the producer floor and the front of the building. An iron walkway along one side of the building (see Fig. 2) connects the front entrance with the producer floor. This iron walk also forms an excellent gallery from which the machinery on the floor below may be viewed.

As the floor of the machinery pit is five feet below the level of the ground water, it is constantly subjected to an upward pressure from beneath of over 300 pounds per square foot. To withstand this the floor was constructed of concrete several feet thick.

The power equipment of this station represents an innovation in small water-works construction. Instead of the usual steam boilers and uneconomical steam pumps, there are installed two complete, duplicate power units, each consisting of a triplex pump driven by an Otto gas engine and an Otto suction gas producer designed for gasifying anthracite coal. The gas generator is of the simple up-draft type with a vaporizer built in the top. The gas passes from the generator to a wet scrubber of the usual tower type. Fig. 3 shows the arrangement of the equipment.

Fig. 4 is a picture of the producers in which may be seen the charging platform, which is on a level with the tops of the generators and is reached from the producer floor by means of an iron stairway. This platform is of steel and is built entirely around the tops of both generators, giving access to them from all points. The platform extends to a door in the side of the building which opens on to the bridge leading to the coal shed, 20 feet away and on the same level. The capacity of the bin covered by this shed is 50 tons of coal. The floor of the bin is of concrete and the front and sides are of heavy timber. The rear wall of the bin is formed by a heavy reinforced-concrete retaining wall, 30 feet long by 7 feet 6 inches high, designed chiefly for the purpose of holding back the embankment, and beneath the front wall of the bin is another heavy concrete retaining wall.

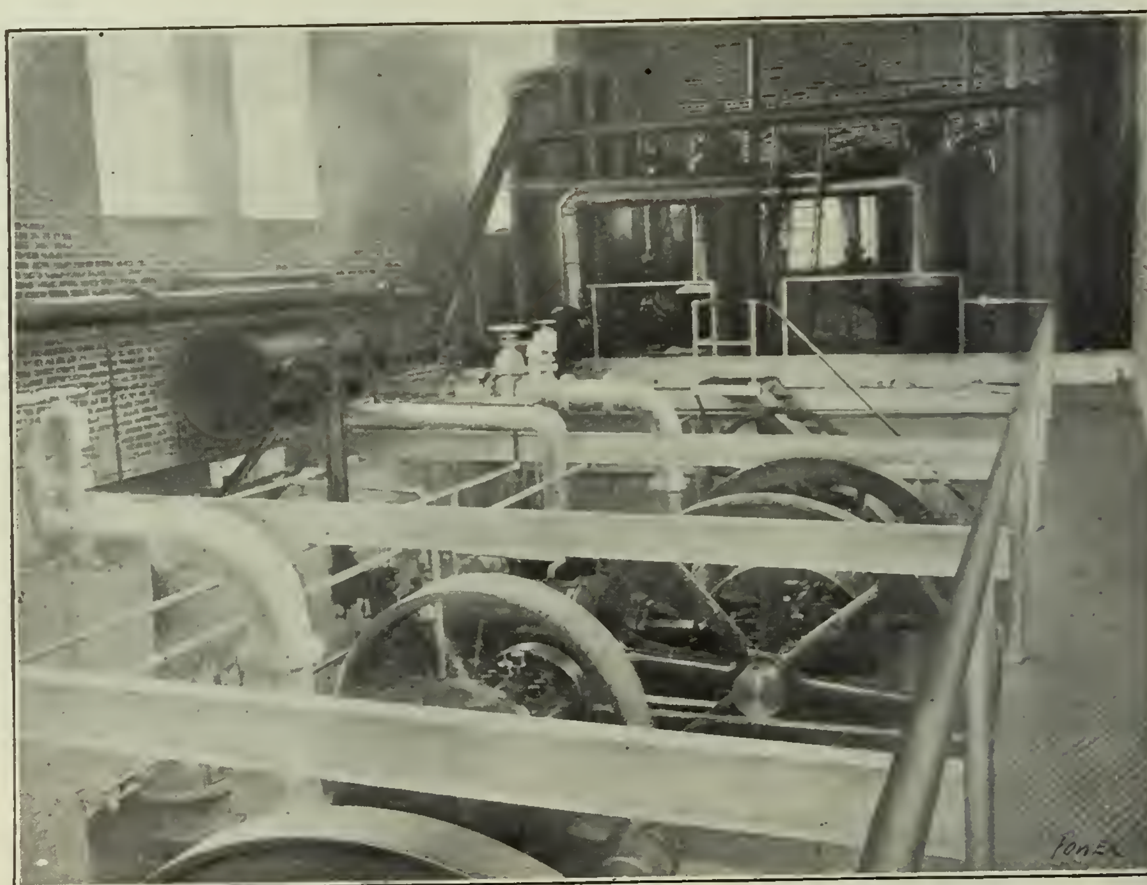

Fig. 2. Interior of Haddonfield Pumping Station

The floor of the machinery pit was put at a low level in order that the suction lift of the pumps would not be excessive, even with the water level in the cistern drawn down by pumping. Each watt-hour. In contrast to this, many modern stations are running upon about three pounds of coal per kilowatt-hour, and in some cases even less. This means that only 30 per cent. as much coal as was demanded twenty years ago is now needed to produce a unit of electrical energy.

In addition to the fact that the development of alternating-current apparatus has enabled the electric-lighting companies to distribute their product from the power station to the consumers at a much less cost, has also made it possible to transmit power for distances which were not dreamed of in the early days. Twenty years ago what little electricity was used was distributed by direct current and the radius of activity was seldom more than half a mile, or a mile at the most. This necessitated the generating stations being placed upon expensive land near the heart of the city, and since the voltage on a direct-current system is limited, it meant a large loss of power in transmission and required a large investment in copper. However, the introduction of high-voltage transmission has made it possible to locate factories, mills and shops at convenient places, instead as in the old days at or near the source of power, and has also greatly reduced the cost of distribution. These facts alone have had a wonderfully beneficial effect upon the entire industrial development of the country.

High-voltage transmission has further permitted the utilization of what were heretofore useless and almost inaccessible waterfalls. Without this development, Los Angeles would be forced to burn thousands of barrels of oil each day instead of using the mountain streams two hundred miles away, and Seattle would not be able to utilize the melting snow and ice from the glaciers of Mt. Rainier to operate all her street cars and other public utilities. Without high-voltage alternating-current apparatus, Niagara power could not be transmitted and used in the lake cities of Canada, or in Buffalo, Syracuse or Rochester. The utilization of Niagara power alone means a yearly saving of at least 2,500,000 tons of coal or the conservation of $5,000,000 to $7,000,000 of fuel annually.

Consider now the apparatus by which the electricity is converted into light, heat and power. Here again scientific study and research have done much to increase the efficiency of the apparatus used. The reduced price of electricity itself, therefore, does not indicate the total saving to the consumer. Are lamps of today are more than 100 per cent. greater in efficiency than those of a few years ago. Incandescent lamps in the early days consumed six watts of energy per candlepower. This consumption was soon reduced to three watts per candle, where it remained for many years and seemed to baffle further reduction, but after years of scientific experimentation this was reduced to 1½ watts per candle, and now there is the tungsten lamp which consumes only one watt per candle power, still further improvement is promised in a lamp which is to consume not over one-half a watt per candlepower.

While all of the matters thus far discussed relate to improvements which have taken place in the physical apparatus of the property, one must not fail to give due credit for the development of the electric-lighting industry, and for the reduction in the cost of light, heat and power, to the scientific management of electric-lighting properties. These have been specialized to a remarkable degree and carried on with most satisfactory results for many years, in spite of the fact that the term "efficiency engineer" is just becoming known to the public. The improvements in electric-lighting properties have been due fully as much to the trained engineer who operates the property as to the engineer who plans it or who designs the apparatus used in it. It is the operating engineer who in many cases has pointed out opportunities for betterment and has suggested to the designing engineer where economies and improvements could be made in the physical apparatus. It is the operating engineer who by careful study of men, machinery and methods has brought about economies in the production of electricity which have resulted in reduced costs. He has instructed his men in their particular duties and has educated them so that they have become experts in their lines.

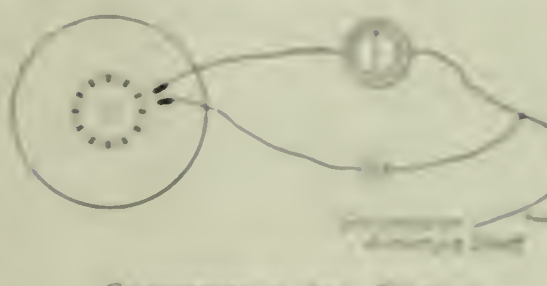
The operating engineer has not only brought about a great reduction in the cost of electrical energy itself, but as the result of a scientific investigation of the customer's needs he has effected, through the use of suitable electrical apparatus, what is in reality a still further reduction in the cost of light and power to the consumer.

The wonderful advance which has taken place in the last twenty years in the electric-lighting industry has been due to the combined efforts of the operating engineer and the designing engineer. It has been a gradual and a steady evolution and is still going on. The industry itself has not reaped all the benefits, for while the returns on electric-lighting investments have been sure they have not been as large as the dividends which the public has received in the reduced cost of electric light and power. Twenty years ago electric lights were high-priced luxuries, today they are inexpensive necessities.

LETTERS

Locating a Grounded Armature Coil

On page 420 of the March 14 issue, Mr. Davies describes a method of testing for the location of grounds in direct-current armature windings which is a good one. However, I think the method I have been using is simpler and easier of application. We have a good deal of this kind of trouble, caused by salt air attacking the copper and insulation, and the test has always been satisfactory. A millivoltmeter or galvanometer, a few cells of primary battery and a few short pieces of wire are all you need. Raise all brushes from the commutator and clean it thoroughly. Connect one terminal of the battery and one terminal of the galvanometer or millivoltmeter together and also to the armature shaft, as indicated



Connections for Testing

in the diagram. Then touch the two free terminals to one commutator bar and note the deflection of the instrument. If there is no deflection, one of the coils connected to that bar is dead grounded and that practically short-circuits the instrument and thereby prevents deflection. If there is a deflection, try another bar and note the deflection; if it is greater than the first one, you are moving away from the grounded coil. Successive tests will finally locate a bar where the deflection is smallest or where there is none; that bar will be connected to the grounded coil and by taking out the leads from the commutator bar and testing them separately the grounded coil will be easily identified.

Smoothing Roughened Collector Rings

Cast-iron collector rings on revolving-field alternators are very hard to smooth after becoming rough from arcing. The "flowers" that have been raised are chilled and cannot be cut with a file. The best way I have found to deal with such cases is to grind a piece of an old emery wheel to the shape of the collector-ring brush, put it in one of the brush holders and run the machine, applying a little oil to the collector ring. It works like magic.

C. L. [illegible]

Dubuque, Ia.

lel, with partial success; closer attention was then given to the electrical part of the unit. It was found that either engine could be operated in parallel with the turbines, provided the field current of the engine-driven unit was greatly decreased, causing the output of the engine-driven unit to have almost unity power factor while the turbine unit would have a very low power factor, as it was then required to furnish practically all of the wattless component of the line current in addition to its load, but the two engine-driven units would operate in parallel with each other but little better than before. The supposition was that the field magnets of the engine-driven units were too close to the saturation point at any power factor much below unity, which would cause poor operation in parallel, as the reaction of the synchronizing current upon a field magnet is much less effective when the magnet is highly saturated. This impression was strengthened by the fact that on rare occasions the machines would run together for hours at a time at slightly reduced voltage, while a slight increase in field current would result in such heavy surges of cross currents that the machines would have to be separated immediately.

It was suspected for some time that the relative positions of the crank pins at the instant of synchronizing made a perceptible difference in the action of the generators, and considerable ingenuity was expended upon an electrical attachment to the engine shafts to indicate, through contact-making devices, when the cranks were in certain relative positions, but a large number of experiments indicated, so far as could be determined, that the relative positions of the crank pins made no difference whatever. When the power factor was favorable, 90 per cent. or higher, the generators would operate satisfactorily with the crank pins in any relative position, and when the power factor was much below 90 per cent. there was no position of crank pins with which they could be made to remain in parallel.

This, which at first appeared to be almost impossible to remedy, proved to be the simplest condition of all. It was reasoned that anything that would operate to maintain the necessary voltage without increasing the field current would assist in maintaining synchronism, and investigation developed that while the engine-driven alternators were rated at 78.5 revolutions per minute, they were running at about 77 revolutions per minute, or about 2 per cent. below speed. When the engine governors had been weighted down until the generators ran at 79 revolutions per minute, they operated in parallel perfectly under all changes in load and power factor. This required about 25 per cent. less field current and, incidentally, the increased speed and consequent higher frequency resulted in a much improved power factor on the entire system, which, of course, reduced the line losses and gave better voltage at remote points in the system.

It will be evident that no one item in the foregoing enumeration can be considered the reason that the alternators would not operate in parallel; correction of all of the deficiencies was necessary to obtain the result desired.

Improvements in Electric Lighting Properties*

By William H. Blood, Jr.

At the present time, when so much is being said about "efficiency" and "scientific management," it may be well to consider what the application of science to the electric-lighting industry has accomplished and to what extent the public has been benefited thereby.

In 1888, the writer tested the largest dynamo that the Institute of Technology possessed, and found the highest ratio of electrical output to mechanical input to be about 70 per cent. Today, machines of this size operate at about 85 per cent. efficiency, while larger units give efficiencies of 95 or even as high as 97 per cent. Assuming this improvement in efficiency to amount to an average of 25 per cent., it would mean that this percentage of the fuel which would have been burned, had there been no improvement in electrical efficiency since the year 1888, is now being saved.

If this figure is applied to the industry as a whole, basing the estimate upon figures given in the census reports on the cost of fuel used by the electric-light and railway plants in the United States, it shows that electrical engineers have brought about the conservation for future generations of approximately $12,000,000 worth of coal per year, and this solely on account of a single item—improvement in the efficiency of electric generators.

This improvement has been accomplished partly through an increase in the size of the units. The first commercial electric-light plant in Boston, built in 1886, contained six machines having an aggregate capacity of about 230 horsepower, two of them being of 15 horsepower each and the remaining four of 50 horsepower each. In 1888 the largest electric generators were of 100 horsepower, and they were regarded as monsters. Today, 15,000-horsepower machines are common and even units of 25,000 horsepower are about to be installed. The 25,000-horsepower generators, besides being more efficient, are much more reliable and are little, if any, more complicated than the older and smaller machines.

*From a paper delivered before the Technology Congress, at Boston, April 11, 1911.

One of the early electric-power plants with which the writer had some connection, contained twenty dynamos of 100 horsepower capacity each, giving a total capacity of 2000 horsepower, and the floor space required for the entire plant, including boilers and engines, was 9000 square feet, which is equivalent to 4.5 square feet per horsepower of capacity. This same company is today building a new station which is to have an ultimate capacity of 140,000 horsepower and which will require but slightly in excess of one-half a square foot per horsepower. The first plant represented an investment of approximately $225 per horsepower, while the new installation will cost about $45 per horsepower. Had there been no improvement made along this line, and had the company been obliged to increase its capital account on the basis of $225 per horsepower up to its present capacity, it would have required an additional investment of some $12,500,000, which would have entailed additional annual interest charges of $750,000.

A still further improvement in power-plant design has been the adoption of steam turbines. These, besides requiring much less room, use higher steam pressures and higher vacuums, and are, consequently, more efficient.

There has also been a great development in the boilers used in power stations. Instead of units of 100 to 125 horsepower, units of 600 horsepower are now in general use and boilers up to 2000 horsepower have been built. In the old tubular boilers 80 to 100 pounds was the common pressure used; this was later increased to 125 pounds, then to 150 pounds, and finally in the water-tube boilers of today 200 is commonly used. Improvements in superheaters, combustion chambers, automatic stoking devices, condensers, ash- and coal-handling machinery, apparatus for analyzing flue gases and other miscellaneous devices have all had their effect in cheapening the process of converting the heat units of coal into steam.

Turning again to the electrical equipment, the modern switchboard, although somewhat elaborate with its remote-control switches and automatic regulating and protecting devices, is simple of manipulation and arranged to give the plant the greatest flexibility of operation. With the increase in size of the units and the development of the modern switchboard, has come a decrease in the number of operators needed, so that today in the dynamo room of a 5000-horsepower plant there would be required only two or three men on a shift, whereas two decades ago eight or ten men would have been required.

In the early days of power-plant operation it required, as a rule, ten or more pounds of coal to produce one kilo-

This matter of securing the position "higher up" is getting so important that it has given rise to all these articles and if a fellow cannot find a helping hand if he makes any effort to "get there," it will certainly not be the fault of the writer of those editorials on the first page.

J. E. POCHÉ.

New Orleans, La.

In a recent issue, Oscar J. Richmond suggested that ideas be given upon the subject of how to proceed to secure a better position, assuming that one is properly qualified for it.

One's early training should prepare him to speak and write intelligently of the things he knows and to be at his ease among the cultured. When he endeavors to secure a higher position he needs to be able to show his prospective employer just why it will be advantageous to secure his services, just as the salesman must show the buyer why it will be to his advantage to buy the particular article that the salesman is offering. General, coupled with technical, education is necessary for this, and the more education an engineer can obtain the better it will be for him.

At all times one should take pains to work up as wide a reputation as possible of being a high-grade man so that when a man is needed for a desirable position in the neighborhood, he will be among the first to be thought of. One should be a mixer both in the associations of his fellow craftsmen and in a general social way. He should, as far as possible, cultivate the acquaintance of employers, and in this his personal appearance will count greatly. He should dress as well as the circumstances and his means will permit and remember that he may lose much more in opportunities for advancement by going poorly dressed than he saves in clothes. The commonly accepted badges of his profession, dirty hands, overalls, etc., should be discarded whenever his duties will permit, while at work he should be as neat personally as possible. The better class of employer takes note of such things and prefers employees that make a creditable showing, both on duty and about the streets and other public places.

One should avoid talking shop and should avoid appearing big-headed but, on the other hand, should make use of his opportunities of showing that he knows his business and knows it well. He should not claim to know it all, but he should let his conversation and actions show that he does know a great deal. Whenever occasion offers he should help his fellow craftsmen and not be afraid that the ideas he thus gives away will help another to get the position he himself desires. If one has the reputation of being a high-grade man among his fellow craftsmen, employers are sure to learn of it and it will be greatly to his benefit. Taking part in discussions in association meetings and writing for the technical journals will assist in working up the desired favorable reputation and will give one greater confidence in his own ability.

It often happens that one is so isolated by the place and conditions of his occupation that the foregoing suggestions are of little help and in such cases the following will more particularly apply.

In many sections of the country there are employment agencies that make a specialty of technical and professional positions and if such an agency is available it will often prove the easiest and best means of securing the desired result. Employers frequently advertise for high-grade men and advertisements for help in the desired line should be watched for and replied to. Replies should be made promptly and whenever possible in person. Take a day off and spend a little money for railroad fare if necessary. The trip will do you good and, though you may be too late to secure the position, it will extend your acquaintance both among employers and members of your own craft, and if a good impression is left with the employer he may call on you when next in need of a man, or recommend you to another. Great pains should be taken to leave a good impression. The clothes should be good but not showy, and the manner natural. No attempt should be made to show off. All questions should be answered carefully and truthfully. If a question be asked about some subject one does not understand he should be frank and admit it. Attempting to conceal is usually the surest way to get into trouble. Besides, no one is expected to know everything and have it all on his tongue's end. The employer should be allowed to do most of the talking. He knows the points he wishes to bring out. Many applicants make the mistake of trying to teach the employer, imagining that they are displaying their knowledge to advantage. The writer once heard an employer tell an applicant that he was looking for someone to do his work and not to teach others how it should be done.

When advertisements cannot be answered in person it is often wise to telephone or to telegraph. Telephoning is best where feasible as it gives the employer opportunity to learn more of the applicant. Lastly, the advertisement may be answered by letter. The letter should be carefully worded and carefully written. As much information as possible that bears directly on the suitableness of the applicant for the position should be given and copies of letters of recommendation should be inclosed. The original letters of recommendation should not be sent as they may be called for if desired and the employer may wish to file the letters with the application. References should also be given, as an indorsement that has not passed through the hands of the applicant is often desired and is of more value. Willingness to give references also shows greater confidence in one's own ability. Every effort should be made to make it easy for the employer to decide at once and to let the applicant know of his decision. Advertisements for help usually secure many replies and the ones that contain the information that the employer desires receive the attention first.

Advertising for a position is often the first means resorted to. The first thing to be considered is the medium to be employed. Care should be exercised to use mediums that reach the greatest number of the class of employers desired. Often, one's own journals are not read to any great extent by the employers he wishes to reach. A manufacturer may employ a number of steam engineers and yet seldom look into a steam-engineering journal. Often, several mediums circulating among different classes should be used.

The proper medium or mediums having been selected, the wording of the advertisement should receive careful attention. One should not be stingy of space but should say enough in the advertisement to convince the man looking for help that the advertiser is the person desired. Bragging should be avoided but at the same time one should show that he has confidence in himself. The employer will often find many advertisements for such positions as he has to fill and the advertiser that appears most nearly to meet his requirements will be the first to be considered. Advertisements should be repeated and varied. Vacancies are usually quickly filled but may occur at any time. One may occur soon after an advertisement for such a position has appeared but employers do not read such advertisements unless in need of help and when needing help will not look through many back numbers. Even if the advertisement is repeated a number of times and in several journals it is still an economical way of securing a position.

Traveling salesmen and supply houses often are instrumental in placing men and their friendship should be cultivated.

Finally, in looking for a new position, one should always show consideration for his present employers. A good and safe rule is always to leave a place so that one can go back again. Never try to climb up by pulling another down. It is more honorable to stay down than to climb at the expense of someone else. On the other hand, one can often help himself by helping another and make his position more secure by assisting others to climb with him.

Questions Before the House

Comment, criticism, suggestions and debate upon various articles, letters and editorials which have appeared in previous issues

Abbreviations and Volatile Matter

In Power, December 27, 1910, under the title of "Coal Characteristics," what is meant by the letters after the name of the coals, such as R. O. M., N. P. & S.; also, volatile matter?

F. S. H.

The abbreviation R. O. M. signifies run-of-mine; N. P. & S. means nut, pea and slack. The volatile matter is the hydrocarbon, etc., distilled from the coal at a red heat as distinguished from the solid carbon.

Steam Bound Pump

If a pump frequently became steam-bound, how could it be remedied without reducing the temperature of the water?

A. R.

The head of water in the receiver is not sufficient to lift the suction valves and let the water run into the pump cylinder. This may be because the valve springs are too stiff or because the receiver is not high enough above the pump.

The tension in the springs may be reduced or the vertical distance between the water level in the receiver and the pump increased.

Installing Oil Burner

Please give little information on installing oil burners as to how should the furnace, combustion chamber, bridgewall and general brickwork be arranged to get the best results.

E. W. E.

The grates and bridgewall should be removed from the furnace and the bottom, side and end walls lined with firebrick. The burners should discharge about midway between the bottom of the boiler and the floor of the furnace. No more air should be admitted than is necessary for the smokeless burning of the oil.

Power of Falling Water

What will be the amount of water necessary to run a 50-horsepower water turbine set vertically under a head of 20 feet, and if set horizontally with the same head?

J. O. D.

To develop 50 horsepower requires the expenditure of $50 \times 33{,}000 = 1{,}650{,}000$ foot-pounds of energy per minute. One pound of water falling 20 feet will have 20 foot-pounds of energy and to develop 50 horsepower the water required per minute will be

$$\frac{1{,}650{,}000}{20} = 82{,}500 \textit{ pounds}$$

At an efficiency of waterwheel of 75 per cent. the actual water required per minute would be

$$\frac{82{,}500}{0.75} = 110{,}000 \textit{ pounds}$$

or approximately 18,000 cubic feet per minute. It will make no difference whether the wheel is set horizontally or vertically if the head and efficiency are the same.

Unloading Boilers

We are about to install new boilers, and as I will have charge I would like to have a little information in regards to the unloading, from the cars. The track is a short spur and it is so arranged that we can drive up alongside of the car. But my intentions are to jack up the boiler high enough so that we can push the car out from under it and then run the wagon under the boiler and let it down on the wagon. If you have a better plan than this, I would like to hear from you. The boilers are 72x18 inches and no dome. As this is the first time I ever had a job of this kind, I would like to do it the best and safest way. What should be the distance between the belly of the boiler and the bridgewall?

F. A. B.

The usual method is to place the wagon by the side of the car and roll the boiler from the car to the wagon on skids. The distance from the bottom of the boiler to the top of the bridgewall should be 10 inches.

Rebounding Dashpot Plunger

What causes a dashpot plunger to rebound after it makes the drop?

W. F. E.

The plunger rebounds because the air valve is open too little and allows more air to be caught in the cushion chamber than is necessary for the proper seating of the plunger.

Efficiency of Injector

What is the efficiency of an injector as a boiler feeder?

E. O. I.

Considered as a pump alone the efficiency is low, but as pump and feed-water heater the efficiency is nearly 100 per cent., as all of the heat not lost by radiation is returned to the boiler.

Lap on Duplex Pump Valves

Why do not duplex pump valves have lap?

L. D. P.

The pump must take steam full stroke, which renders lap inadmissible, as with lap cutoff would occur before the end of the stroke.

Compound-wound Machine with Open Shunt Field Circuit

What effect would the breaking of the shunt field circuit have on a compound-wound dynamo; what effect on a motor?

S. G. R.

The dynamo voltage would be considerably reduced and would become unstable, increasing with an increase of load and decreasing with a decrease of load. The motor would probably tend to run away; it would speed up until its torque just balanced the "pull" of the load, unless it went to pieces before that speed was reached and unless the torque of the load exceeded the torque of the motor with series field excitation alone; in the latter case, which is an improbable one, the speed would decrease until the motor torque balanced the load torque.

Candle Power of an Incandescent Lamp

Can the candlepower of an incandescent lamp be calculated from the watts it takes?

L. B. S.

Not unless you know the "characteristic" of the lamp filament; that is, the relation between watts per candlepower, volts and amperes at different voltages, which is a very uncertain one. A carbon lamp taking 3.1 watts per candle at rated voltage will take 4.7 watts per candle and only 80 per cent. of the total normal watts at 90 per cent. of the rated voltage. The candlepower at this voltage, therefore, would be

$$\frac{3.1 \times 0.8}{4.7} = 0.53$$

(53 per cent.) of the rated candlepower.

The Poetry of the Fireroom

In "Heat a Mode of Motion," Tyndall calls up a picture of the regeneration in a hot box of the radiant energy of an ancient sunshine and of the failure of the man who is trying to cool it off to grasp the real significance of the homely phenomenon.

How many men who are shoveling coal into a furnace realize that they are burning the verdure of a by-gone age compacted by centuries of storage and pressure into the mineral form of coal?

How many realize that in the process of combustion going on under their charge the carbon separated from its oxygen by the subtle action of the sunlight and built into the structure of a forgotten forest is satisfying its long deprived affinity for oxygen; that it is the velocity acquired by these minute bodies rushing together under the force of their mutual attraction and acquiring velocity as does a body falling to the earth impelled by the force which it and the earth exert upon each other, which they see and feel and recognize as heat? That the velocity acquired by the molecules of the gas is communicated to the molecules of steel which compose the heating surfaces and, imparted from one to another of these, is communicated to the molecules of the water until the velocity acquired by them causes them to fly off like the stone from a sling shot and by their impact produce the pressure which moves the engine piston and drives the mill?

To the man who has read Faraday's "Chemistry of a Candle," to whom a coal pile is not a heap of grimy stuff to be shoveled but a heritage from the ages, full of the energy from that source of all terrestrial power, so full that the energy in it would project it to the height of between two and three miles, who understands the processes of combustion and is interested in carrying them to perfection, the life in a boiler room rises far above the menial and becomes full of meaning and of interest.

The engine room, with its finely designed and highly finished machinery, with its indicator and valve setting and air of applied science, has too long been the center of interest and of effort for the engineer. There is infinitely more chance for applied science in the boiler room. A careless fireman, an illy proportioned furnace, can waste more coal than the most elaborate engine can save. There is more chance for the application of highly specialized knowledge and training in the design and setting of boilers, in the selection and burning of coal, in the treatment and heating of the feed water, than there is in all the processes over which the man in the engine room has any control. Chemistry, physics, mechanics and accounting all have here the wider field and the better opportunity, and managers and owners are commencing to recognize this and to place in responsible charge of boiler-room operations not mere laborers, as has been too often the case, but men who are qualified by education and training to direct the burning of the hundreds of dollars' worth of coal which is used there daily. It is dirty work but it earns clean money and is full of training and opportunity. In a large station near New York, provision is being made for running the boiler room from a bridge or gallery where the trained attendant will have at hand the readings of pressure gages, water meters, CO recorders, flue-gas thermometers, feed-water temperatures and everything that bears upon the continuous and economical operation of the boiler plant, with a laboratory for coal, ash and feed-water analyses and the verification of the CO_2 recording apparatus close at hand.

Only recently the head fireman of a large textile mill was transferred to a new and larger mill of the same company as engineer-in-charge of the entire power plant.

The day may not be so far off when to be the head fireman of a large boiler plant will come to be "some pumpkins."

Mr. Parsons Approves the Initial Velocity Stage

We have several times called attention to the present tendency on the part of steam-turbine manufacturers to use a compounded velocity stage for the initial expansion. The very considerable fall in pressure and temperature before the steam enters the casing relieves the pressure upon the stuffing box and avoids excessive temperature changes, while in turbines of the Parsons or reaction type it avoids the multiplicity of short blades used for the stages which it replaces. It is gratifying to notice that Mr. Parsons himself has placed the seal of his approval upon the practice. In a lecture delivered recently at the Royal Institution, Mr. Parsons said that in the smaller class of land turbines, the high-pressure end of the reaction turbine has always been less satisfactory than the lower-pressure section. On account of the low blade speeds the number of rows required had been large, which had added to the length of the shaft, reducing its stiffness and increasing the allowable clearance. He did not, however, approve of the use of two or more of these velocity compounded stages before passing the steam to the reaction blading.

Advantages of Safety Appliances

Simplicity of design in power-plant equipment is undoubtedly wise engineering practice. Complicated machinery will, of course, give more trouble than that of simple design, and, likewise, the more machines or devices put in a plant the more chances there are for trouble to arise.

Many engineers put in no more apparatus than is absolutely necessary to operate the plant in an economical manner. In fact, some plants are so simple in equipment that they are nothing more than a small country isolated plant enlarged. Ordinary boilers, hand-fired furnaces, water columns and gage glasses, steam gages and safety valves, the necessary appliances for safety, and Corliss engines with the necessary pipes and fittings comprise the outfit.

An engineer can look over such a plant and congratulate himself on the design, on the absence of a hundred and one so called "frills" and especially so if he can operate more efficiently than other steam plants which contain more elaborate equipment.

There are, however, various apparatus that could well be installed, and, although they might not be called upon to perform their function for years, perhaps never, their presence gives a sense of security and if occasion does arise their worth in preventing a serious accident will prove a paying investment.

An engineer may debate as to the advisability of equipping his engines with a speed-limit safety device, and finally decide that one is not necessary. But a few months after the plant has been started up the governor gear becomes deranged, a flywheel goes to pieces and beside doing a lot of damage to the plant, kills the engineer on watch. Under such a circumstance the safety stop would have been a mighty good investment.

While this incident is cited as an example of what might happen it is at the same time a good illustration of what has happened.

Another engineer designs a steam plant along sound engineering lines. To him the matter of a nonreturn valve in the main steam line comes up. The matter is thought over and the decision arrived at is that the services of the valve would not be required once during the life of the plant. The decision is not a rash one; hundreds of steam plants have operated for years without such a valve, and were none the worse off. Nothing ever gave way, and the valve would have only been an additional first cost.

But, on the other hand, suppose that a nonreturn valve had been put in the line, and a steam pipe had burst or a valve or a blank flange fractured from water hammer or some other cause, the valve in the main steam line would stop the flow of steam and it is evident that the damage from escaping steam would be insignificant as compared to what would be done if the boilers emptied themselves, or valuable minutes were used in closing stop valves over the boilers by hand.

Using precaution is a good thing, and if one is to ere in the matter of safety devices it is better to ere on the side of safety.

A Friendly Suggestion

It would probably surprise most of our readers to know how many letters of inquiry concerning engineering matters we answer by mail each week. Nothing gives us more pleasure than to help a reader over a rough spot, however, and we do not begrudge the huge volume of correspondence involved; but we wish to offer one suggestion to any and all who may desire information: Before asking us for it, see if you cannot find it in some back number of the paper; if you can, you will not need to ask us for it. If you are unable to find in your back numbers what you want to know, write and we will gladly answer your letter—this is not a kick, merely a suggestion inspired by the fact that within two weeks we have answered by mail nine requests for information that had been printed in POWER within a year—some of it within a month.

Getting the Full Benefit

It is the common experience of most readers of engineering papers that upon looking through an old number of a paper one is likely to find an article that is of much interest and value and that the reader does not remember having seen at the time when that number of the paper was received. This experience proves conclusively that the man who has it is not getting the full benefit of the fund of material presented by his periodicals.

The remedy is simple: A card index. If every reader of POWER, for example, would preserve his copies and keep a card index of all subjects discussed in them—not merely those subjects which interest him at the moment of publication—he would have a "ready-reference" library in a few years that would be astonishing.

There is another method of making published information readily available; that is the scrap-book method. It entails the disadvantages, however, of not being able to classify an article under more than one head and of having to get an extra copy of almost every issue of the paper in order to paste clippings from both sides of a leaf. The card index is simpler, takes less time and is more general in scope and flexible in application.

The Fusibility of Ash

A great deal of emphasis has lately been placed by E. G. Bailey, M. E., of Boston, on the fusibility of ash. A coal having but a small percentage of ash the fusing point of which is below that obtaining in the lower strata of the fire will be a very troublesome and uneconomical fuel, for the ash will melt and run together, forming a plaster clinker which flows over the grates, shutting off the air supply, requiring the constant working of the fire, reducing the efficiency of the furnace by lack of continuity of operation and by restricting the supply of oxygen and involving a large percentage of carbon in the ashpit waste. On the other hand, a coal comparatively high in ash will work quite satisfactorily and reach its limit much less quickly if the nature of its ash is such that it will not melt at the ordinary furnace temperatures. Although the weight of ash produced in a given time is greater it remains in the form of powder and can easily be gotten rid of with a few passes of the fire tools or a movement or two of the grate. Mr. Bailey is able by determining the fusibility of its ash to estimate the real fuel value of a sample of coal and to predict its behavior much closer than by any analysis or determination of heat content.

Have you noticed that some managers will listen to a mud carrier? In the end they generally find that the mud soon turns to dust and blows away.

Conservation of water power means its use. Every drop that flows to the sea is just that much power lost forever.

Have you noticed that some men are always so busy that it is a wonder they can find time to sleep and eat?

Investors in water-power developments want to know what the Government will do with their property at the end of a limited franchise.

A man may have knowledge, but lacking energy will not amount to anything.

An engineer cannot get experience for nothing; it must be paid for.

Refrigeration Department

Principles and operation of ice making and refrigerating plant and machinery

With this issue we start a refrigerating department. Hitherto, we have published miscellaneous articles at odd intervals, but have decided that the subject is of enough importance to our readers to give it a definite location in the paper. From now on this department will appear every second issue. Contributions on the practical operation of refrigerating machinery and apparatus are especially solicited, and will be received as a token of the interest taken in the department.

The Specific Heat of Calcium Chloride Brine

By H. G. Fairview

The true specific heat of brine is often of great value in determining the performance of refrigerating machinery. It is a well known fact that the specific heat of water is not constant but varies with the temperature; and the use of steam tables, in which this variation is taken into account, for finding the "heat of the liquid" at any temperature is familiar to all engineers. The steam tables are calculated for pure water, the specific gravity of which is unity.

If a salt, such as calcium chloride, is added to the water the solution is known as brine, the specific heat of which varies not only with the temperature but also with the density; the denser the solution the less the specific heat. A dense solution is one containing a large amount of salt, that is, one having a high specific gravity. This variation with two quantities makes the task of preparing a comprehensive table of specific heats more complex because of the large number of brine densities that are in common use. So far as the writer knows there was not until quite recently any effort made to prepare such a table.

While doing some experimental work with a refrigerating plant a little more than a year since, it was necessary to know the specific heat of the brine accurately in order to make a heat balance for the system. A careful search failed to reveal anything more extensive than the well known tables of Landolt and Börnstein, giving the specific heat of various brine solutions at from 30 to 64 degrees Fahrenheit, but without any statement as to the variation with the temperature. All other available tables gave the specific heat at about the same temperature, and moreover the values did not show good agreement besides being for temperatures much above that of the test.

The only apparatus available at the time for finding the specific heat was a Parr coal calorimeter. The determinations were made with this, using standard benzoic acid of known heating value as the source of heat. At that time plans were made to go into the work more fully, and to use Dewar flasks instead of the calorimeter in order to reduce the radiation loss, and an electric heating coil instead of the benzoic acid. The Dewar flasks were purchased, but before the work was begun the Bureau of Standards published a bulletin on "The Specific Heat of Some Calcium Chloride Solutions Between − 35 degrees Centigrade and + 20 degrees Centigrade," giving the desired information in detail. The work was very carefully done by an electrical method, with all possible refinements, and the values may be taken as correct.

The results are presented both in tabular and graphical form for the various solutions. And further to make the results apply to all possible densities the authors have deduced the following empirical formula which represents their results to within 0.1 per cent.

$$D = 2.8821 - 3.0272\,S + 1.7794\,S^2$$

D = Density at 20 degrees Centigrade or 68 degrees Fahrenheit;

S = Specific heat at 0 degrees Centigrade or 32 degrees Fahrenheit.

For each degree Centigrade change in temperature the specific heat changes by an amount varying from 0.0006 to 0.0009, the usual value being between 0.0006 and 0.0007. In all cases the specific heat decreases with the temperature; the correction value 0.0009 applies only to brine of density 1.200 at temperatures below − 10 degrees Centigrade.

It is interesting to compare the results given by this equation with that obtained with the Parr calorimeter. The mean of two calorimeter determinations for brine of density 1.244 gave the value of the specific heat as 0.6944. Applying the formula to the same solution and solving:

Sp. Ht. at 0° C. = 0.7068

Making the proper temperature correction to change to 0 degrees Fahrenheit,

Sp. Ht. at − 17.7° C. = 0.6949

The difference between the two results is 0.0005, a percentage difference of 0.07 per cent. This is a remarkable agreement when one considers the practical difficulties of making such determinations at low temperatures. The equation gives equally as good results at higher temperatures. From Landolt and Börnstein's tables for a density of 1.231 at 60 degrees Fahrenheit, the specific heat is 0.700. Using the above equation the result is

Sp. Ht. at 0° C. = 0.6850

Applying the temperature correction,

Sp. Ht. at 60° F. = 0.6968

It is well at this point to call attention to the fact that the Bureau of Standards' values are slightly lower than Landolt and Börnstein's and differ considerably from some commercial tables.

The above formula was deduced for chemically pure calcium chloride solutions, but the experimenters found that the specific heats of various commercial solutions differed from that of the chemically pure by less than 0.3 per cent, being in some cases higher and in others lower; so that for practical purposes the formula may be safely used, and may be expected to give more reliable results than a direct determination because of the difficulty of making the latter at low temperatures. The formula is convenient, as it needs to be solved only once for each density.

In applying the formula the following points should be kept in mind:

First: Determine the density at or near 20 degrees Centigrade (68 degrees Fahrenheit).

Second: The equation gives the specific heat at 0 degrees Centigrade (32 degrees Fahrenheit).

Third: That this result must be reduced to the desired temperature conditions as before noted.

The importance of determining the density at the proper temperature is shown by the following table, showing the variation of density with the temperature:

Problem in Refrigeration

By F. E. Matthews

How much refrigeration will be produced by the circulation of 50,000 *cubic feet of brine per month, the average temperature going out being* 28 *degrees Fahrenheit and that of the return* 32 *degrees?*

The amount of cooling that a given quantity of brine will do depends not only upon the number of degrees rise in temperature, but upon the density and kind of brine. As the problem does not state whether the brine used is calcium or salt or what its density is, it may be well to show how the problem is solved in the general case and illustrate by taking a single example based on assumed conditions.

The most important element in the selection of the kind of brine to use is the temperature to be produced, which fixes the temperatures at which the brine must be circulated. Saturated salt brine, by which is meant brine so strong that it will dissolve no more salt, freezes at about 5 degrees Fahrenheit below zero and would be safe for brine-tank temperatures above zero. Salt brine of lower densities freezes at correspondingly higher temperatures, the limit being reached when the amount of salt is reduced to nothing in which case the brine becomes water and freezes at 32 degrees Fahrenheit.

Saturated calcium brine freezes at about 55 degrees Fahrenheit below zero and according to its densities is adapted to brine temperatures from 40 degrees below zero up. The specific heat of either salt or calcium brine upon which depend their refrigerating capacities per pound per degree rise in temperature, decreases as the strength increases.

The refrigerating capacity of water per pound per degree rise in temperature is one British thermal unit. As salt or calcium chloride is added to the water this value decreases until its value at saturation (maximum strength) is only 0.77 B.t.u. In the latter case, about 30 per cent. more brine must be circulated, to accomplish a given amount of cooling for a given rise in brine temperature, than would be necessary were the desired temperatures sufficiently high to allow water to be employed as a medium for conveying heat, instead of brine. Tables showing the properties of salt brine and calcium brine are published in almost every handbook on mechanical refrigeration as well as in many ice-machine catalogs.

The unit by which cooling effects are measured is the ton of refrigeration. This is equal to the amount of cooling produced by the melting of one ton (2000 pounds) of ice having a latent heat of fusion of 144 B.t.u. per pound. Cooling at the rate of one ton per day would amount to the extraction at a uniform rate of

$$2000 \times 144 = 288{,}000 \ B.t.u.$$

per 24 hours;

$$288{,}000 \div 24 = 120{,}000 \ B.t.u.$$

per hour or

$$288{,}000 \div (24 \times 60) = 200 \ B.t.u.$$

per minute.

The amount of refrigeration, expressed in tons T per 24 hours, produced by a rise in temperature from t_1 to t_2 of a certain number of pounds p of brine circulated per minute and having a specific heat s, would be,

$$T = \frac{S\,(t_1 - t_2) \times p}{200} \qquad (1)$$

If p represents the number of pounds of brine circulated per hour, or per 24 hours, the expression would be the same except the constant 200 would be replaced by 12,000 and 288,000 respectively.

The circulation of 50,000 cubic feet of brine per month is equivalent to

$$\frac{50{,}000}{30 \times 24 \times 60} = 1.157 \ cubic\ feet$$

per minute. Assuming that it has the specific gravity commonly employed of 1.2, its weight per cubic foot will be

$$62.5 \times 1.2 = 75 \ pounds$$

or

$$75 \times 1.157 = 86.775 \ pounds$$

will be the amount circulated per minute under the given conditions. The rise in temperature as given in the original problem was from 28 to 32 degrees Fahrenheit and the specific heat of brine having a specific gravity of 1.2 is 0.7. Substituting these values in formula (1)

$$T = \frac{0.7\,(32 - 28) \times 86.775}{200} =$$

$$\frac{242.97}{200} = 1.2148 \ tons$$

A rough rule for calculating the number of tons of cooling effect produced by brine is to allow 25 heat gallons per minute per ton. Apply this rule to the foregoing case as follows: Since 1 cubic foot equals 7.48 gallons, 1.157 cubic feet equals 8.654 gallons and the rise in temperature is 4 degrees Fahrenheit. Hence,

$$8.654 \times 4 = 34.617 \ heat\ gallons$$

which is equivalent to

$$\frac{34.617}{25} = 1.38 \ tons$$

an amount somewhat larger than that given by the regular formula.

The percentage of saturation or the specific gravity having been determined, a table, giving the properties of the kind of brine employed, may be referred to and the specfic heat, corresponding to that density, found. Also the weight of the brine per gallon may be found and from this may be calculated the weight of brine circulated per minute. These quantities should then be substituted in formula (1) and the result will be the required cooling effect expressed in tons per 24 hours.

This approximate rule is intended to apply roughly to brines of the higher densities and, since it does not take into consideration possible variations in the value of the specific heat of the brine, it cannot be expected to apply accurately to brines of all densities. For example, according to formula (1) the amount of refrigeration produced by the circulation of 200 pounds of water per minute with a rise in temperature of one degree Fahrenheit would be

$$T = \frac{1 \times 200 \times 1}{200} = 1 \ ton$$

According to the rule, which ignores the specific heat of water, which is unity, the cooling effect would be, since 200 pounds of water is equivalent to 24 gallons,

$$\frac{24}{25} = 0.96 \ ton$$

For accurate determinations of the cooling effect the density of the brine should be determined by either a salonometer or some other form of hydrometer that will allow either the percentage of saturation or the specific gravity of the brine to be determined. In taking such hydrometer readings care should be taken to bring the temperature of the brine to that at which the instrument is calibrated. This method is less likely to lead to error than that of applying a correction factor for reducing the readings taken at other temperatures to what they would be if taken at the standard temperature.

Device for Charging an Absorption Ice Machine

By T. H. De Saussaure

It is often difficult to make a pump take suction from a drum of aqua ammonia when it is desired to add to the charge of an absorption ice machine while it is in operation. This is particularly true when the ammonia in the drum is warm, as the gas given off destroys the vacuum in the suction pipe, and the pump will not lift the ammonia.

Having a machine which required constant additions to the charge, I devised the following arrangement, which makes the operation a very simple and sure one.

I first built a substantial table large enough and strong enough to sustain the weight of a drum of ammonia, and placed upon the top of this table four friction rollers, as shown in Fig. 1. The rollers are each made of oak, 8 inches in diameter, and have a piece of 1-inch round iron through the center for the axle. When mounted on these rollers the drum is on a higher level than the pump, and can be easily rolled over until the bung is on the under side.

I then took a piece of 3½-inch wrought-iron shafting, 4 inches long, and turned and threaded it so that it could be screwed into the bung hole of the drum. Through this plug I made an opening for a suction pipe and another for an air pipe, Fig. 2. The air pipe is made of ⅛-inch wrought-iron pipe and is of such length that it will reach to within 1 inch of the side of the drum diametrically opposite the bung plug when the latter is screwed to a joint in the bung. Both the suction-pipe connection and that of the air pipe have valves on them, placed near the plug.

When it is necessary to add to the charge of ammonia in the machine the fresh drum is placed on the table and the new plug, with both air and suction

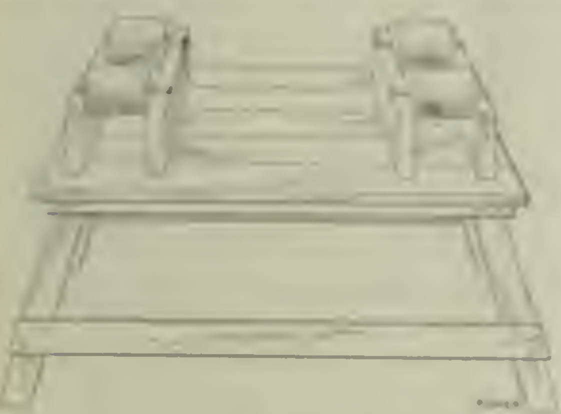

FIG. 1. BENCH FOR HOLDING AMMONIA DRUM

valves shut, is used in place of the one usually sent. The drum is then turned on the friction rollers until the bung is on the bottom. Connection is then made between the suction opening on the bung plug and that of the ammonia-circulating pump, and between the air pipe on the bung plug and the discharge opening of an ordinary plumbers' force pump. About five pounds of air pressure is pumped into the drum with the force pump; then the valve on the suction pipe is opened and the pump takes suction immediately.

FIG. 2. ARRANGEMENT OF PIPING TO PUMP

I have never had it fail in several years' use. It is necessary to keep a slight pressure in the drum so that the air may take the place of the ammonia pumped out.

The objection might be raised that there is danger of getting a quantity of air into the machine after the ammonia is all pumped from the drum; but if the ear is held against the head of the drum while the pumping is being done, one can detect the instant when the last drop of liquid is pumped out and the suction valve can be shut immediately.

The device has this advantage also—one can get the last drop of ammonia out of the drum and into the machine without any waste at all.

LETTERS

Fitting a Gasket on Compressor

Gaskets for the head of the ammonia cylinder of a vertical ice machine often cause trouble when not put on properly. The gasket frequently blows out into the water jacket or into the cylinder, specially where a pressure of 160 to 180 pounds or perhaps higher is carried. In nine out of ten cases the gasket gives out on the discharge side.

When a gasket is put on as illustrated, it will hold if the surfaces of the cylinder flange and the head are smooth. The old gasket should be scraped off on both surfaces, and to remove the grease use a clean cotton or linen rag (no waste) moistened with coal oil. Then take another clean rag and wipe off the coal oil.

The best rubber available should be used and it should not be thicker than

GASKET FOR AMMONIA CYLINDER

1/10 inch. The gasket should be cut accurately and the holes must fit snugly over the studs. The edges of the gasket where it is cut out for the suction and discharge should lap a little over the openings. No graphite or oil should be used on the gasket or metal surfaces, so that the gasket will not slip when tightened. It is very important to see that the nuts are tightened evenly. They should be tightened up with the fingers first and then with the wrench, starting with one nut and then following up on the nut diametrically opposite. It is a good plan for two men to do the tightening on the first six nuts. Then one wrench should be used by the two men to complete the job, starting on one nut and going all the way around.

Once I had a machine on which no gasket would hold tight. It was always blown out into the cylinder, no matter how carefully it was put on. A small groove was cut around the discharge opening, as indicated in the drawing, which proved to be a success. If a gasket blows out into the cylinder the defect may be detected by a sharp blowing noise, a hot suction pipe and an unusually high back pressure.

When the head of an ammonia cylinder, where no graphite was used, has to be taken off and a chain fall will not do the trick, loosen the nut at the crosshead and screw the rod out about three or four turns; then turn the engine over by means of the starting bar and the head will be forced off.

WILLIAM L. KEIL.

Philadelphia, Penn.

Connecting Ammonia Compressor

In answer to H. S. Free in the March 21 issue, I would advise the following:

In the first place, he does not state the combined capacity of both condensers, which would assist in explaining what is best to do.

First of all, a 2-inch pipe for a discharge on a 50-ton machine is too small; it should be at least 3 inches. The 25-ton machine should have a 2½-inch discharge pipe. The total area of these two pipes would be over 12 square inches, so it is plain that all the gas from the two compressors cannot pass through the one 2-inch three-way valve. It is ridiculous to attempt such a thing. It would be advisable to connect both condensers with a bypass so that either or both combined could be used for either compressor. But by all means increase the size of the discharge pipe from each compressor to the condenser and make a 2½-inch bypass at a convenient place, with as few elbows as possible. The three-way valve would do in the bypass if your employer will not allow the expense of a larger one.

WILLIAM NOTTBERG.

Kansas City, Mo.

A recent issue of the *Brass World* contained a simple method for removing rust from surfaces that were afterward to be electroplated, but the method might be applied equally well to other rusty surfaces. It consists in dipping the articles first into a strong, hot potash bath for about half an hour, and then immersing in a cold muriatic-acid pickling solution, composed of two parts of water to one of acid. This removed the rust in a few minutes, leaving the metal apparently attacked but very little. The previous soaking in the strong, hot potash solution is responsible for this rapid pickling, as it was proved that without the previous dipping 40 minutes were required by the acid bath, against four minutes when previously treated in the potash bath. Apparently a chemical reaction is set up, changing the character of the rust, softening it and making it readily soluble. The appearance of the rust as it comes from the potash bath is swollen or fine.

Handling Coal in a Modern Boiler Room

Probably no two boiler rooms in modern buildings present quite the same problems for solution. Conditions of location, space and requirements are such widely varying factors that the engineer is constantly called upon to devise new methods of adapting modern devices to suit his precise needs and yield the highest efficiency.

An ideal system would enable the coal to be dropped into the bunkers direct from the car or lighter, and fed to the grates without rehandling. This is manifestly impossible in any modern city building—or indeed in any but a few boiler rooms enjoying an exceptionally favorable situation.

An interesting solution of a-coal-handling problem is found in the new Fifth Avenue building at the corner of Twenty-third street and Broadway in New York City.

Fig. 2. Hoist Picking Up Ash Can

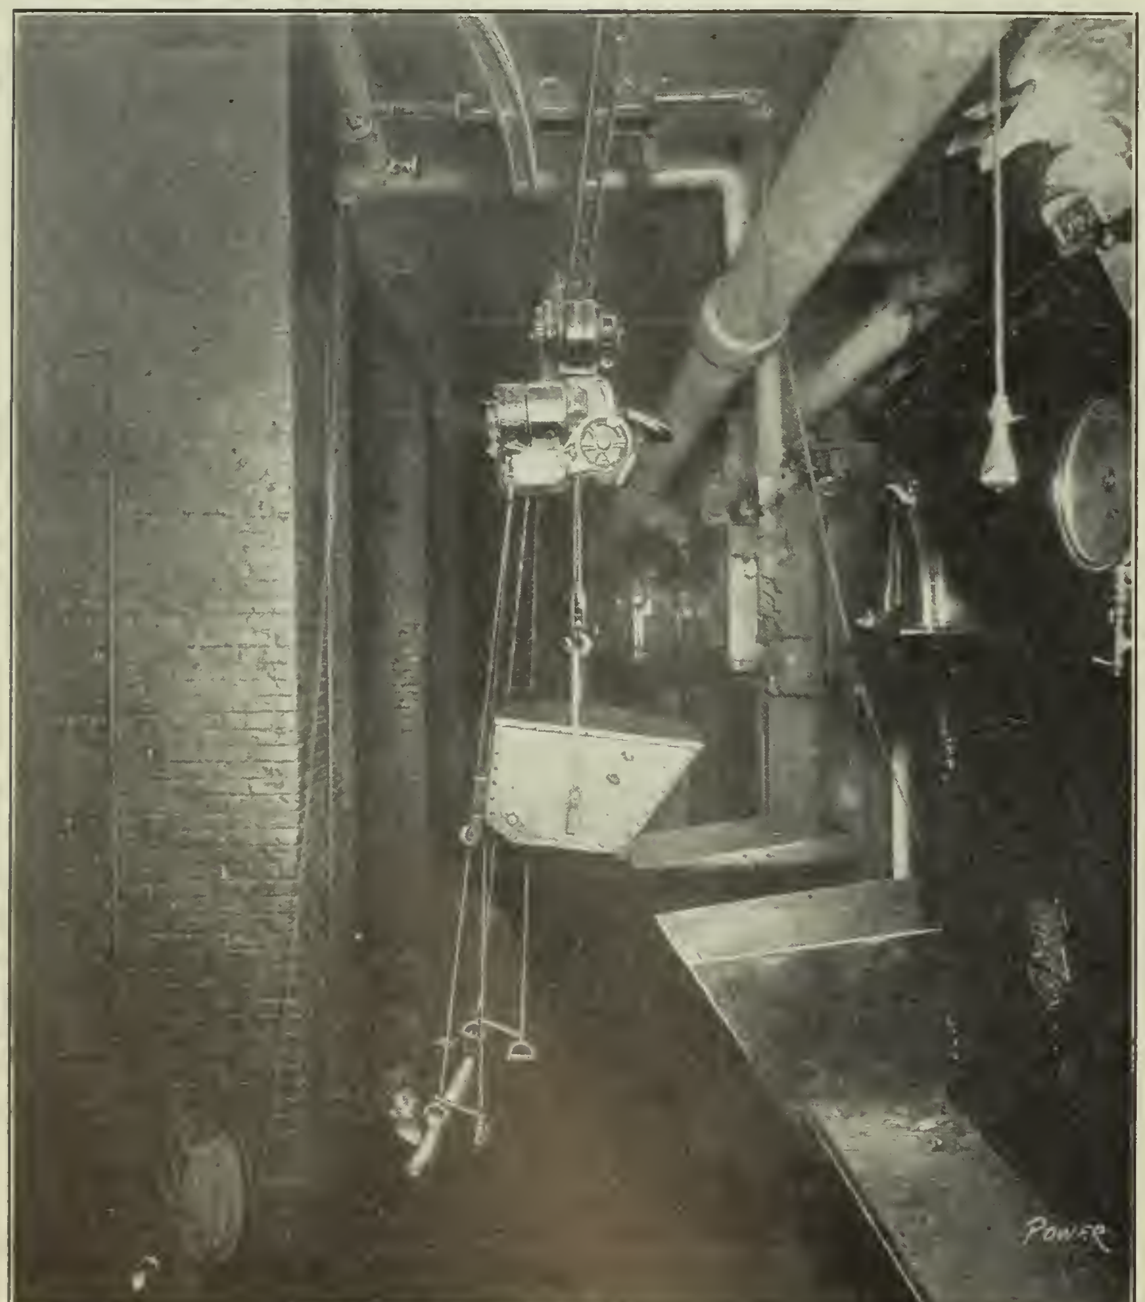

Fig. 1. Yale & Towne Hoist and 600-pound Coal Bucket

The boiler room is located three stories below the street level and the coal supply is carried in bunkers, which are as favorably located in relation to the boiler room as the general conditions will permit.

There are 2000 horsepower of Heine boilers, equipped with automatic stokers. The transfer of the coal from the bunkers to the hoppers of the stokers is effected in this instance in iron buckets holding about 600 pounds. These buckets are hung from the hook of a Yale & Towne electric hoist, which in its turn is built into a trolley running on an overhead track leading from the bunkers to the hoppers of the various stokers.

In operation, the buckets are lowered to a point opposite the mouth of the bunker chute to permit the coal to flow into them by gravity from the bunkers. A pull on the switch then starts the electric hoist and the bucket is lifted high enough to enable it to start on its journey to the hoppers of the stokers.

This journey, accomplished by means of a smaller motor (attached to the trolley) which is geared to and drives the trolley wheels, is made in a few seconds, and the coal is then dumped into the hoppers of the stokers.

A switch in the overhead track enables the hoist to be run to a point where it can pick up the ash cans.

The whole electrical installation is under the control of the operator. The hoist will raise or lower the bucket by fractions of an inch, if necessary, and the load is automatically held at all times. The control of the trolley motor is also quite as complete, and the load may be advanced or withdrawn at will.

The hoisting problem in this case is not in itself particularly difficult, but the conditions under which the hoist operates are severe. The temperature at the top of the boiler room probably averages 135 degrees and a considerable amount of dust and fine particles of coal is naturally present. Up to the present writing the hoist has continued to perform its work satisfactorily, and no diminution in efficiency has been apparent.

It is reported that the New York, New Haven & Hartford railroad is equipping a number of its locomotives with oil burners. Oil has been used successfully and with considerable saving by a number of railroads in the Southwest, but the relatively high cost of this kind of fuel in the central Atlantic and New England States has been largely responsible for its limited use. Undoubtedly the locomotive, where, due to the excessive draft, a large percentage of the coal goes up the stack, furnishes an attractive field for the application of oil fuel.

The Thomas Electric Gas Meter

Some time since Prof. Carl C. Thomas, now of Madison, Wis., made, at Schenectady and later at Sibley College, some experiments upon the specific heat of superheated steam, the results of which were given in a paper presented by him

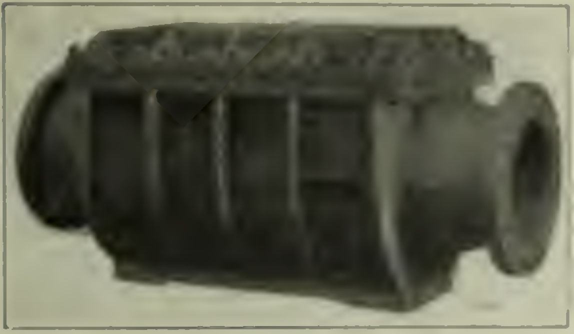

FIG. 1. CASING FOR THOMAS METER

to the American Society of Mechanical Engineers in 1907 and published in Volume XXIX of the *Transactions*. The method was to pass steam, known to be dry, through an electric heater, and to note the amount of current necessary to raise its temperature an observed amount. The weight of steam treated was determined by condensing and weighing it. Reducing the electrical energy to its equivalent in heat units, and knowing the weight of steam heated and the number of degrees its temperature was raised, it was a simple matter to compute the amount of heat necessary to raise one pound one degree on an average for the observed range.

Later Professor Thomas reversed the process and produced a meter for gases which was described in a paper presented by him to the Mechanical Engineers in 1909 and published in Volume XXXI of the *Transactions*. If the specific heat of a gas is known, the weight passing through the device can be determined by measuring the electricity necessary to heat it a given amount; that is, by ascertaining the increase in temperature produced by a known amount of energy. Reducing the measured current to its heat

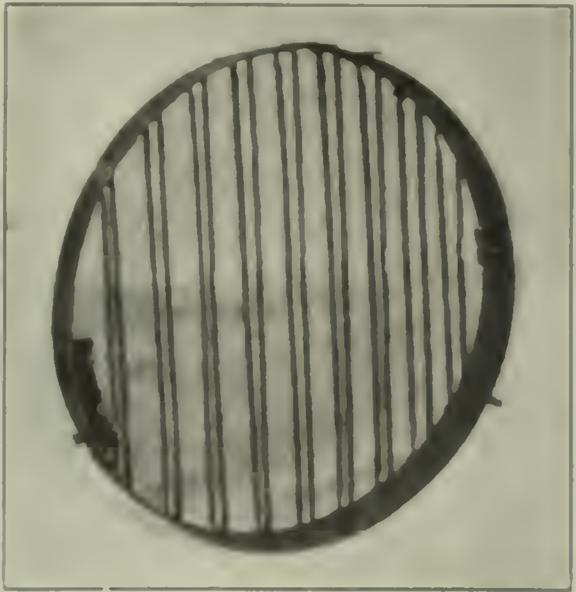

FIG. 3. SCREEN OF RESISTANCE WIRE FORMING THERMOMETER

equivalent gives the B.t.u. expended and knowing the number of B.t.u. necessary to raise one pound of the substance one degree the determination of the number of pounds necessary to absorb the observed amount of heat when heated through the observed range is a matter only of simple division. In the commercial form of the meter this process is automatically carried out in such a manner that the record, either indicating, graphically recording, or integrating, reads directly in "standard cubic feet" of gas per unit of time.

In the latest form of the meter a constant temperature rise of about two degrees Fahrenheit is preserved, and the regulating mechanism necessary to effect this as well as the perfection of recording mechanism brought it within the field of the Cutler-Hammer Manufacturing

FIG. 4. HEATER LOCATED IN METER CASING SHOWN IN FIG. 2

Company, of Milwaukee, which is putting it upon the market.

The meter proper, as they make it, is shown in perspective in Fig. 1 and diagrammatically in Fig. 2. A meter having a 10-inch outlet will take care of 750,000 cubic feet per hour.

The thermometer consists of a continuous length of very fine nickel wire, the electrical resistance of which varies considerably with its temperature. This is carried back and forth in parallel lines across a circular frame as shown in Fig. 3, and bound by silk threads crossing it at right angles. One of these thermometers is placed at the inlet and another at the outlet end of the meter. Between them is placed a heater, shown diagrammatically in Fig. 2 and in perspective in Fig. 4. This is simply a resistance coil wound upon a [illegible] frame so that all the gas passes over a heated wire. The thermometers form the two sides of a Wheatstone bridge and the current is regulated so as to maintain a constant temperature difference between them in the manner shown diagrammatically in Fig. 5. The controller is, in effect, a galvanometer and Wheatstone bridge combined. The movable member is caused to swing to the left or right

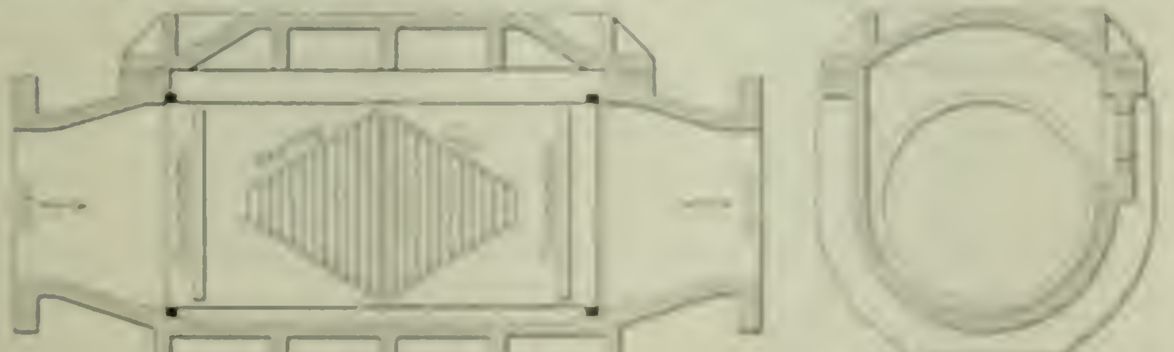

FIG. 2. SECTIONS OF METER CASING, SHOWING POSITIONS OF HEATER AND THERMOMETERS

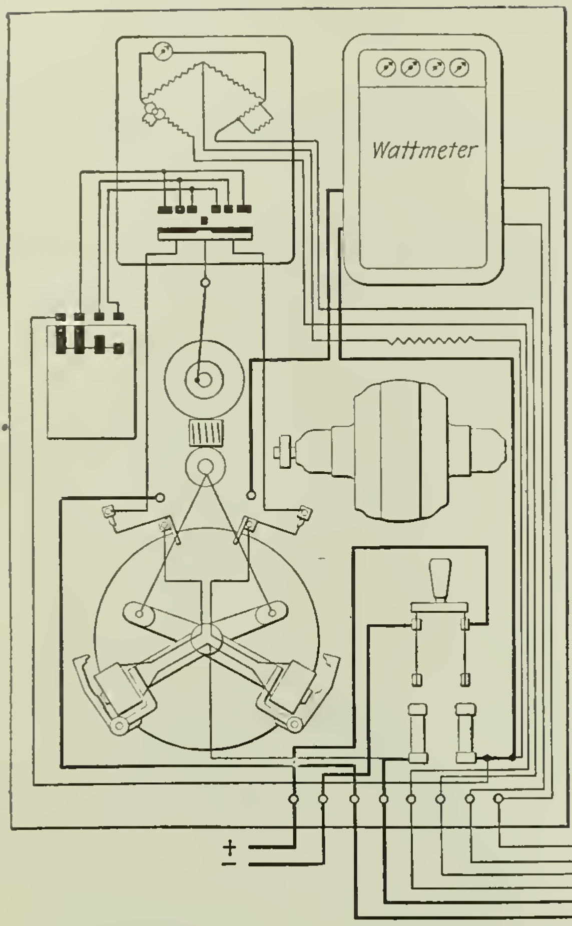

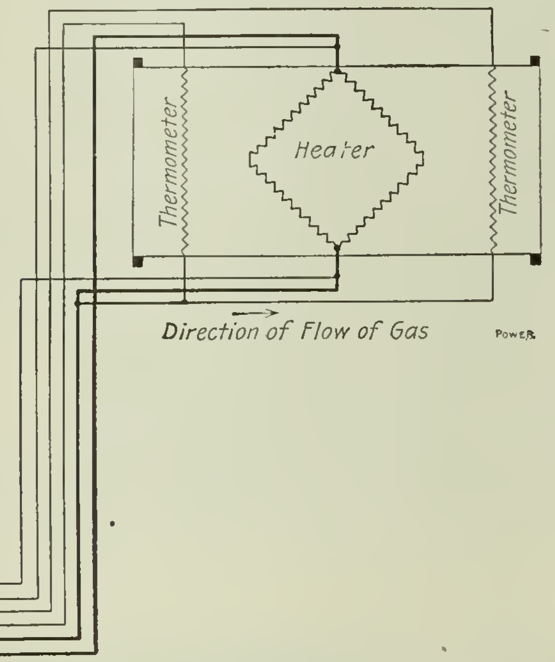

FIG. 5. DIAGRAM OF ELECTRICAL CONNECTIONS OF THOMAS METER

of a fixed position according as the difference in resistance of the thermometers is greater or less than that corresponding to the desired temperature difference of two degrees between the inlet and outlet of the meter. The motor (1/8 horsepower) operates continuously, and by means of a crank causes a bar to move up and down, clamping the needle at the top of the stroke. It also drives, at a slow but constant speed, a contact drum and two eccentrics which give the rheostat pawls a reciprocating motion through a small arc along the edge of a toothed wheel on the rheostat shaft. On the drum are three segments of different lengths corresponding to one, two and three teeth on the wheel. If the needle is clamped in position on the right of the zero position the solenoid on the pawl which will turn the rheostat in the direction to increase the heater energy is energized and holds the pawl up long enough to move the wheel one step and it will continue to do this until by successive strokes the rheostat has been turned enough to restore the desired temperature difference and thus balance the system. A very slight fall of temperature in the gas will cause it to do this. When the temperature difference is restored the needle returns to zero, makes no contact when it is clamped and the rheostat remains stationary. If the temperature difference increases above two degrees the needle swings to the left of the zero mark and the same process works to reduce the current. The wattmeter in the upper right-hand corner shows the energy which has been used to heat the gas, which is proportional to the amount flowing, so that the wattmeter may be made to read in any units. A graphical wattmeter may also be used to show the variation in gas flow. The appearance of the board carrying the regulating and recording mechanism is shown in Fig. 6. It need not necessarily be located near the meter but may be in the manager's office or at any convenient point.

When the physical condition of the substance measured does not change by reason of the heating, as by the drying out of moisture, and when the specific heat is known the meter would seem to promise a solution of the difficult problem of measuring gas and air in large quantities with considerable accuracy. When the material contains moisture it is suggested that a drier consisting of a steam coil be used just before the meter. With regard to measuring saturated steam the uncertainty of complete dryness and the serious effect of the absorption of heat in evaporation, may complicate its use as a steam meter, for which indeed, we do not know that it is intended. Superheated steam can, however, be successfully measured by a meter of the kind described. For a stable substance like natural gas with a practically constant specific heat it has been doing excellent work for some time. For artificial gas and other products occasional analyses will enable the specific heat to be determined with sufficient accuracy for commercial purposes.

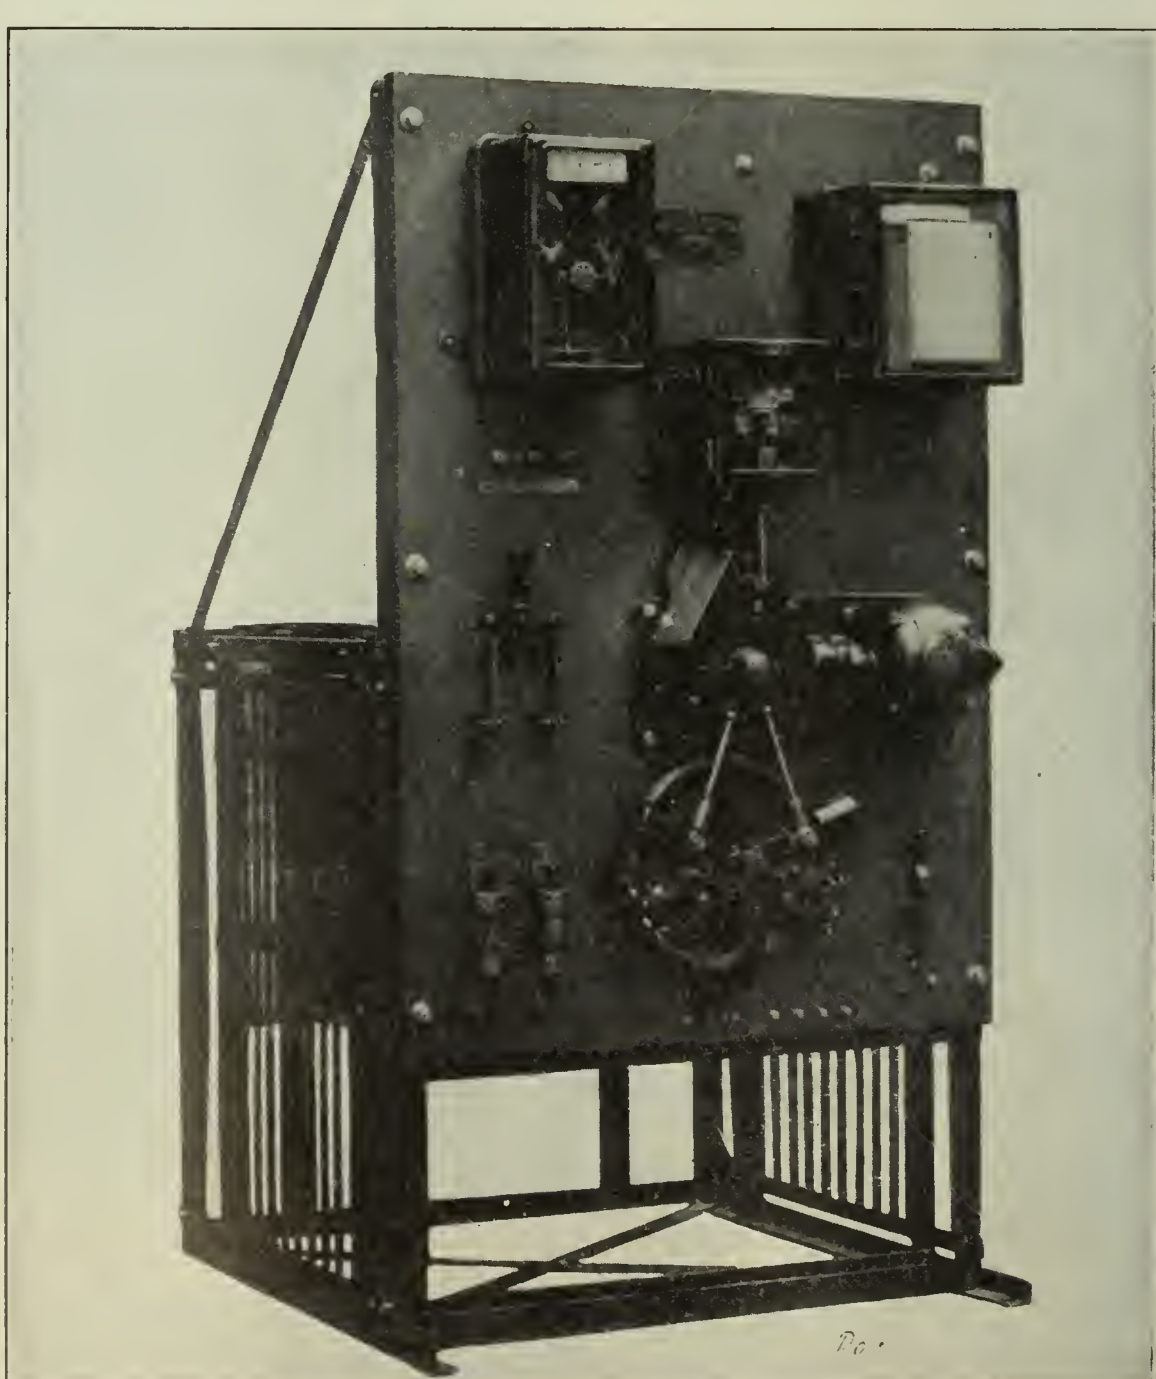

FIG. 6. SWITCHBOARD AND RECORDING INSTRUMENTS FOR THOMAS METER

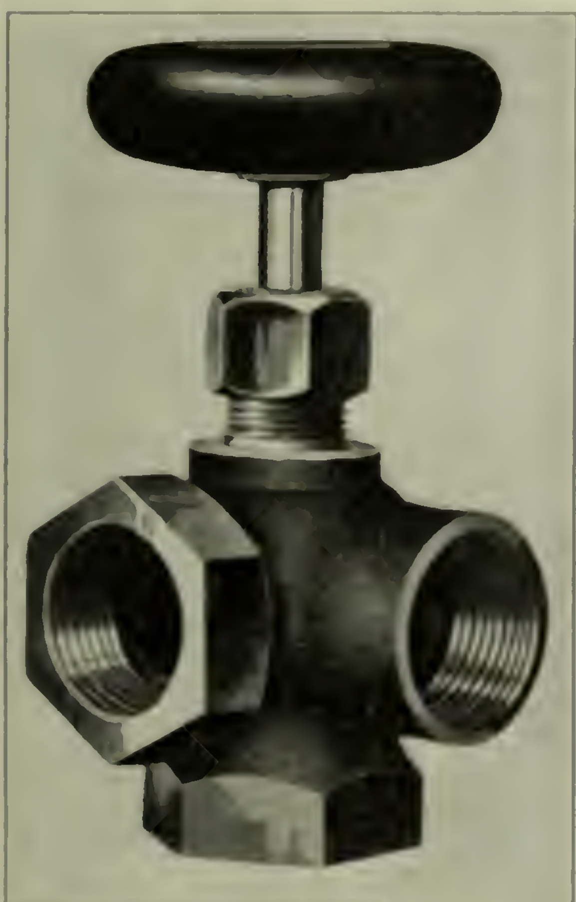
Detroit Three Way Valve

The accompanying illustration shows the Detroit quick-opening three-way valve, which is used on water-cooled gas and gasolene engines to turn the necessary amount of water into the water-cooled muffler or exhaust, after it has passed through the water jacket on the cylinder, and has turned the rest of the water to waste.

This valve permits any quantity of water to be diverted into the muffler by a slight turn of the indexed valve handle. All the rest of the water goes to waste without any further regulation.

The valve consists of a globular body with three openings, one at the base through which the water enters and two



Detroit Three-way Valve

at the sides, at right angles to each other. The shell is so arranged that all of the water coming up through the opening in the base can be turned through either one of the side openings or it can be graduated to divert any required volume of water through either of the openings and turn the rest through the other hole. The handle is indexed and shows what proportion of water is wasted.

The valve is manufactured by the Detroit Lubricator Company, Trumbull avenue, Detroit, Mich.

The blowing off of a cylinder head at the works of the Hope Webbing Company at Pawtucket, R. I., on the afternoon of April 15, caused two men to be painfully, if not seriously, scalded. The peculiar feature about the accident is that the steam was shut off at the time.

Fatal Tube Blowout in Winsted, Conn.

By George L. Strait

A fatal accident occurred at the woodworking plant of J. H. Rowe in Winsted, Conn., on Saturday, April 15. The owner, Mr. Rowe, sustained severe injuries and lived only a few hours. The cause of the accident was a defective tube. The boiler is of the locomotive type, having sixty 3-inch tubes, and is used for heating the shop and dry kiln, and carried from 40 to 50 pounds gage pressure. It has been in the Rowe plant for 18 years and was an old boiler when installed. Upon examination it was found that four tubes in the bottom row and two in the second row from the bottom were stopped with pine plugs which had been driven in with no rod running through the tubes to hold them in place. The stem on the handhole plate was badly corroded and looked as if it had not been taken out in years. The safety valve was of the ball and lever type, and an effort to raise it showed that it was stuck fast. I learned from an employee at the plant that the boiler had never been cleaned to his knowledge since being installed.

It is the writer's impression that there was from 6 to 8 inches of mud in the bottom as this could be seen from the place where the defective tube burst. The ends of all the tubes in the two bottom rows were corroded so that they could easily be broken off with a hammer. From all reports the boiler had never been inspected.

Mr. Rowe was fixing up the fire for the night when the accident occurred. The door in front of the boiler room was closed so that he could not escape that way on account of the steam and hot water; he finally got out through a window and his cries attracted a passerby who came to his assistance.

This is another case of negligence on the part of owners and operators of steam plants. The laws of Connecticut are very lax in this respect; there is no law requiring experienced men to be employed in caring for steam plants, although there is a bill before the present house of representatives which, if passed, will in a measure remedy this deficiency.

A 110-foot steel smokestack in course of construction at the factory of the Keyes Products Company at Mansville, Conn., collapsed on Saturday, April 15, as the third section was being raised into position. The tackling appears to have slipped in some manner, allowing a piece of steel weighing several tons to fall and crash through the roof of the mill building below. Fortunately no one was hurt although several workmen had narrow escapes.

SOCIETY NOTES

At the last meeting of the executive committee of the Institute of Operating Engineers, Hubert E. Collins was elected secretary in place of M. W. Rice, resigned. W. P. F. Hill was elected treasurer in place of Adam Harkness, whose term had expired.

J. B. Linbrey, secretary of the Practical Refrigerating Engineers Association, with headquarters in Shreveport, La., reports that the growth of the association since its organization last December has been phenomenal and has far exceeded the most sanguine expectations. The association is composed of white refrigerating engineers of good moral character, who have had one or more years' experience in operating ice and refrigerating plants.

Several important papers on "Patents" will be presented at the New York meeting of the American Society of Mechanical Engineers, 29 West Thirty-ninth street, on Tuesday, May 9. The subject will be discussed by E. W. Marshall, D. Howard Haywood, Edwin J. Prindle, all of New York. The purpose of this meeting is to outline to the engineer and manufacturer the fundamental principles of the patent law, the position and qualifications of a patent expert and the industrial development for the purpose of establishing a patent monopoly.

PERSONAL

Frank B. Davenport, who has been employed by the G. B. Markle Company in the mechanical department to design a new breaker at Hazleton, Penn., resigned recently to open a consulting engineer's office in Wilkes-Barre, Penn.

Moments with the Ad. Editor

A department for subscribers edited by the advertising service department of Power

The other day the Chief Engineer of an electric light and power plant in Iowa wrote to the editor of POWER for some information on recording instruments.

"Would it pay," he asked, "to install a recording thermometer on the feed-water line, a recording pressure gage, a recording flue-temperature instrument, a CO_2 recorder, recording switchboard instruments, recording pressure gage on an exhaust-steam heating system, etc.? I am in favor of such instruments, but only want such as will warrant the investment and must be able to prove same to my company before they can be had.

"Would like to get opinions as to what instruments we need and don't need, and why."

To which the editor replied: "Whether the purchase and installation of the various recording instruments named in your letter will 'pay' depends entirely upon how much you wish to know about the conditions obtaining in your plant.

"Unless your plant is being operated under exceptionally good conditions, a CO_2 recorder will, if the records are intelligently read and appreciated, save its price in a very few weeks.

"The charts from recording instruments of all kinds make a daily history of the plant and are often used to show whether one set of men is doing as well as, or better, than another, and to excite a spirit of emulation which will put every man on his mettle to do as well as possible.

"In short, if you have any desire to keep your plant at or near the head of the list of uptodate plants, recording instruments are a necessity."

Here is the case of a man who didn't realize the value of reading and acting upon the ads in the paper.

If he had read them he wouldn't have needed to write the letter—he would have learned much more about recording instruments from the ads—and from the advertisers' own printed matter than our editor could tell him in a letter.

And this is a good example of just what we are trying to teach in our own weekly talks on this page.

There are many engineers who want who really need information on some kind of power-plant equipment or other, and it doesn't occur to them that they have a veritable encyclopedia of just that information coming to them every week in the Selling Section of POWER.

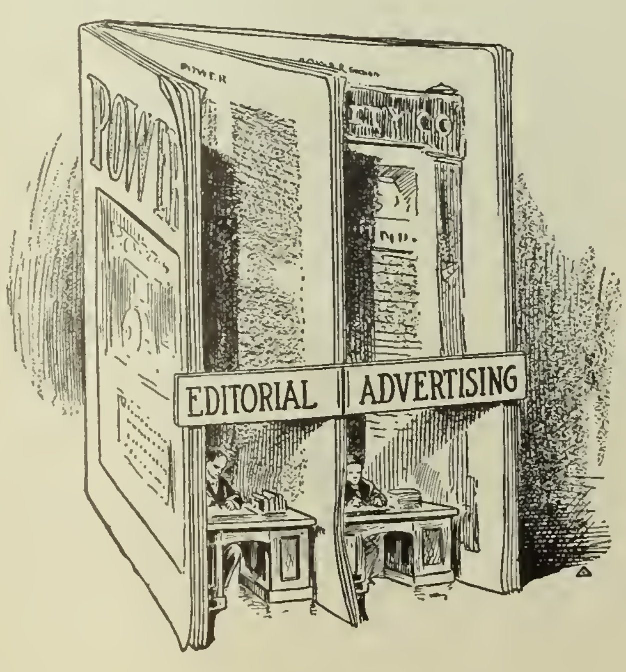
For of course the very best information possible on everything for the power plant is printed in the advertising pages.

The manufacturers rely on their ads to explain their products and all their features, advantages, savings, etc., to the readers—who are possible buyers.

What they cannot tell in the ads they put forth in booklets, catalogs and letters, which are sent to any reader on request.

Where else could you hope to get as complete details and information?

The engineer whose letter we have quoted is the right sort—he wants to know about any device that will help him get better results for his employers—he is worth every cent of his salary, for he's not content to stand still.



But—he will find that the grand parade of Progress doesn't stop with the reading pages of POWER. The reviewing stand is located in the advertising section and he—and all of you—want to book a seat in the front row where you can see all that's going on in the fast-moving march of the aforesaid procession.

The advertising pages are the heralds of Progress. Read them and heed them.

POWER

NEW YORK, MAY 9, 1911

AMBITION is, in all cases, the mainspring of the action which leads to success, and nothing worth while is ever accomplished without it.

There are instances of the peculiar fitness of some men for particular lines of work. The accomplishments of these men are often labeled the work of geniuses. But upon even superficial examination it is found that their achievements are the results of persistent effort.

Genius has been characterized by someone as nothing beyond a capacity for hard work.

In the everyday life of the engineer may be found almost numberless illustrations of this. Among the employees about the power plant of a large cotton mill in New England some years ago, there was an undersized and rather frail young man wheeling coal from the yard to the boiler room. Thinking little or nothing of the man except that to all appearances he was a misfit for the job, the chief engineer suggested that he try to get work in the weave shed as it was perhaps more suited to his physical strength.

Answering the suggestion the young man said: "I am well satisfied at present, although the work is near the limit of my strength, but I do not intend to be a coal passer all my life. I expect to be the chief engineer of this mill, or a bigger one, perhaps, so it will not hurt me to know how coal should be handled."

With the position of chief engineer as his goal the young man bent all of his energy to the task of fitting himself for it. Step by step he conquered each difficulty and when the chief who had advised the seeking of a lighter task resigned, this man with a definite aim in life was selected to take the place.

This is not an unusual story. It is only one from thousands which are never told.

Every change is rung upon the achievements of Watt, Corliss and Edison, while the more modest attainments of humbler workers are never mentioned. So, the worker grows into the habit of thinking that only great things are worth a struggle.

The coal passer chose a goal within the reach of men of average mental equipment and made that goal the chief object of his life. His was not an uncommon success because his aim was not unusually high, but it shows that with a fixed aim a man may compel opportunities by preparing for them.

There is nothing between any man and his goal, no obstacle to overcome, no barriers to be broken except himself. He alone sets the limits by which attainment is measured.

Not all men are possessed of a desire to stand so much above their fellows. Not every soldier can be a general or even a major, but each should cherish at least the ambition to be among the best of his class.

Municipal Pumping and Power Plant

By Warren O. Rogers

In this plant at Orange, N. J., alternating current is generated to drive induction motors coupled to direct-current arc machines. Two 3,000,000-gallon water works pumping engines with no atmospheric exhaust are installed. Both engines and pumps are run condensing without the aid of circulating pumps, the water being bypassed through the condensers from the suction pipe.

After several years of litigation, the city of Orange, N. J., has installed its own electric-lighting plant, which it is now operating. In 1908 a new pumping plant was built and enough boilers were installed to operate a city lighting plant; an engine room was also reserved between the boiler and pump rooms. The Public Service Corporation of New Jersey, however, was naturally opposed to the installation of a municipal plant as it would mean a loss of $28,500 per year to them, so they zealously fought the project.

They instituted proceedings against the city which delayed matters until February 13 of this year, when the current was cut off from the lines of the Public Service Corporation. With this event the price of $85 per lamp per year for 340 arc street lamps became a thing of the past.

The red-brick building housing the machinery is located on Chestnut street and as one turns the corner to enter the boiler room, the brick coal-storage house is seen. This building is divided into six compartments, each capable of holding 40 tons, or a total of 240 tons of coal. All fuel is carted to the storage house and is then loaded into a one-ton car that runs on an industrial railway. When run into the boiler room each car of coal is weighed on a Hunt platform scale.

Boilers

There are four Heine boilers, each of 225 horsepower capacity. They are set in one battery and each furnace is provided with a grate area of 52 square feet. Fig. 1 represents a view of the boilers and a partial view of the piping above them. Fig. 2 shows the piping arrangement more in detail. There is but one outlet from the steam drum of each boiler. To this outlet a tee connection is secured and an Ashton pop-spring safety valve is bolted to the top outlet. To the side outlet a stop valve is attached and to this valve a long-radius bend connects with the header which runs over the rear of the four boilers. At the central point of this header is a tee to which the main steam pipe, with a stop valve in the line close to the boiler header, connects. This line runs up over the economizer and through the wall between the boiler and engine rooms and dropping down, connects to a header in the engine

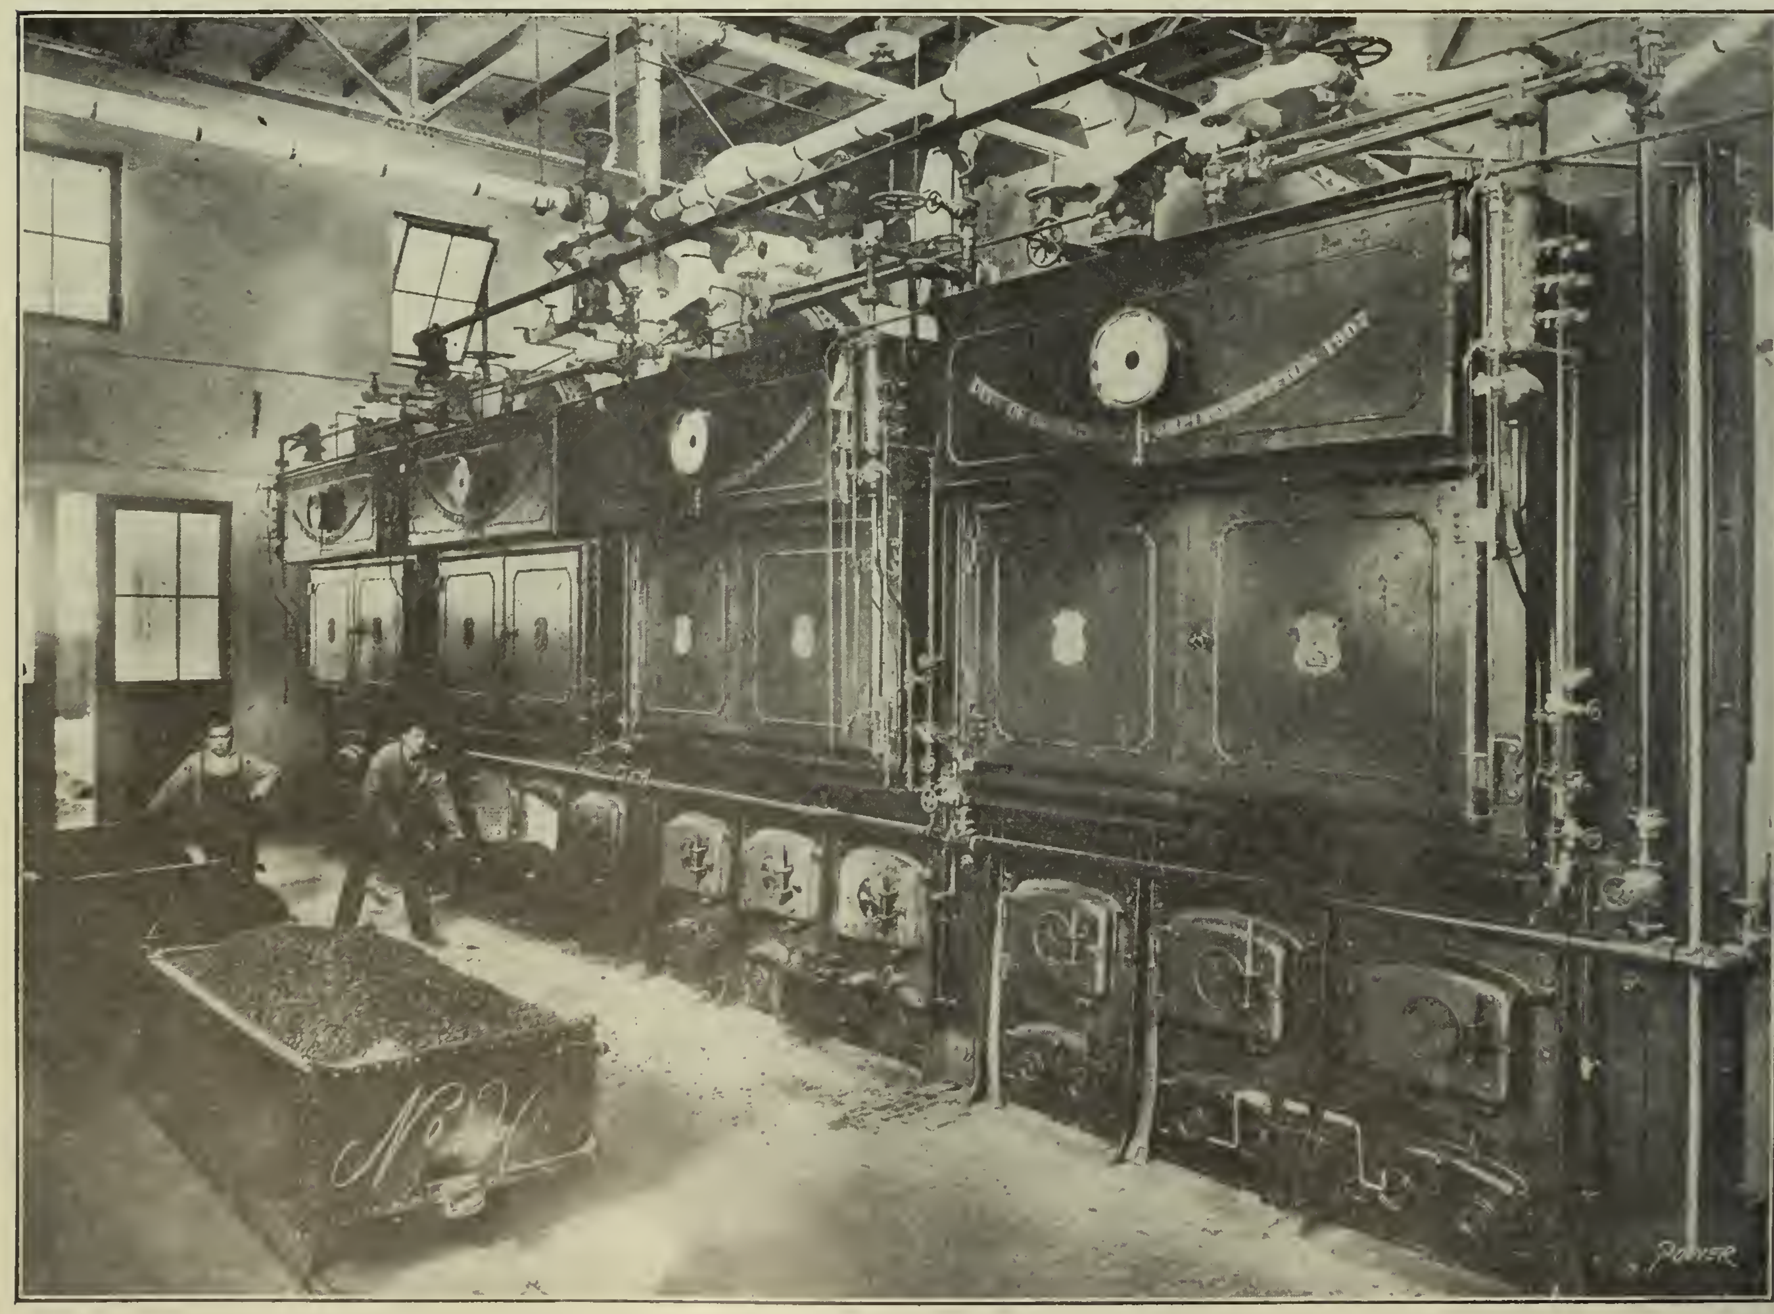


Fig. 1. Boiler Room of the Orange, N.J., Municipal Electric-light Plant

room. From this header the main feed pipes pass down through the engine-room floor and are run under the floor to the two large engines.

At the opposite end of the header a pipe is connected and runs across the end of the engine room with branches to the two pumps in the pump room.

The boilers are hand fired, and No. 1 buckwheat is burned. The average water evaporation for the last month was eight pounds per pound of coal. A steam pressure of 150 pounds per square inch is carried. Two boilers easily carry the night load. One boiler, if run to its capacity, would supply steam for operating the large service pump that is run continuously, but operating conditions make it more economical to run two boilers during the day than banking the fires under one and breaking the fire out for the night load. The two working boilers are, therefore, run light during the day and are ready for the night load when required, without the loss of fuel which the other method would entail.

Fig. 2. Piping Over the Boilers

Economizer

A Greene fuel economizer is located at the rear of the boilers. It contains 252 four-inch by 8-foot tubes. The feed water is passed through a feed-water heater and is heated by the steam from the exciter engine when it is running or by the steam from the boiler-feed pump, and the vacuum pump, the latter operating when the engines are running. As the economizer is designed for four boilers and as but two are used, the feed water is at present heated to but 170 degrees Fahrenheit.

A smoke flue reaches across the back end of the boiler on top and one end is connected with the smoke passage in the

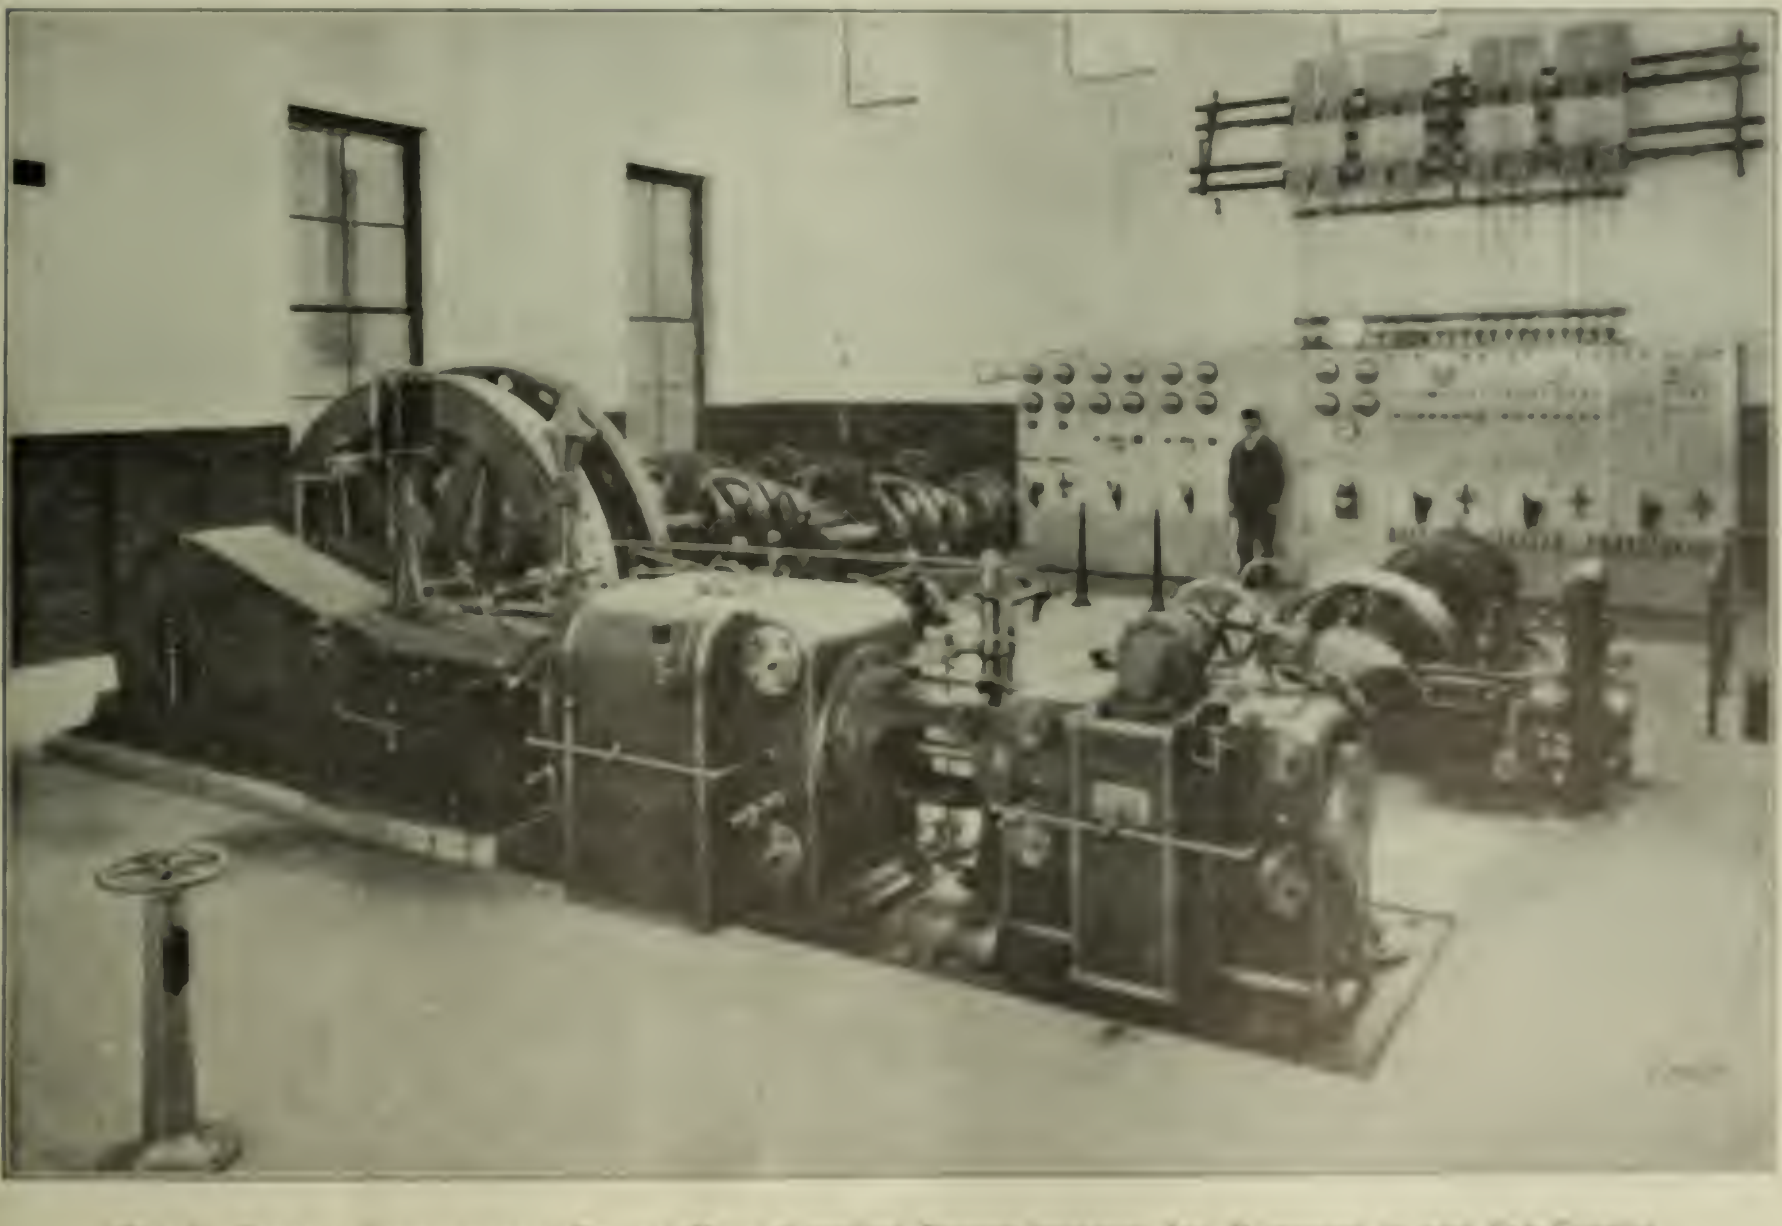

Fig. 3. Partial View of the Engine Room Showing Direct-current Arc Machines in the Far Corner

economizer. The other end is connected directly with a 175-foot Keeler radial-brick chimney, the base of which is 9 feet and the top 6 feet inside diameter.

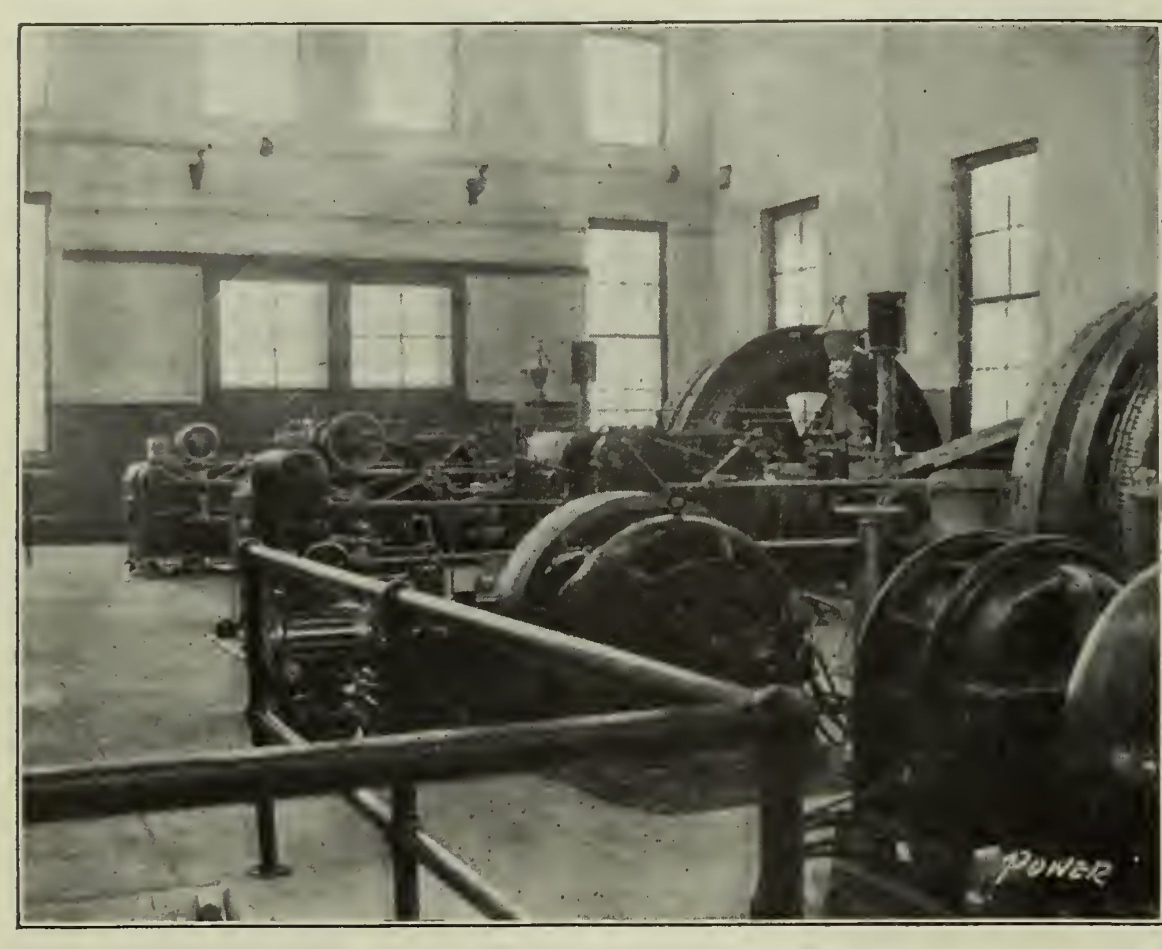

FIG. 4. ANOTHER VIEW OF THE ENGINE ROOM

Natural draft is used, although a Greene engine and fan-blowing set is installed in the blower room adjoining the base of the stack. Air-ducts running to the boiler setting have also been constructed.

ENGINE ROOM

Passing into the engine room, a view of which is shown in Figs. 3 and 4, one is confronted by two Hewes & Phillips' engines, 11 and 22x30-inch tandem-compound Corliss engines. Each runs at a speed of 150 revolutions; this high speed is practical, due to the new Franklin valve gear with which both engines are equipped. Each engine is direct coupled to a two-phase 250-kilovolt-ampere, 2200-volt Fort Wayne alternating-current generator. Contrary to general practice these machines do not deliver electrical energy outside of the building, but generate energy for three Fort Wayne induction motors which drive five arc machines. Two of these motors are of 120 horsepower capacity and are each coupled, by means of two flexible insulated couplings, to two Brush 9000-volt 4-ampere arc generators, which run at a speed of 700 revolutions per minute. The third motor is of 60 horsepower capacity and is coupled to one arc machine of the same capacity as the others. The grouping of these machines is shown in Fig. 3.

The coupling between the motor and generator shafts is shown in Fig. 5. It consists of a flange mounted on each shaft to be coupled together. Each flange has four arms which are made with a rim about 4 inches wide. Between the eight arms of the two coupling flanges are placed four pieces of round rubber. They are prevented from working out at the top of the arm by the overlap of the rim face and from working out at the side by flat plates which are secured to each arm of the coupling, by means of screws.

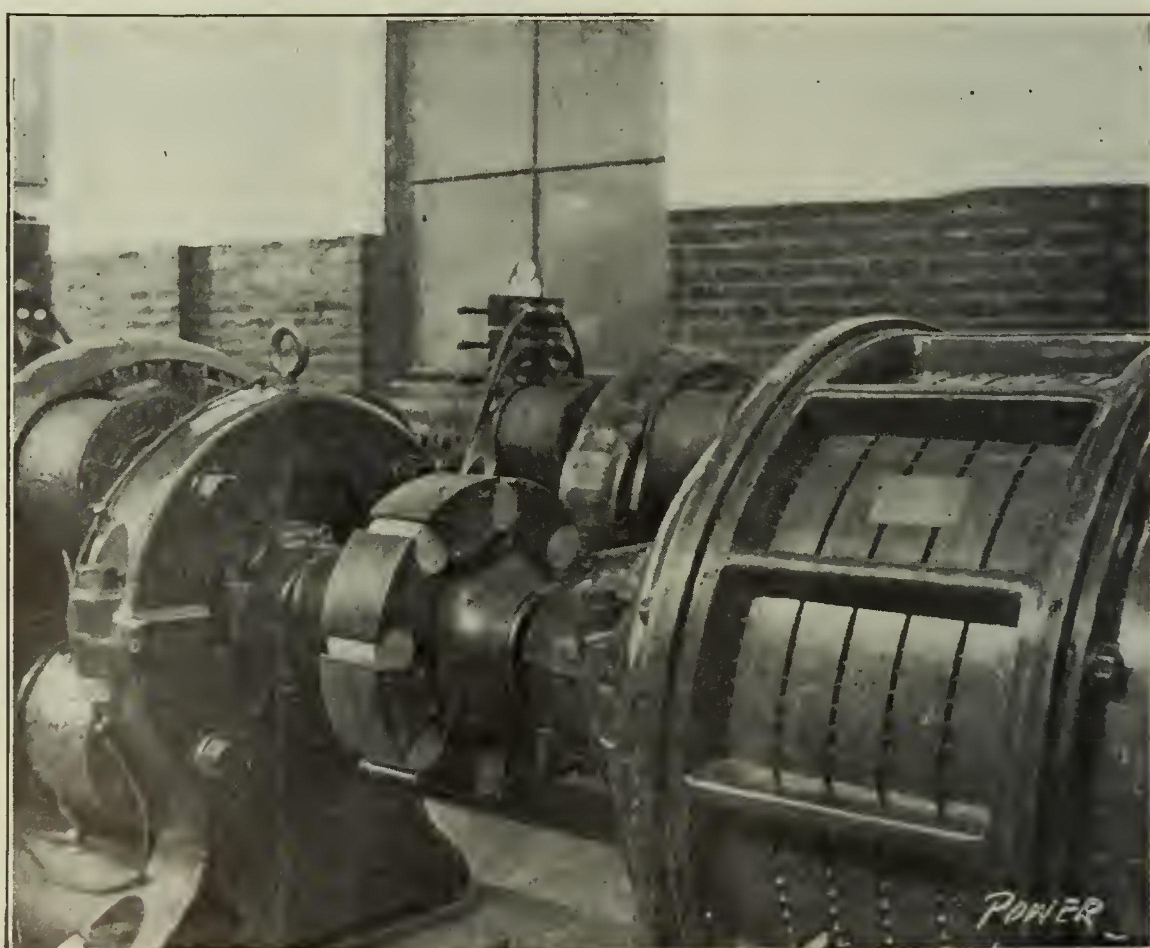

FIG. 5. METHOD OF COUPLING MOTOR AND GENERATOR TOGETHER

EXCITER UNITS

There are two exciter units. One consists of a 15-kilowatt, 125-volt direct-current Wood generator which is directly coupled to a Flemming automatic engine, running at 350 revolutions per minute. The other unit consists of one 25-kilowatt,

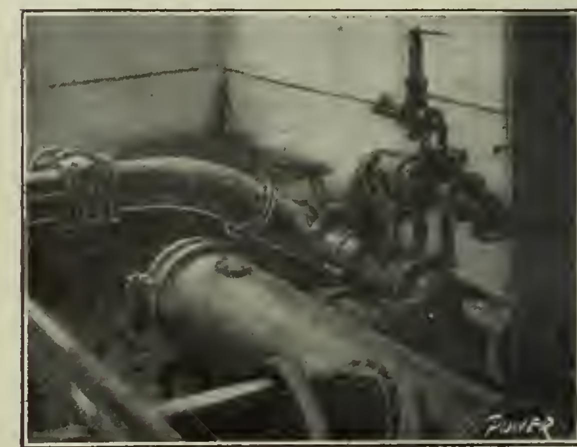

FIG. 7. RELIEF VALVE ON SUCTION PIPE OF PUMPS

125-volt direct-current Wood generator, directly coupled to a 40-horsepower induction motor, running at 900 revolutions per minute.

SWITCHBOARD

The switchboard is made up of seven panels of blue Vermont marble. Three are used for the plug switches of the arc-light circuits, two for the generators, one for the exciters and one is a spare panel for an extra generator unit, for which space is provided. The machine panels have the usual recording and indicating instruments, switches and other devices.

PUMPS

Beyond the engine room is the pump room, in which there are two Snow pumping engines, each of 3,000,000 gallons water capacity per 24 hours at 39 revolutions per minute. These pumps deliver city water to a 6,000,000-gallon storage reservoir against a 288-foot head.

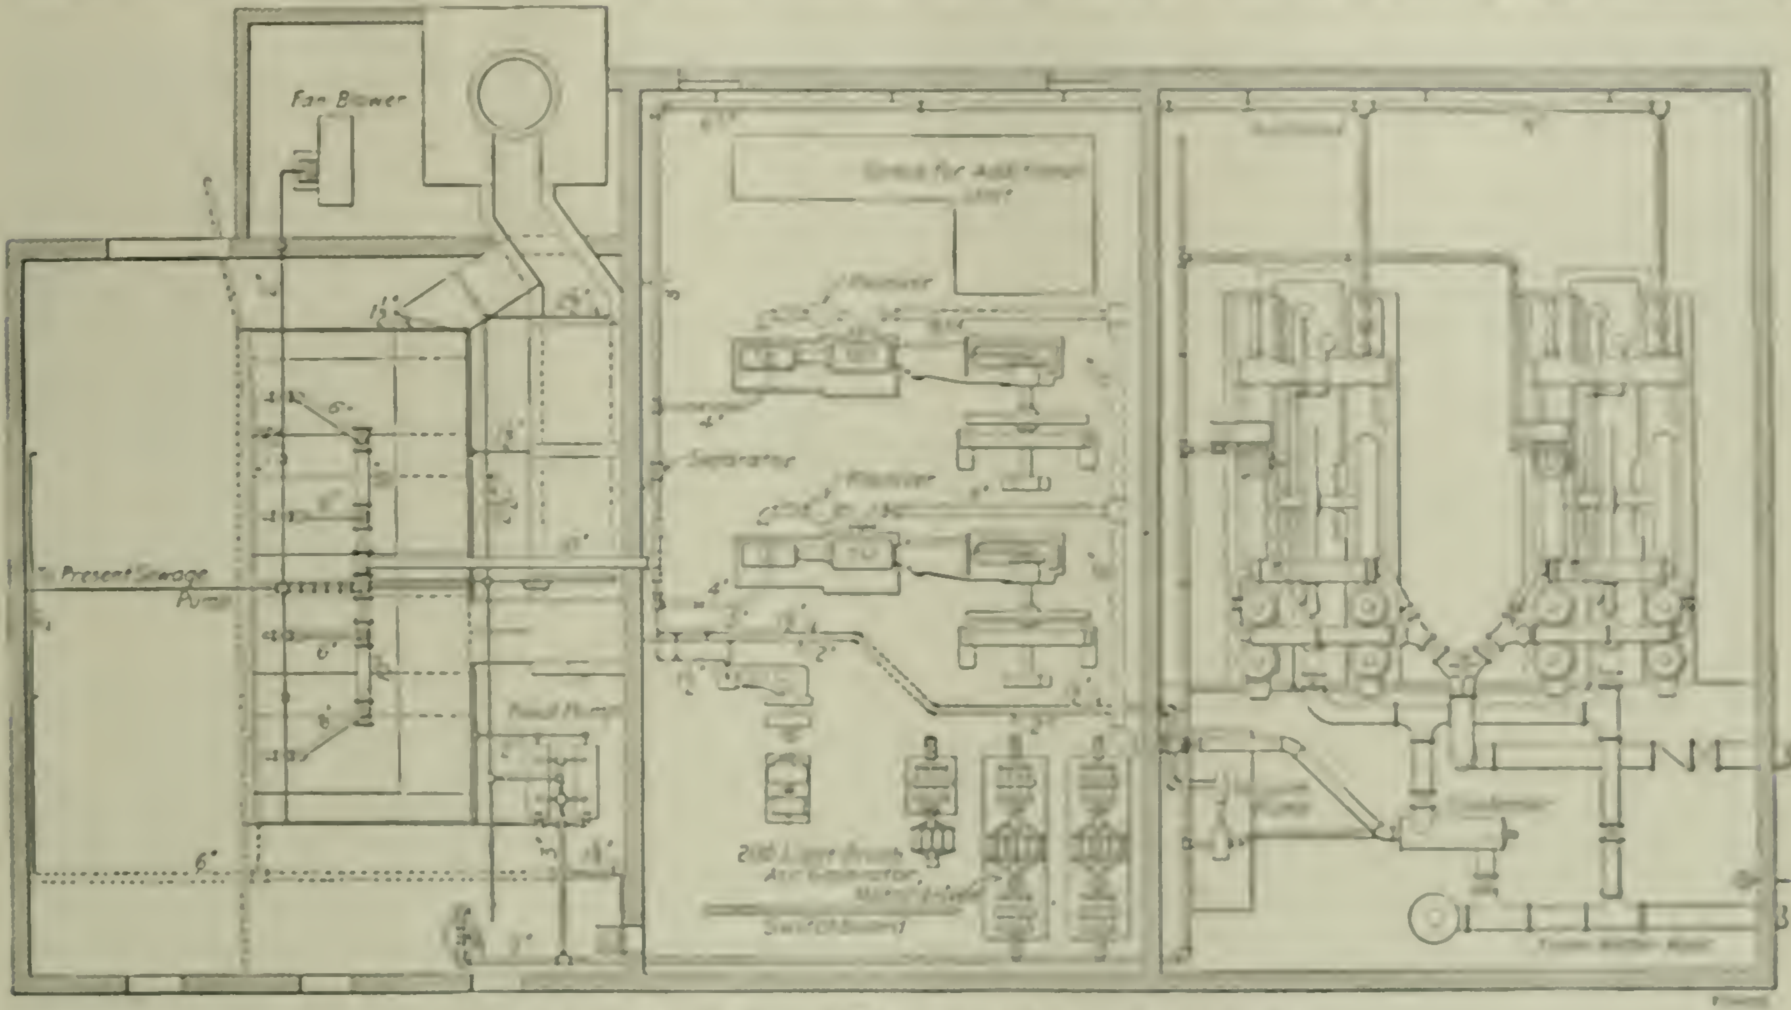

FIG. 8. PLAN VIEW OF BOILER, ENGINE AND PUMP ROOMS

But one pump operates at a time. Both pumps run condensing. In fact, they can run in no other way, as neither is fitted with an atmospheric exhaust pipe. Fig. 6 shows two views of the pumps.

At one time considerable trouble was

FIG. 6. VIEWS OF THE TWO LARGE PUMPING ENGINES

experienced by excessive pressure in the suction line of the pumps. This pressure would occur when the valve gear on the pumping engine failed to engage once or twice in succession, or when carelessly shutting down. As the pump takes the water from the suction pipe about as fast as it can flow by gravity, due to a 49-foot fall from the source of supply, the pressure was built up in excess of 90 pounds per square inch. To eliminate this dangerous condition, Chief Engineer Berg decided to put in a relief valve on the suction line. Accordingly a 7-inch Lombard relief valve was installed, as shown in Fig. 7. It is set to operate at 25 pounds pressure per square inch on the suction pipe and so the danger from a pressure greater than this is eliminated.

CONDENSERS

The principal generating units and the pumps are operated condensing, but the arrangement of the condenser differs from that found in most power plants. A Worthington surface condenser is placed on a stand made of pipes and is located in the basement of the pump room. No circulating pump is used, but a vacuum of [illegible] inches is easily maintained. The exhaust steam enters the condenser at one end and surrounds the tubes within the shell. The cooling water is drawn from the suction pipe of the large service pump and is passed through the tubes of the condenser, entering the suction pipe at the other end. The inches of vacuum are regulated by means of a valve in the bypass pipe leading to the condenser.

This novel method of supplying cooling water eliminates the first cost of a circulating pump and also the expense of its operation. As one of the pumping engines is always in operation, circulating water for the condenser is always available.

A similar arrangement is also carried out in working both of the large pumps. The condenser, however, is located above the water end of each pump, as shown in Fig. 6. In the case of the pumps, however, the exhaust steam passes through the condenser tubes. They are surrounded by the water and passing through the condenser, the condensing waters enter the discharge pipe of the pump and mix with the water which is pumped for domestic use. One would at first suppose that this arrangement would affect the temperature of the city water, but as the rise is but 4 degrees in the summer time, it is not objectionable. The condensed water from the pump surface condenser discharges the condensed water by gravity to a hotwell from which it is pumped to the boilers by one of the two Knowles 7½ and 5x6-inch outside packed feed pumps. They are both located at the rear of the boiler setting, as shown in Fig. 8, which is a plain view of the entire plant. Fig. 9 shows a side elevation of the power apparatus.

The condensation from the engine condenser is handled by a Burnham 8 and 12 by 12 vacuum pump, which is placed in the basement pit at the rear end of the pump room.

Another feature not found in most power plants is the Worthington recording liquid weigher. It is so connected that the water of condensation taken from the engine condenser can be automatically weighed and the steam consumption determined without preparation.

At present there are 374 arc lamps on the various circuits, as against 340 that were carried by the Public Service Corporation. There are also 145 incandescent lamps placed in series.

Owing to the short time this plant has been in operation no figures are available for comparison as to the cost of operating the street lights under the two systems. Later on, when figures for comparison are available, it will be possible to compare the costs under a municipally operated electric-lighting plant and a private central station.

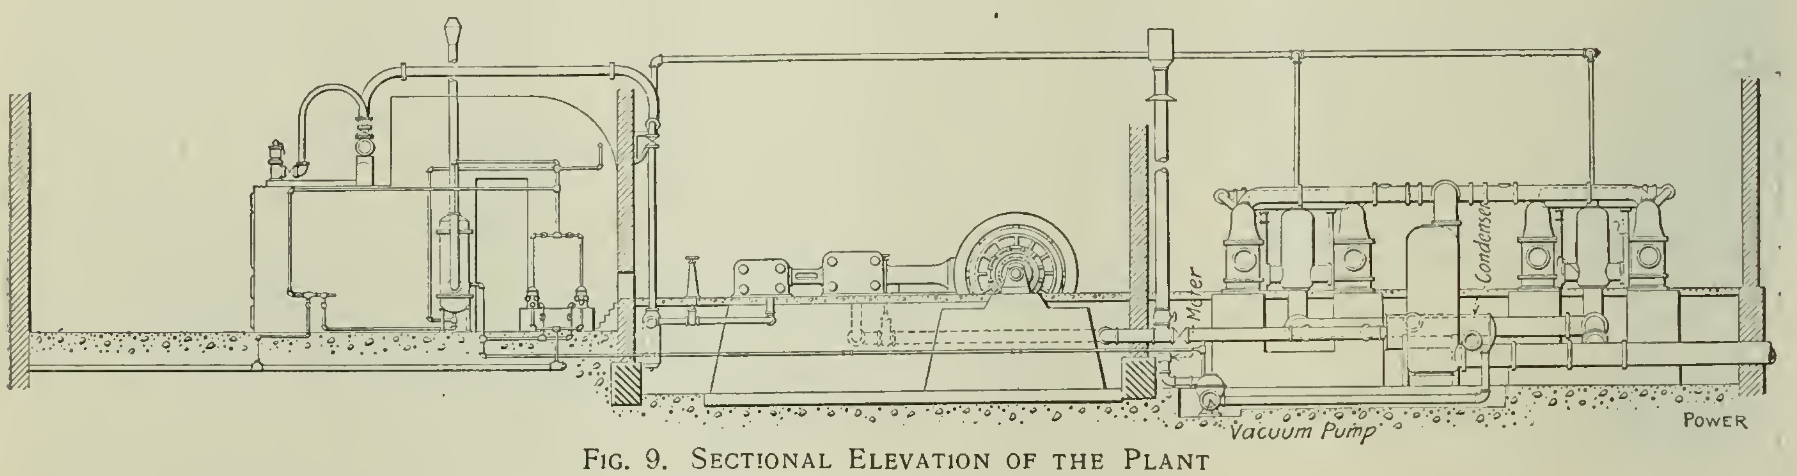

FIG. 9. SECTIONAL ELEVATION OF THE PLANT

High Boiler Efficiency with Oil Fuel

By Frank T. Clarke

A series of tests upon one of the boilers of the Redondo plant of the Pacific Light and Power Company, using crude oil as fuel and showing an average efficiency of 80.47 per cent.

When the Redondo plant of the Pacific Light and Power Company was built a few years ago it attracted considerable attention, owing to the fact that reciprocating engines were selected as prime movers instead of turbines. The main units are each of 5000 kilowatts capacity and are arranged on the panel system. Each panel consists of six oil-fired Babcock & Wilcox boilers supplying steam at 175 pounds and 100 degrees superheat to a double horizontal and vertical McIntosh & Seymour compound-condensing engine running at 100 revolutions per minute, the latter direct connected to a three-phase, 50-cycle, 18,000-volt generator.

In December, 1908, a paper was read before the American Society of Mechanical Engineers, giving the figures of a test upon this plant which showed an exceptionally high overall efficiency. But, as the figures represented the performance of the complete plant, it was impossible to separate the individual efficiencies of the boilers, engines and auxiliaries. However, the results of a test upon one of the boilers have now become available and, although this was made some time after the complete plant test referred to, it is reasonable to assume that the boiler efficiency had not changed appreciably. In view of this it would appear that the boilers were largely responsible for the very high plant efficiency.—EDITOR.

The object of the tests, the results of which are here shown, was to determine the efficiency, under average operating conditions, of the burners and furnaces. The seven tests covered by this report were all made with Hammel patent furnaces and burners, and it is believed that the results would justify the statement that these trials represent the highest economies ever obtained under similar conditions.

The boiler tested was of the Babcock & Wilcox type, of which there are eighteen in the plant, each containing 6042 square feet of effective heating surface and rated at 604 boiler horsepower. It was designed to carry steam at 200 pounds gage pressure, but is ordinarily operated at 185 pounds.

The superheaters, which were designed to give 100 degrees superheat at the nozzle, are also of the Babcock & Wilcox type, having two loops of tubes in two decks and approximating 960 square feet of superheating surface to each boiler.

There are three passes in the boiler, the products of combustion rising through the first pass, which is baffled along the lower row of tubes from the first flame plate to the bridgewall by fire tile. The gases then pass over and through the superheater to the second pass, and from there to the last pass, from which they escape to the uptake.

The furnace was of the Hammel type, having a separate tunnel for the air supply to each burner. The burners were also of the Hammel patent inside-mixer type, there being three to the furnace. These were arranged under an arch in the bridgewall, and the direction of the flame was toward the furnace front. Fig. 1 shows the arrangement of furnace and burners; while Fig. 2 is a view of the burner.

The feed water was measured by means of platform scales and tanks, and precautions were taken to detect any leakage.

The fuel oil was pumped from one of the three auxiliary storage tanks, adjacent to the boiler room, at a temperature of 80 degrees Fahrenheit, through a 3-inch quick-acting valve into a weighing tank, from which it flowed through a 4-inch suction pipe to a second pump located near the boiler under test. This pump discharged the oil directly into a Goubert oil heater, where its temperature was increased by the exhaust steam from the pump. From the heater it was discharged to the line leading to the burner. Between the oil pump and the heater there was a bypass which discharged to the reservoir tank. This gave the necessary circulation and allowed a means of pressure regulation.

Samples of the oil were obtained from a tap in the pump discharge between the boiler and the heater. The steam for atomizing purposes was taken from directly under the stop valve of the boiler; consequently, this contained the same degree of superheat as was shown by the thermometer at the boiler nozzle.

For obtaining flue-gas analysis a standard Orsat machine was used. The samples were collected every half hour from the center of the last pass.

The flue temperatures were taken by a Hohmann & Maurer thermometer, reading to 800 degrees Fahrenheit, this being placed between the two dampers at the center of the boiler breeching. Temperatures were taken of the steam at the boiler nozzle; of the oil at the discharge from the heater; of the feed water in the reservoir tank, and of the boiler room at a point about ten feet in front of the boiler and at an elevation above the floor of five feet.

The draft pressure was measured by means of three Ellison differential draft gages, one located at the boiler front, for the ashpit draft, and the other two mounted on the side of the boiler, one being piped to the furnace and the other directly inside the flue dampers. All draft gages were insulated from the boiler setting to prevent error due to heating. The precaution was taken to have the outlets of the draft pipes arranged at right angles to the direction of the flow to prevent inaccuracy due to the velocity. For taking the high temperatures at the different parts of the boiler a Bristol electric pyrometer, reading to 2500 degrees Fahrenheit, was used.

All scales and instruments were calibrated before and after the tests, and were found to be substantially correct.

The blowoff valves on both the boiler and the superheater were disconnected and the water-column outlets were at all times visible for inspection. Also, leakage from the feed-pump glands was collected and returned to the feed-water reservoir.

During all the tests the water level was maintained practically constant at a point four inches from the bottom of the gage glasses. To avoid error due to change of temperatures in the water columns and their connections, the glasses were not blown down at any time immediately prior to or during the tests.

All readings were taken at fifteen-minute intervals during the tests, and every hour the water and oil levels were brought to the same point and calculations made. Besides the power company's testing engineer, there were four men engaged in the tests: one fireman, one temperature reader, one water weigher and one oil weigher. In addition to this crew the company making the burner also had a man in each of these capacities who kept independent log sheets. At the conclusion of each test the logs were compared and they agreed in all cases. Smoke observations were taken every fifteen minutes, and during none of the trials was anything heavier than a light haze observed; this is particularly true of the maximum-capacity test.

The oil was sampled every fifteen minutes during each run, and, before taking a sample, precaution was taken to see that the sampling pipe was drained. The sample from each test was analyzed twice by the Los Angeles branch of the New York Testing Laboratories and the average results used.

CONDITION OF THE BOILER

Before starting the tests it was found necessary to rebuild the division wall

between the boiler under test and the one forming the other half of the battery. The boiler was cleaned about four days prior to starting the first test, and was in operation two days before the test was begun. The tubes were dusted off through the dusting doors, by means of a steam jet, every morning before starting a test. As the tests were to be, as far as practicable, representative of operating conditions it was considered that this cleaning was sufficient to fulfil the average conditions.

The setting was in extremely poor condition, and it was found advisable to stop up the worst cracks. During the tests there was quite a number of small air leaks in different parts of the setting which did not receive any attention.

Prior to making the tests herein recorded, an inspection was made of the tubes as a result of which four in the first row were replaced. At the conclusion of the tests the tubes were again inspected and they were all found to be in good condition; also, the furnace brickwork was given a careful inspection and there was no apparent injury.

Starting and Stopping Trials

All tests were started and stopped by a whistle signal. The boiler was operated at the load under which it was tested for a period of three to four hours before actual starting, and as the fires were maintained uniform the water level was practically constant at the time of starting and stopping. The water glasses were provided with washers at fixed points, and no trouble was experienced in having the water at these fixed levels at the start and finish. Therefore, it was found unnecessary to make any corrections for difference in levels.

Fig. 2. Hammel Burner

The boiler was at "standby" about four hours every night, but the four-hour period of service before the test was considered sufficient to heat the setting thoroughly and to eliminate the possibility of heat storage.

Results Of Tests

Fig. 3 shows graphically the efficiency referred to the boiler horsepower developed, while Fig. 4 shows the efficiency as plotted against the water evaporated from and at 212 degrees Fahrenheit per square foot of heating surface. In both curves it will be noted that the points at 33.6 and 64 per cent. above rating are somewhat below the curve. This is accounted for by the fact that at the point

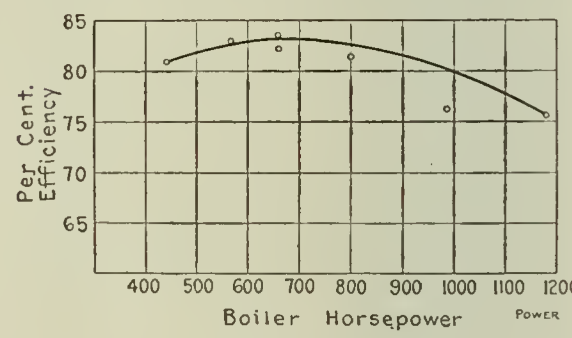

Fig. 3. Efficiencies at Various Horsepowers

of maximum capacity it was found that the ¼-inch pipe which the makers supplied with the burners was entirely too small for atomizing the oil at the higher loads, and to make the maximum-capa-

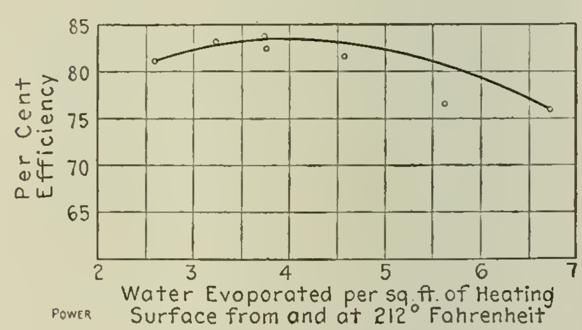

Fig. 4. Efficiency Referred to Evaporation per Square Foot of Heating Surface

city test ⅜-inch pipe was substituted. This is indicated by the drop in burner efficiency at those points. In order to get the maximum capacity it was also found necessary to increase the width of the tunnels and to provide a greater number of air openings through the grates.

It is regretted that the two tests mentioned were not repeated, but lack of time prevented and it is reasonably certain that had additional tests been made it would have shown these points very close to the curve.

Fig. 5 shows the efficiencies referred to the pounds of water evaporated per pound of oil, corrected for moisture, and in Fig. 6 is given a curve showing the relation between the percentage of carbon dioxide and the boiler horsepower.

Fig. 7 shows the relation between the boiler horsepower and the water evaporated per square foot of heating surface, from and at 212 degrees Fahrenheit.

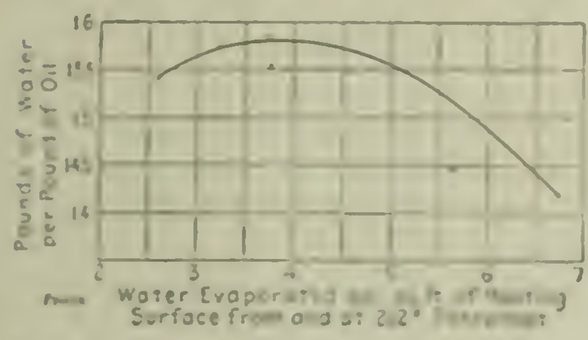

FIG. 5. EVAPORATION PER SQUARE FOOT OF HEATING SURFACE REFERRED TO EVAPORATION PER POUND OF OIL

CALCULATIONS

In calculating the factor of evaporation the specific heat of superheated steam was taken as 0.6 for the gage pressure obtained.

The amount of steam used by the burners was obtained by placing the burner in the water-weighing tank, with the connecting piping and fittings the same as were used during the tests. The average steam pressure for the different tests was then maintained on the burner line for a period of half an hour. The amount of condensation was then weighed and this was checked by figuring the amount of discharge by temperature readings. For additional accuracy several different trials were made at each point, and these all agreed within a very small per cent. In the burner-efficiency calculations there is a small discrepancy between the actual and the test conditions due to the difference between the pressure of the oil and of the water. Under operating conditions the steam in the burner head is retarded in its flow by the pressure due to the oil in the mixing chamber, while the tests made by the tank method gave a greater steam flow due to there being only a very slight water pressure.

It was also found that with heavy boiler loads the tubes directly exposed to the fire suffered much less than with the light loads. This is accounted for by the fact that on the heavy loads the distribution of heat throughout the boiler was much more uniform than with the light loads, which had a tendency to concentrate the heat in the front part of the boiler, due to the difference of draft.

CONCLUSIONS

In order to demonstrate what advantage a long furnace would have over a short one, a furnace was installed having a total length of eight feet, which was two feet shorter than the one installed by the boiler company at the time the boiler was erected. A test demonstrated clearly that far better results could be obtained with the long furnace, having a length of ten feet from the face of the bridgewall to the inside face of the boiler front, and it was at this point that the first six tests were made.

To obtain the maximum capacity it was found necessary to increase the width of the tunnels to give a slower air velocity through the grates, and to increase the number of openings through the grate. At that time the bridgewall was also moved back another six inches, which increased the cubical contents of the firebox about 10 cubic feet, and greatly assisted the combustion at high loads. It is also believed that the large firebox would greatly assist the combustion at the lower evaporative points. In all cases it was found that the best results were obtained by leaving the front dampers wide open, and controlling the admission of air entirely by the rear damper. By this means the velocity of the gases was kept at a minimum, which seems to be essential for the best combustion.

In several instances during preliminary trials the temperature of the oil in the reservoir tank was increased to 120 degrees Fahrenheit, and it was found that by so doing the efficiency of the boiler dropped considerably. This would indicate that for average conditions it is a great mistake to heat the oil to excessive temperatures except in cases where it is absolutely essential for handling. During the tests, with oil having a specific gravity of about 13, the temperature was maintained at 80 degrees Fahrenheit, which temperature gave the most satisfactory results. The excessive heating of the oil causes decomposition of the hydrocarbons.

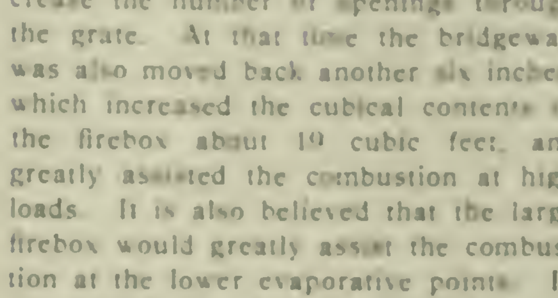

FIG. 6. RELATION BETWEEN CO_2 AND HORSEPOWER

It is believed that the efficiencies of all tests would have been materially improved had it been possible to obtain a steady oil pressure on the burners. The pump was not supplied with any sort of automatic-control device, and as a result it was impossible to keep the pressure from varying from five to fifteen pounds.

It was found that the better known burners could be divided into three classes: those using excessive amounts of steam for atomizing—over 3 per cent. of the total steam generated; those whose steam consumption is less than 1½ per cent., and the ones whose steam consumption lies between the two. In the first case the different pipes and burner openings are of large area and offer small resistance to the passage of dirt, with the result that these burners do not become obstructed and can be operated at a very low maintenance cost. This, however, is offset by the excessive steam used. In the second case the passages must be extremely small and the burner consequently becomes obstructed very readily, resulting in excessive maintenance costs, which more than equal the steam economy. It is obvious, therefore, that a burner fulfilling the requirements between the two extremes is best adapted for general use.

FIG. 7. RELATION BETWEEN HORSEPOWER AND EVAPORATION

It is to be regretted that sufficient data was not obtained from the analysis of the oil samples to permit the working up of a "heat balance," but it is believed that the information given will otherwise be found complete.

An Expert and a Strap Brake

"Yes," said Jones, "our superintendent at the Throwmtogether Engine Works was the engine man for you. He wouldn't let any engine out of the shops without taking cards running free and with all she could pull. You should have seen the slick rig he got up to load them. He fixed up a long wooden beam with a piece of belting and bolts (strap brake). Well, of course, he didn't get onto this rig first shot. Instead of letting the arm shove against the floor, he hooked it with it on the other side and had enough of the lads sit on it to hold it down. Anyway, this worked fine until one time the brake seized and threw a bunch of the men over the engine. Of course, you seen the sensitive engine men can get those fancy charts without him then."

An employee in a sawmill near Duluth, Minn., was killed in a peculiar manner. One of the balls of a steam-engine governor flew off and struck him on the head, causing instant death.

The Cooling of Circulating Water

By Edward F. Miller

A method of calculating the volume of air required to cool a given amount of circulating water passing through a cooling tower, and calculations showing that under certain conditions it is better to employ a moderate vacuum than a high one where a cooling tower is used.

Whenever possible, large power plants are located near a river or near tide water, in order to obtain an abundant supply of condensing water; in many cases, however, plants have to be located where there is either no supply or but a limited supply of water which can be used for condensing purposes. In such cases if the plant is to be run condensing, it becomes necessary to cool the condensing water after it has passed through the condensers so that it may be used over and over again. Some of the various devices for cooling the water are: Cooling towers, spray nozzles, cooling ponds, and spray nozzles combined with cooling ponds.

In every case, with the exception of the "cooling ponds," the greater part of the cooling is effected through the evaporation of a small part of the water circulated, each pound of water evaporated taking approximately one thousand heat units from the water left. This method of cooling by the rapid evaporation of a part of the liquid was known and made use of in India 2000 years ago.

According to Dalton's law, the weight of steam required to fill a certain volume at a given temperature is the same regardless of whether any air is present. The resulting pressure is the sum of the pressure exerted by the air and that exerted by the steam, considering that each occupied the same volume separately. The weight of moisture required to saturate one cubic foot of dry air, or that which will occupy one cubic foot, can be calculated from any reliable tables giving the properties of saturated steam.

The curved line (Fig. 1) was computed by taking from the steam tables values representing the reciprocal of the volumes of one pound of steam at the different temperatures. From this it is evident that at 66 degrees, 0.0010 pound is required to saturate a cubic foot of dry air and at 130 degrees, 0.0063 pound is required. If air at 66 degrees were 70 per cent. saturated, or had a relative humidity of 70, then the amount of moisture in a cubic foot of such air would be

$$0.7 \times 0.001 = 0.0007 \textit{ pound}$$

and if the air were saturated at 130 degrees the additional amount taken up would be

$$0.0063 - 0.0007 = 0.0056 \textit{ pound}$$

Cooling Towers

Probably cooling towers are used to a greater extent for cooling water than spray nozzles or cooling ponds, although spray nozzles are coming into frequent use now that engineers know more about them.

The amount of water surface in a cooling tower varies from 23 to 27 square feet per indicated horsepower, more surface being needed in a natural-draft tower than in a fan tower. The amount of air required depends to a large extent upon the humidity of the air entering the tower and upon the temperature of the water entering the tower. The air leaving the tower is usually saturated. It is not advisable to send an abnormal amount of air through a tower as the cost of the increased power required to run the fan and the greater shrinkage in the bulk of water due to evaporation may amount to more than the gain made by the increased vacuum on the engine.

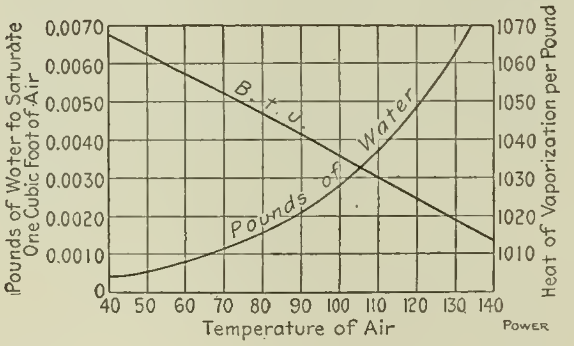

Fig. 1. Water Required to Saturate Air and Heat of Vaporization

The materials used inside of cooling towers for bringing as large a surface of cooling water as possible into contact with the air, without obstructing the free flow of air, are tiers of tile paper, galvanized-iron wire screens set nearly vertical, galvanized-iron troughs set horizontally and arranged so that the water flows from trough to trough as it descends, boards, brush or other material.

The amount of air to be supplied to a tower and the shrinkage of water due to evaporation, may be calculated with sufficient accuracy from the following equations:

$$W(Q_h - Q_c) = \frac{V_c}{0.736\,\frac{T_c}{P_c}} \times 0.24\,(T_h - T_c)$$

$$+ r\left(\frac{V_h}{\text{Specific volume of steam at the temperature of the air at top}} - \frac{V_c}{\text{Specific volume of steam at the temperature of the air at bottom}} \times \textit{relative humidity}\right)$$

where,

W = Weight of cooling water entering the condenser per pound of steam;

V_c = Cubic feet of cold air entering the tower per pound of steam condensed. This air may enter by natural draft or be forced in by a fan;

V_h = Absolute temperature of air leaving the tower; condensed and is equal to $\frac{V_c T_h}{T_c}$;

T_c = Absolute temperature of entering air;

T_h = Absolute temperature of air leaving the tower;

P_c = Absolute pressure of air entering the tower in inches of mercury;

Q_h = Heat contained in hot condensing water;

Q_c = Heat contained in cold condensing water;

r = Heat of evaporation corresponding to temperature at top of tower.

The first factor,

$$\frac{V_c}{0.736\,\frac{T_c}{P_c}} \times 0.24\,(T_h - T_c)$$

represents the heat given up directly to the air and the second part of the equation

$$r\left(\frac{V_h}{\text{Specific volume of steam at the temperature of the air at top}} - \frac{V_c}{\text{Specific volume of steam at the temperature of the air at bottom}} \times \textit{relative humidity}\right)$$

represents the heat given up by evaporation of some of the water. This expression divided by r represents the weight of water evaporated from the pond per pound of steam condensed; represent this by E.

If E is greater than one pound the excess must be supplied by makeup water. For a surface condenser E represents the makeup water.

If the excess pressure of the air entering the tower is measured by the difference of water level in a U-tube, P_c will equal the sum of the barometric reading and $\frac{0.0365}{0.491}$ times the difference in water level.

In nearly every case P_c varies so little from the reading of the barometer that the barometric hight in inches of mercury may be substituted for it.

Example:

A cooling tower receives water from a surface condenser at 122 degrees Fahren-

*From a paper presented at the Congress of Technology, at Boston, April 11, 1911.

heit; the water leaves the cooling tower at 90 degrees Fahrenheit; temperature of outside air 72 degrees, relative humidity 80 per cent.; temperature of condensed steam 95 degrees; vacuum in condenser 25 inches; barometer 29.7 inches. Engine of 500 horsepower and consumes 20 pounds of steam per horsepower-hour.

Find the amount of air needed per pound of steam condensed and the per cent. loss of cooling water due to evaporation.

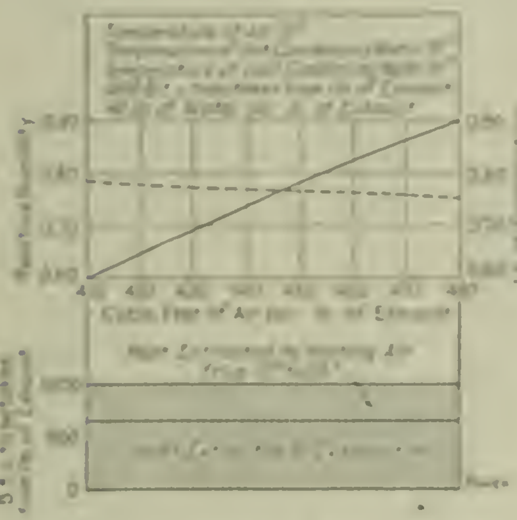

FIG. 2. CONDITIONS WITH 28-INCH VACUUM

$$W = \frac{1053.2 - 63.1}{90.0 - 58.1} = \frac{990.1}{31.9} = 31.8$$

Substituting in the foregoing formula

$$31.8(90 - 58.1) = \frac{V_e}{\frac{0.736 \times 513.3}{29.7}} \times 0.24(30)$$

$$+ 1025.2\left(\frac{V_e \, 481.6}{531.5 \times 149.7} - \frac{V_e}{813} \times 0.80\right)$$

$$990.1 = 0.902\, V_e + 1025.2$$

$$(0.00508\, V_e - 0.000981\, V_e) = 0.902\, V_e + 4.806\, V_e$$

whence

$$V_e = 173 \textit{ cubic feet}$$

$$E = (0.00508 - 0.000981)\, V_e = 0.815$$

$$\frac{0.815}{31.8} = 0.0256 \textit{ or } 2.56 \textit{ per cent.}$$

To illustrate more fully the use of the equation and to illustrate also the extra cost (at the cooling tower) of a high vacuum over a moderate vacuum two cases will be considered.

First: A condenser maintaining a 28-inch vacuum with hot condensing water at 95 degrees Fahrenheit, or 7 degrees below the temperature corresponding to the vacuum, cold condensing water at 70 degrees Fahrenheit, and exhaust steam containing 4 per cent. moisture. Forty pounds of circulating water are figured as the minimum needed to abstract the heat from a pound of the exhaust steam. Calling the relative humidity 90 per cent. and applying the foregoing formula:

$$40(95 - 70) = \frac{V_e}{0.736\frac{[illegible]}{29.92}} \times 0.24\,(95 - 70)$$

$$+ 1048.5\left(\frac{V_e \, 554.4}{434.8 \times 529.5} - \frac{V_e}{[illegible]} \times [illegible]\right)$$

$$1000 = 2.077\, V_e$$

whence,

$$V_e = 481 \textit{ cubic feet}$$

The evaporation from the tower per pound of steam condensed in the condenser is 0.748 pound and

$$1038.5 \times 0.748 = 776.8 \textit{ heat units}$$

carried off by the water evaporated; the balance, 223.2 B.t.u., is taken up in heating the air.

With 80 per cent. humidity, 455 cubic feet of air would be needed and 0.761 pound would be evaporated. Similar calculations for 70 and 60 per cent. of humidity give, respectively, 430.9 cubic feet of air and 0.772 pound of water evaporated and 410.7 cubic feet of air and 0.781 pound of water evaporated.

Second: Suppose that the vacuum to be carried is 26 inches with air at 70 degrees and hot condensing water at 119 degrees, or 7 degrees below the temperature corresponding to the vacuum. Cold water at 70 degrees and 4 per cent. moisture in the exhaust steam. The heat to be abstracted per pound of exhaust is 983 B.t.u. and 20.6 pounds of cooling water is the minimum required per pound of exhaust.

From calculations similar to the preceding it appears that the amounts of air needed and the evaporations are as follows:

Relative Humidity	Cubic Feet Air	Evaporation in Pounds
90	186.1	0.793
80	184.1	0.797
70	180.6	0.800
60	176.5	0.801

The amount of water evaporated per pound of steam condensed is about the same in each case.

In the first case the evaporation averaged 0.77 pound in 40 pounds of water sent into the tower, or 1.92 per cent.; in the second case about 0.80 pound in 21 pounds of water, or 3.81 per cent.

The results of the calculations are plotted in Figs. 2 and 3. It is evident from these that the amount of heat taken up in the heating of the air was about the same for any one case, regardless of the humidity.

PERCENTAGE OF ENGINE POWER REQUIRED BY COOLING-TOWER FAN AND BY THE EXTRA DISCHARGE HEAD ON THE CIRCULATING WATER DUE TO THE TOWER

Referring to the first case cited, with a relative humidity of eighty, 455 cubic feet of air were found to be needed. Suppose a disk fan is to be used and a dynamic head of 0.3 inch of water maintained at the fan. As the static head is zero the velocity head will be 0.3 inch. This corresponds at 70 degrees to a velocity of 2200 feet per minute. Suppose that the main engine uses 14 pounds of steam per horsepower per hour, then the steam per minute is 14 ÷ 60 and the cubic feet of air sent through the tower per pound of steam is $\frac{14}{60} \times 455$

The horsepower input to the fan is, for this case, if 30 per cent. is assumed as the fan efficiency:

$$\textit{Horsepower} = \frac{0.3 \times 5.2 \times \frac{14}{60} \times 455}{33{,}000 \times 0.30} = 0.0167, \textit{ or } 1.67 \textit{ per cent.}$$

of the engine power.

To this should be added the power due to pumping $\frac{14 \times 40}{60}$ pounds of cooling water per minute through an additional head of about 30 feet. This amounts to 0.00848 horsepower.

If the fan were driven by a small engine using 35 pounds of steam per horsepower-hour and the circulating apparatus were also steam driven, using 40 pounds per horsepower-hour, then the extra steam required by the cooling-tower outfit would be

$$0.0167 \times 35 + 0.00848 \times 40 = 0.923$$
